Diboron tetrahalides undergo complex pyrolysis reactions resulting in interesting higher molecular weight subhalides with boron:halogen ratios of 1. These compounds are structurally analogous to the polyhedral boranes (*see* ***Boron Hydrides***), but exhibit significant differences in reactivity and other properties. The polyhedral boron hydrides are colorless liquids or white solids, whereas many polyhedral perhaloboranes are intensely colored, ranging from yellow to purple and black. The simplest polyhedral derivative is tetraboron tetrachloride, B_4Cl_4, which has tetrahedral geometry. This yellow solid is also prepared using radio frequency discharge syntheses. The bromide and the mixed chlorobromo derivatives can be prepared by the exchange reaction of diboron tetrachloride with boron tribromide. Larger polyhedral perhaloboranes, including B_nCl_n ($n = 8-12$) and B_nBr_n ($n = 7-10$) have been described. Although structures have yet to be determined for all of the B_nX_n clusters, it is clear that most of them do not conform to the electron counting rules to which the polyhedral boron hydrides and many other inorganic cluster systems generally adhere. For example, the structure of B_8Cl_8 is that of a regular closed 8-vertex polyhedron, yet this compound has only $2n$ framework electrons (for n vertices), rather than $2n + 2$ framework electrons stipulated by electron counting formalisms. The structures of several boron subfluorides, including B_8F_{12} and $B_{10}F_{12}$, were recently determined revealing unusual open structures.[92] The chemistry of boron subhalide compounds remains an area of academic research interest.

H_2OEP = Octaethylporphyrin; PPN = Bis(triphenylphosphino)iminium(1+); PSEPT = Polyhedral skeletal electron pair theory; TMEDA = N,N,N',N'-Tetramethylethylenediamine; nbd = Norbornadiene; *cod* = 1,5-Cyclooctadiene.

Glossary

Metallacarbaborane (also called metallacarborane): an *electron-deficient compound,* usually a polyhedral *cluster* comprising an array of boron–hydride (BH), carbon–hydride (CH), and metal (ML_x, where L = ligand) fragments; the inclusion of a substituted carbon fragment CR (R = alkyl, aryl, or trimethylsilyl) in place of a CH unit is common

1 INTRODUCTION

Metallacarbaboranes (or metallacarboranes) are compounds that contain cluster polyhedra comprising carbon, boron, and metal atoms in various combinations. The first metallacarbaborane clusters were prepared by Hawthorne in 1965,[1] and were derived from the icosahedral *closo*-carbaborane 1,2-$C_2B_{10}H_{12}$ (*see* ***Boron: Polyhedral Carboranes***) by the replacement of one BH vertex with a metal center. Compounds such as $[Fe(C_2B_9H_{11})_2]^{n-}$ (n = 1 or 2) can be represented as the *commo*-metallacarbaborane (**1**) or as the *sandwich compound* (**2**). Structure (**1**) emphasizes that the iron atom is an integral part of $[Fe(C_2B_9H_{11})_2]^{n-}$, while (**2**) shows that $[Fe(C_2B_9H_{11})_2]^{n-}$ can be considered as consisting of two *nido*-carbaborane clusters, each of which behaves as an η^5 ligand to the Fe(II) or Fe(III) center. The $[C_2B_9H_{11}]^{2-}$ (dicarbollide) ligand (**3a**) behaves in a similar fashion to a Cp^- ligand (**3b**)[2] and, therefore, a parallel can be drawn between the iron(II) metallacarbaborane $[Fe(C_2B_9H_{11})_2]^{2-}$ and the organometallic π-complex $FeCp_2$ (*ferrocene*). Despite the apparent analogy between $[C_2B_9H_{11}]^{2-}$ and Cp^-, experimental observations indicate that metallacarbaboranes are often more stable than their metallocene analogs. The carbaborane units are typically robust, and metallacarbaborane chemistry is generally more extensive than metallocene chemistry.

(**3b**)

Early studies of metallacarbaboranes centered on the icosahedral framework.[3] The precursor 1,2-$C_2B_{10}H_{12}$ was readily prepared from $B_{10}H_{14}$ (*see* ***Boron Hydrides***), and the 1,7- and 1,12-isomers of $C_2B_{10}H_{12}$ were obtained by thermolysis of 1,2-$C_2B_{10}H_{12}$ (see equation 24). Studies pertaining to the chemistry of smaller metallacarbaboranes followed in later years, and a recent advance has been the isolation of clusters with more than 12 vertices (see Section 4.10). Two frameworks have received particular attention: metallacarbaboranes containing MC_2B_4 cores and those with $M(C_2B_3)_2$ sandwich units.[4–8] Metallacarbaborane chemistry

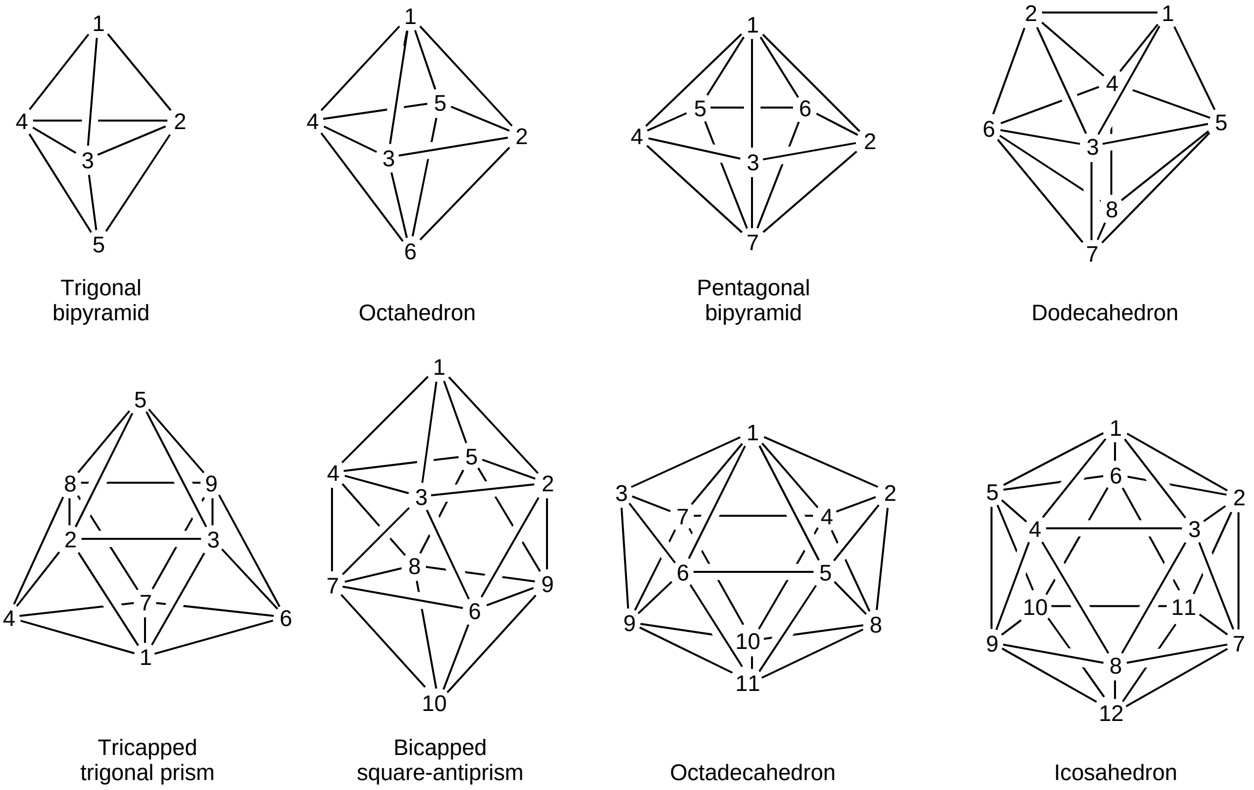

Figure 1 Closed deltahedra (polyhedra with triangular faces) with 5–12 vertices and the IUPAC numbering system for each cage. The structures of most metallacarbaboranes are based on or derived from these eight deltahedra

is especially well developed for icosahedral and pentagonal bipyramidal cages (see Figure 1), and it has progressed from the inclusion of d-block metal atoms to main group[9,10] and f-block[6,11,12] metal atoms.

Three general reference works cover metallacarbaborane chemistry in a systematic manner up to around 2005,[4–6] and several books include articles covering topical developments.[13–16] Annual reports[17] have surveyed advances in the subject since 1971, and continue to do so.

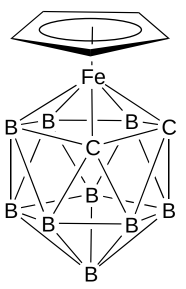
Details of the preliminary IUPAC nomenclature for metallacarbaborane clusters are described in the 1990 recommendations.[18] However, care is needed in interpreting compound names in the literature. Over the years, there has been some variation with respect to the order in which boron, carbon, and metal atoms are numbered in a given cluster. An example is (**4**), which is described as 3-Cp-3-Fe-1,2-$C_2B_{10}H_{12}$ by the IUPAC 1990 recommendations, but is also found in the literature as 3-(CpFe)-1,2-$C_2B_{10}H_{12}$, 1-Cp-1-Fe-2,3-$C_2B_{10}H_{12}$, or 1-(CpFe)-2,3-$C_2B_{10}H_{12}$.

Most of the structures of metallacarbaborane clusters derive from triangular-faced polyhedra. Figure 1 shows regular deltahedra up to the icosahedron with the corresponding IUPAC vertex numbering schemes. General cluster classes are *closo* (a complete deltahedral structure), *nido* (a deltahedron with one vertex vacant), *arachno* (a deltahedron with two vertices removed), and *commo* (a structure derived from the fusion of, for example, two deltahedra sharing a common vertex).

2 CLASSES OF COMPOUND AND GEOMETRICAL ASPECTS

2.1 Single Cages

In a single-cage metallacarbaborane, the cluster skeleton consists of one complete polyhedron or one polyhedral fragment. Examples of *closo*-metallacarbaboranes in which one metal fragment has replaced a BH unit in the carbaborane 1,2-$C_2B_{10}H_{12}$ are $CpFeC_2B_9H_{11}$ (**4**), $CpCoC_2B_9H_{11}$, $(OC)_3RhC_2B_9H_{11}$, and $[(OC)_3MoC_2B_9H_{11}]^{2-}$. Each of these compounds adopts an icosahedral framework. Many metallacarbaborane clusters with closed-cage structures smaller than the icosahedron are known, for example, the 11-vertex *closo*-1-(η^6-MeC_6H_4-4-*i*-Pr)-2,3-Me_2-1-Ru-2,3-$C_2B_8H_8$ (**5**). A large group of metallacarbaboranes adopts the *closo*-C_2B_4M core and each possesses a pentagonal bipyramidal structure, for example, 1-Cp*Co-2,3-$C_2B_4H_6$ (**6**), 1-Ge-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_4$ (**7**), and 1-Fe$(CO)_3$-2,4-$C_2B_4H_6$ (**8**).



B = BH, C = CH

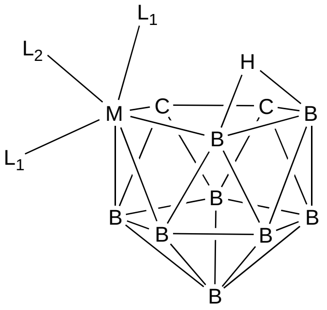
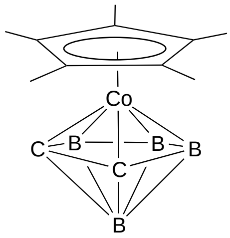
B = BH, C = CH

(**5**)



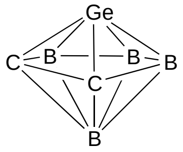
(**9**) B = BH, C = CH, M = Pt, L_1 = PEt_3, L_2 = H

(**10**) B = BH, C = CH, M = Rh, L_1 = L_2 = PMe_3



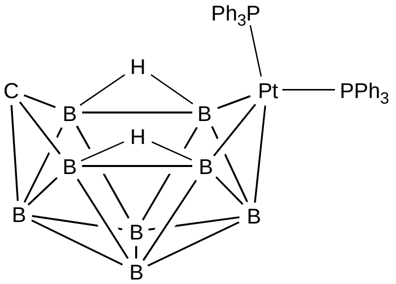
B = BH, C = CH

(**6**)



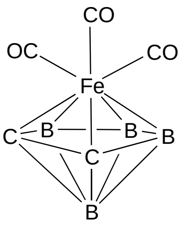
B = BH, C = C($SiMe_3$)

(**7**)



B = BH, C = CH_2

(**11**)



B = BH, C = CH

(**8**)

The number of metallaboranes and metallacarbaboranes in which the metal is from the s block has grown over the past two decades,[19–21] but is still not large when compared to metallacarbaboranes incorporating d-block metal centers. Single-cage metallacarbaboranes include *closo*-1,1,1,1-$(MeCN)_4$-1,2,4-$CaC_2B_{10}H_{12}$,[22] (*closo*-1,1,1-$(MeCN)_3$-1,2,4-$SrC_2B_{10}H_{12})_n$,[23] and *closo*-1-Mg(TMEDA)-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_4$.[24] Group 1 metal ions are often associated through interactions to the outside of the cage rather than being part of the skeleton of the cluster. An example, in which M^+ participates in both the roles, is [*exo*-Cs(TMEDA)-1-Cs-$(SiMe_3)_4C_4B_8H_8]_n$.[25] Metallacarbaborane clusters incorporating f-block metal atoms are actively being developed, and the last 15 years have seen a significant growth in this area.[11,12]

Large numbers of metallacarbaboranes in which the metal atom effectively closes an otherwise open carbaborane cluster are known. However, there are also many compounds in which the metal fragment occupies a site in an open (*nido* or *arachno*) polyhedral cage, for example, *nido* clusters (**9**–**11**).

2.2 Sandwich Complexes

The open face of *nido*-$[C_2B_9H_{11}]^{2-}$ may behave in a similar manner to a cyclopentadienyl ring (see Section 1) and coordinate to M^{n+} to give sandwich complexes such as *commo*-$[Fe(C_2B_9H_{11})_2]^{n-}$ ($n = 1$ or 2), (**1**) and (**2**). Related clusters are the chromium(III) complex *commo*-$[Cr(C_2B_9H_{11})_2]^-$ and the nickel(IV) complex $Ni(C_2B_9H_{11})_2$. In f-block metal complexes, the higher coordination numbers of the metal center lead to the addition of halide or solvent ligands and a concomitant tilting of the carboranyl ligands, for example, in $[(C_2B_9H_{11})_2MX_2]^{2-}$ (M = U, Th; X = halide) (see below).[26,27] Mixed metallacarbaborane/π-organometallic complexes such as (**4**) may also be recognized as sandwich molecules. Similarly, the zirconium(IV) metalloporphyrin–carbaborane compound (OEP)$Zr(C_2B_9H_{11})$ (**12**) can be classed as a sandwich complex.[28]

Like *nido*-$[C_2B_9H_{11}]^{2-}$, the dianion *nido*-$[C_2R_2B_4H_4]^{2-}$ (R = H, Me, $SiMe_3$) exhibits an open pentagonal face, and the frontier orbitals of the two *nido*-carbaborane anions are similar. Thus, it is not surprising to find complexes of the type *commo*-Ge{2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_4\}_2$ (**13**) and *commo*-FeH_2(2,3-Me_2-2,3-$C_2B_4H_4)_2$ (**14**) in which the pentagonal faces of the two *nido*-carbaborane ligands are parallel to one another. The tin(IV) complex *commo*-Sn{2-$(SiMe_3)$-3-Me-2,3-$C_2B_4H_4\}_2$ (**15**) adopts a bent-sandwich structure, with the two C_2B_3 rings subtending an angle of 142.5° at the metal center. This observation is of interest in view of the bent geometries observed for the stannocenes Cp_2Sn and $Cp^*{}_2Sn$.

The first actinoid metal-containing metallacarbaborane, $[U(C_2B_9H_{11})_2Cl_2]^{2-}$, was reported in 1976; the $[C_2B_9H_{11}]^{2-}$ ligands are in a bent-sandwich geometry.[29,30] The same feature is observed in $[(THF)_2Sm(C_2B_9H_{11})_2]^-$ (**16**), one of the first *closo*-lanthanacarbaboranes to be reported[31]; in anion (**16**), the open faces of the $[C_2B_9H_{11}]^{2-}$ ligands subtend an angle of 131.9(5)° at the Sm atom. The bent geometry is a general feature of f-block bis(dicarbollide) complexes because donor or solvent molecules also tend to coordinate the lanthanoid metal ion. In $[(THF)_2Eu(C_2B_{10}H_{12})_2]^{2-}$ (**17**), the *nido*-$[C_2B_{10}H_{12}]^{2-}$ coordinates through its six-membered open face.[32] Larger molecular architectures can result from the involvement of B–H–M bridges from one cage on one sandwich unit to the metal center of another, for example, in $[(\eta^7\text{-}C_2B_{10}H_{12})_2(\eta^6\text{-}C_2B_{10}H_{12})_2U_2]^{4-}$.[33]

(**17**)

Advances in the substitution chemistry of $[C_2B_9H_{11}]^{2-}$ have allowed linked dicarbollide *nido* clusters to be prepared. Ligands with the built-in capacity to form sandwich complexes can therefore be accessed to give the so-called Venus flytrap clusters (VFCs)[34,35] (see also Section 8). The length of the chain linking the two carbaborane clusters must be short enough to allow the approach of the linked dicarbollide ligands to the metal ion that is being bound into the sandwich. The interligand gap is controlled by both the nature of the bridging group and the mutual twisting of the two metal-bonding faces. The first such metallacarbaborane was the zwitter-ionic cobalt(III) compound (**18**). In (**19**), the small pyrazole bridging unit restricts the two C_2B_9 cages to an eclipsed conformation.[34] (The description ''eclipsed'' is used to refer to the relative positions of the two five-membered rings rather than the relative positions of the C and B atoms in the two rings.) In both (**18**) and (**19**), the carbaborane cages are B-substituted. Examples of C-substituted VFCs were reported in 1992.[35] Ether-bridged VFCs have been prepared as model compounds for the development of radiotransition metal carriers.[36]

2.3 Stacked Complexes

Extended stacks containing small boron–carbon rings acting as spacers between metal centers are well established.[37–39] *nido*-Carbaborane ligands such as $[C_2B_4H_6]^{2-}$ can terminate a stack that has a central π-organometallic sandwich unit. Combined with a variety of organic π ligands, metallacarbaborane units can be incorporated into linked stacks. In the simplest type of stack, a carbaborane unit sandwiches together two organometallic fragments, as in $CpCo(C_2Me_2B_3H_3)CoCp$ (**20**). This is called a *triple-decker sandwich* because it contains two metal atoms and three π ligands. Similarly, a tetradecker sandwich is constructed from three metal atoms and four π ligands. By choosing suitable polyarene bridging ligands, linked stacks such as (**21**) can be prepared. The structural variation within the class of stacked complexes can be controlled by careful choice of molecular precursors. One significant development in this area has been to combine the CpM(carboranyl) units into nanoscale assemblies, the properties of which are of active research interest.[40–44] For example, the electrochemical behavior of the planar macrocycle (**22**) is consistent with significant intramolecular electronic communication.[42]

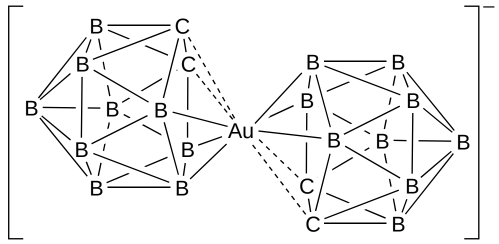
(**21**)

2.4 Slip Distortion

In a sandwich complex, one might expect the two π ligands on either side of a metal atom to lie directly over one another, and to be mutually eclipsed or staggered. However, the occurrence of *commo*-metallacarbaboranes with slipped geometries (a so-called slip distortion) is quite common, notably in cases where a d-block metal ion has a near-complete d-electron configuration, e.g., Ni^{II}, Cu^{II}, or Au^{III}. Thus, in $[Au(C_2B_9H_{11})_2]^-$ (**23**), the gold(III) center interacts more strongly with the boron than the carbon atoms in the open faces of the two ligands. Rather than being similar to a metal–cyclopentadienyl complex, a slipped-sandwich complex starts to resemble a metal–allyl complex (*see* ***Cadmium: Inorganic & Coordination Chemistry***). This structural phenomenon is also observed in many main group *commo*-metallacarbaboranes.[20,45] In the chromium(IV) complex *commo*-$Cr(2,3\text{-}(SiMe_3)_2\text{-}2,3\text{-}C_2B_4H_4)_2$, slip distortion in the opposite sense is observed; the M–C bond lengths are



B = BH, C = CH

(**23**)

shorter than the M−B distances ($Cr{-}B_{av} = 232.1$ pm and $Cr{-}C_{av} = 217.9$ pm).

In single-cage *closo*-metallacarbaboranes containing a main group metal atom, the slippage of the heteroatom with respect to the open face of a *nido*-$[C_2B_9H_{11}]^{2-}$ or *nido*-$[C_2B_4H_6]^{2-}$ ligand, or C-substituted analogs of these ligands, is commonly observed.[20] In general, interaction with the three boron atoms is greater than that with the two carbon atoms. The p-block atom may or may not carry a terminal substituent. In cases where a bare metal atom is incorporated into the metallacarbaborane cluster, it may function as a Lewis acid. In 1-Sn-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_4$ (**24**), distances from Sn to the adjacent B and C atoms are $Sn{-}B_{av} = 242.8$ pm and $Sn{-}C_{av} = 249.8$ pm. In the adduct 1-(bipy)-1-Sn-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_4$ (**25**), not only is the slip distortion more pronounced than in (**24**) ($Sn{-}B_{av} = 248$ pm and $Sn{-}C_{av} = 273$ pm) but the plane of the donor 2,2′-bipyridine (bipy) molecule is acutely tilted with respect to the metallacarbaborane cluster core. Tilting of terminal substituents or donor molecules is observed in many related metallacarbaboranes, e.g., 1-Me-1-Ga-2,3-$C_2B_4H_6$ (**26**), 1-Me-1-In-2,3-$C_2B_4H_6$, 1-bipy-1-Sn-2,3-Me_2-2,3-$C_2B_9H_9$, 1-THF-1-Sn-2,3-Me_2-2,3-$C_2B_9H_9$. For the donor−acceptor complexes, the trend is for an increase in the slip distortion and a decrease in the tilting of the donor ligand as the Lewis acid−base interaction becomes stronger. A number of theoretical studies have addressed the origins of slip distortion.[9]

(**26**)

2.5 Ion Pairing

In most metallacarbaboranes, the interaction between the metal atom and carbaborane cage is considered to be essentially covalent, and this is supported by the experimentally determined M−B and M−C distances. However, in [3-Tl-1,2-$C_2B_9H_{11}]^-$, the distances from the thallium(I) center to the C and B atoms in the open face of the C_2B_9 cage are particularly long, suggesting Tl^+ $[1,2\text{-}C_2B_9H_{11}]^{2-}$ ion pairing. Consistent with this is the fact that the Tl(I) center is readily displaced by other metal ions. In the solid state, variation in the structure of [3-Tl-1,2-R_2-$C_2B_9H_9]^-$ (R = H or Me) is observed as a function of the counterion; slip distortion is observed in all cases and is extreme in Tl[3-Tl-1,2-$C_2B_9H_{11}$]. Table 1 lists selected structural data for the [3-Tl-1,2-R_2-1,2-$C_2B_9H_9]^-$ anion in several salts. In [PPN][3-Tl-1,2-$C_2B_9H_{11}$], dimer formation for the anion (**27**) is observed in the solid state with an internuclear separation between the symmetry-related thallium atoms of 424.1 pm; the dimeric structure is stabilized by B−H−Tl bridges.[46] A novel case of ion pairing is exemplified in {[*closo*-1-Nd(μ-H)$_6$-2,4-$(SiMe_3)_2$-2,4-$C_2B_4H_4]^+$ [1,1′-$(THF)_2$-2,2′,4,4′-$(SiMe_3)_4$-5,5′,6,6′-(μ-H)$_4$-1,1′-*commo*-Nd(η^5-2,4-$C_2B_4H_4$)]$^-$}$_2$. This complex consists of a half-sandwich cationic neodymacarbaborane coordinated to an anionic, fully sandwiched neodymacarbaborane.[47]

Table 1 Structural data to illustrate the interaction of Tl(I) with the C_2B_3 open face of the [1,2-R_2-1,2-$C_2B_9H_9]^-$ ligand in [X][1,2-R_2-3-Tl-1,2-$C_2B_9H_9$][(a)]

X	R	Tl−B (pm)	Tl−C (pm)

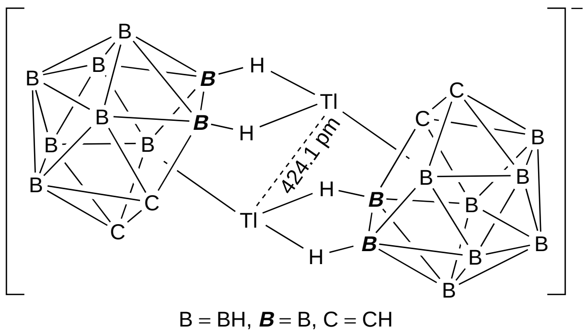
[(a)]Distances should be compared with the sums of appropriate covalent radii: r_{cov} for B = 82, C = 77, Tl = 155 pm. [(b)]The structure of the anion is dimeric in the solid state; see (**27**).

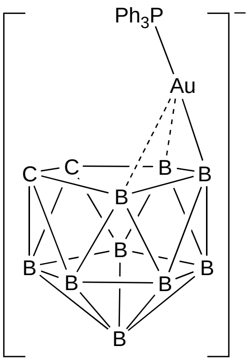


B = BH, ***B*** = B, C = CH
(**27**)

2.6 σ-Bonded and Edge-bridging Metal Fragments

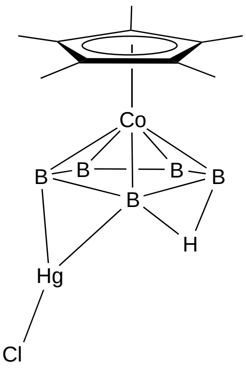
In the extreme, the slip distortion described above leads to the C_2B_3 face of a dicarbollide ligand interacting with a metal atom through only three B atoms. The similarity to an organometallic allyl complex results in the term *borallyl* being used for this type of bonding mode. Examples where the metal binds to only one or two B atoms are also known, that is, M

replaces H in a terminal (B−H) or bridging (B−H−B) unit. In anion (**28**), the $AuPPh_3$ unit interacts strongly with one boron atom (Au−B = 222.2(9) pm) and weakly with the two other boron atoms (Au···B = 248.6(9) and 252.8(9) pm). A similar situation is observed for the $Ph_3PHg(II)$ unit in 10-(Ph_3PHg)-7,8-$C_2B_9H_{11}$. Such metallacarbaboranes show a tendency toward the metal fragment being bonded externally to the polyhedral cage via a direct two-center two-electron M−B σ bond. An example involving a p-block metal is [10-(Ph_3Sn)-10-μ-H-7,8-$C_2B_9H_{10}$]$^-$, which is structurally similar to (**28**) but with the Sn atom bonded to only one B atom; the Sn−B interaction is supported by a bridging hydrogen atom.



B = BH, C = CH

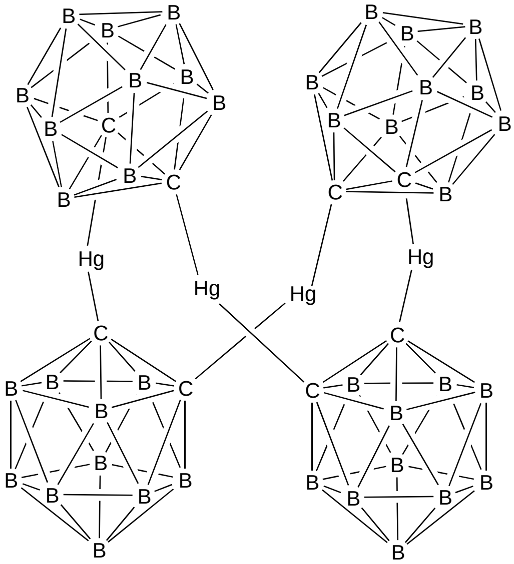
(**28**)



B = BH, C = CH

(**29**)

Copper(I), silver(I), gold(I), and mercury(II) fragments exhibit a tendency to bridge the edges of polyhedral clusters of various types. In metallacarbaborane clusters, one example is (μ-$AuPPh_3$)-9-SMe_2-7,8-$C_2B_9H_{10}$; the structure is related to that of (**28**) except that the gold(I) unit bridges one B−B edge asymmetrically. The preference is for the metal atom to bridge a B−B rather than a B−C or a C−C edge, and this reflects the observed preferences for bridging H atoms in borane and carbaborane clusters (*see* ***Boron: Polyhedral Carboranes***). An example of an edge-bridging mercury(II) unit is shown in (**29**). In the above examples, the metal atom associates with the carbaborane polyhedral cage via a boron−metal bond. Association through a carbon−metal σ bond is also well established. Important precursors to C-substituted derivatives (not necessarily metallated derivatives) of $C_2B_{10}H_{12}$ are the lithiacarbaborane 1,2-Li_2-1,2-$C_2B_{10}H_{10}$ and its 1,7- and 1,12-isomers (see later). The presence of an M−C bond means that members of this class of metallacarbaboranes can be considered as organometallic complexes. Some of the examples are the organomercury complexes $Hg_4(C_2B_{10}H_{10})_4$ (**30**)[48] and (9,12-$Me_2C_2B_{10}H_8Hg)_3$; the latter reacts with LiI to give the unusual sandwich complex (**31**).[49] In contrast to the usual linear coordination environment observed at Hg(II), that in $Hg_4(C_2B_{10}H_{10})_4\cdot(THF)_4\cdot 2H_2O$ is nonlinear (C−Hg−C = 167.7(8)°).



B = BH

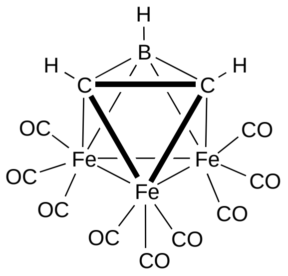
(**31**)

2.7 Exo-metallated Clusters

In some metallacarbaborane clusters, a metal fragment is supported on the outside of the carbaborane skeleton, typically by B−H−M interactions, for example, complex (**27**) involves exo interactions between the Tl(I) atom of one cage and two terminal boron−hydrogen bonds of a second cage. The exo descriptor illustrates the relationship of the metal fragment to the carbaborane and the *nido* descriptor classifies the carbaborane cage.

2.8 Metal-rich Clusters

In almost all metallacarbaboranes, the total number of B and C atoms in the polyhedral cluster exceeds the number of metal atoms. A rare example of a metal-rich metallacarbaborane is *closo*-$Fe_3(CO)_9BHCHCMe$ (**32**); the complex has also been described in terms of an η^3-borirene ligand coordinating to an Fe_3 unit.[50]



(**32**)

3 BONDING

The polyhedral structures adopted by most metallacarbaborane compounds can usually be rationalized using polyhedral skeletal electron pair theory (PSEPT) (*see* ***Electronic Structure of Clusters***). This approach is summarized as follows:

- A *closo* cluster has a closed deltahedral (triangular-faced) structure with n vertices and has $(n+1)$ pairs of cluster-bonding electrons.
- A *nido* cluster possesses a cage based on an n vertex deltahedron with one vertex vacant and has $(n+1)$ pairs of cluster-bonding electrons.
- An *arachno* cluster has a cage based on an n vertex deltahedron with two vertices vacant and has $(n+1)$ pairs of cluster-bonding electrons.

Figure 2 shows the *closo, nido,* and *arachno* skeletons for an eight-electron pair ($n = 7$) cluster based on a pentagonal bipyramid. A BH or BR unit (where R is a one-electron substituent such as an alkyl or aryl group) provides two electrons, and a CH or CR unit provides three electrons for cluster bonding. A transition metal fragment ML_y provides x electrons where x is defined in equation (1) and a main group metal fragment EL_y provides x electrons where x is defined in equation (2). When a main group metal atom is incorporated into a cluster as a naked metal atom, it retains a lone pair of electrons localized outside the cluster and contributes the remaining valence electrons to cluster bonding.

$$\text{Fortransitionmetalfragment}: \quad x = v + l - 12 \qquad (1)$$

$$\text{For main group metal fragment}: \quad x = v + l - 2 \qquad (2)$$

(v = number of valence electrons of metal atom;

l = number of electrons provided by ligans, L)

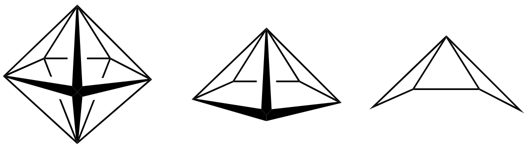


Figure 2 The *closo, nido*, and *arachno* skeletons for an eight-electron pair ($n = 7$) cluster based on a pentagonal bipyramid (seven vertices)

Examples are as follows; in each case, PSEPT predicts the skeletal geometry but not the particular isomer(s) that is (are) adopted in practice.

1. In $(CpCo)C_2B_9H_{11}$, the CpCo fragment provides two electrons, each BH unit is a source of two electrons, and each CH unit gives three electrons. The metallacarbaborane has 13 pairs of electrons with which to bind the 12 cluster units. This means that $CpCoC_2B_9H_{11}$ is a *closo*-metallacarbaborane with an icosahedral skeleton (Figure 1).
2. In $Ge(CSiMe_3)_2B_4H_4$, the Ge atom contributes two electrons, each $CSiMe_3$ unit gives three electrons, and each BH unit gives two electrons. $Ge(CSiMe_3)_2B_4H_4$ has eight pairs of bonding electrons for seven cluster units. Thus, $Ge(CSiMe_3)_2B_4H_4$ has a *closo* structure with a pentagonal bipyramidal structure; in practice, the isomer shown in (**7**) is observed.
3. In $PtH(PEt_3)_2C_2B_8H_{11}$, the $PtH(PEt_3)_2$ unit provides three electrons, each CH unit gives three electrons, each BH unit provides two electrons, and the extra H atom provides one electron. The metallacarbaborane has 13 pairs of electrons for cluster bonding over 11 cluster centers, and $PtH(PEt_3)_2C_2B_8H_{11}$ has a *nido* structure based upon an icosahedron with one vertex left vacant. The observed isomer is (**9**). The extra H atom adopts a B–H–B bridging position on one edge of the open face of the *arachno* cage (*see* ***Boron Hydrides***).

Compounds like $[Fe(C_2B_9H_{11})_2]^{n-}$ can be represented either as *commo*-metallacarbaboranes comprising two vertex-fused icosahedra (**1**) or as organometallic-type sandwich complexes (**2**) (see Section 1). Similarly, two approaches can be taken when considering the bonding in such compounds: they may be described in terms of the two separate polyhedra by using PSEPT or in terms of the 18-electron rule (*see Effective Atomic Number Rule*). With regard to bonding, complexes with icosahedral cluster units give rise to some exceptional cases (see below). A better general example is *commo*-$FeH_2(2,3\text{-}Me_2\text{-}2,3\text{-}C_2B_4H_4)_2$ (**14**). This structure comprises two pentagonal bipyramidal cages fused via a common FeH_2 unit. Each $(CMe)_2B_4H_4$ unit possesses $[(2 \times 3) + (4 \times 2)]$ electrons for cluster bonding. An Fe atom has an s^2d^6 configuration; of these eight electrons, six

occupy nonbonding orbitals. The FeH_2 unit therefore has four electrons available for cluster bonding, two for each half of the *commo* cluster. This gives a total of 16 electrons (eight pairs) per half-cluster and so each half-cluster has a *closo* structure. Alternatively, if $FeH_2(2,3\text{-}Me_2\text{-}2,3\text{-}C_2B_4H_4)_2$ is similar to a π-organometallic complex, then the 18-electron rule can be applied to the Fe atom. Each $[(CMe)_2B_4H_4]^{2-}$ ligand is a 6π-electron donor to the Fe(II) center (d^6 configuration); in this model, the H atoms are counted as protons and provide no electrons. A neutral-atom model can also be adopted in which each neutral $(CMe)_2B_4H_4$ unit is a 4π-electron donor to the Fe(0) center (s^2d^6 configuration). In this model, each H atom provides one electron to the Fe(0) atom. Either way, the 18-electron rule is satisfied.

Bonding within multiple stacks such as (**20**) and (**21**) is best dealt with in terms of the organometallic model, extended to give electron counts for the stack as a whole. Triple-decker stacks (three ligands and two metal atoms) usually require 30 electrons overall to give a stable diamagnetic complex, although there is flexibility and between 26 and 34 electrons can be accommodated. For an extra unit of the stack, 12 more electrons should be added; thus, a tetradecker stack (four ligands and three metals) is stable with 42 electrons. Units within the stacks are often derivatized Cp^- or $[C_2B_3H_5]^{2-}$ ligands; both are sources of 6π electrons.

We now return to clusters with icosahedral cages. By PSEPT, the 12-vertex *closo* icosahedral cluster requires 26 bonding electrons. However, there are numerous examples in which the number of electrons observed deviates from 26. In $CpFeC_2B_9H_{11}$, the total electron count for cluster bonding is 25. In $[Fe(C_2B_9H_{11})_2]^-$, it is not possible to allocate 26 electrons to each half-cluster. For clusters with 24–26 electrons, an icosahedral cage is usually adopted despite the apparent violation of PSEPT. An increased number of electrons provides an explanation for the origin of the slip distortion described earlier, for example, in $[Au(C_2B_9H_{11})_2]^-$ (**23**), each half-cluster has 27 electrons (for each half-cluster, 2 CH = 6 electrons, 9 BH = 18 electrons, Au^- contributes three electrons per cluster after six electrons have been accommodated in nonbonding orbitals).

4 SYNTHESIS

Although, in this section, an attempt has been made to systematize some synthetic routes to metallacarbaboranes,[4–6,51] many other syntheses have been reported, which lack the strategic quality that is desirable for efficient preparative chemistry.

If a metallacarbaborane is represented as {MCB}, then obvious methods of synthesis would be based on the following combinations: (i) {M} + {CB}, (ii) {MB} + {C}, (iii) {MC} + {B}, or (iv) aggregation of {M}, {C}, and {B}. The nonspecific nature of particle aggregation makes (iv) unattractive in most instances.

4.1 Carbaborane Anion with Metal Halide

The most general synthetic strategy in the preparation of metallacarbaborane clusters is the addition of a metal fragment to an anionic carbaborane cluster, that is, {M} + {CB}. Many methods involve the metallic capping of a *nido*-carbaborane to generate a *closo*-metallacarbaborane. The examples given in equations (3–6) illustrate cases in which the electron count for the cluster remains unaltered during the reaction and hence the polyhedral skeleton of the *closo* product is related to that of the *nido* precursor. In each case, the metal fragment being added provides two electrons to cluster bonding. In equations (3) and (4), the two electrons from the metal fragment replace those originally provided by the 2− charge. In equation (5), the monoanionic precursor loses H^+ during the reaction.

$$nido\text{-}[C_2B_9H_{11}]^{2-} + SmI_2(THF)_x \longrightarrow closo\text{-}Sm(THF)_4C_2B_9H_{11} + 2I^- \quad (3)$$

$$nido\text{-}[C_2Me_2B_9]^{2-} + SnCl_2 \longrightarrow nido\text{-}SnC_2Me_2B_9H_9 + 2Cl^- \quad (4)$$

$$nido\text{-}[C_2(SiMe_3)_2B_4H_5]^- + SnCl_2 \xrightarrow{THF} closo\text{-}Sn(THF)_2C_2(SiMe_3)B_4H_4 \xrightarrow{100\,^\circ C} closo\text{-}SnC_2(SiMe_3)_2B_4H_4 \quad (5)$$

$$nido\text{-}[C_2Me_2B_9H_9]^{2-} + W(CR)Br(CO)_4 \quad R = 4\text{-}MeC_6H_4 \longrightarrow closo\text{-}[W(CR)(CO)_2(C_2Me_2B_9H_9)]^- \quad (6)$$

The addition of a metal fragment to a *nido*-carbaborane anion may result in an increase in the number of cluster-bonding electrons. For example, in equation (7), the reaction of *nido*-$[C_2B_8H_{11}]^-$ with $RhCl(PMe_3)_3$ leads to the displacement of Cl^- and the combination of the carbaborane anion and $[Rh(PMe_3)_3]^+$ fragments. The latter is a source of three electrons (see equation 1) and hence the total cluster-electron count increases by two during the reaction. Such an increase will generate a change in skeletal geometry (see Section 3). Both $[C_2B_8H_{11}]^-$ and $(PMe_3)_3RhC_2B_8H_{11}$ are *nido* clusters, but each is based on a different deltahedral framework. An alternative pathway might have been for $(PMe_3)_3RhC_2B_8H_{11}$ to extrude H_2 or a PMe_3 ligand, thus effectively reducing the electron count by two.

$$nido\text{-}[C_2B_8H_{11}]^- + RhCl(PMe_3)_3 \longrightarrow nido\text{-}(PMe_3)_3RhC_2B_8H_{11} + Cl^- \quad (7)$$

The reaction of *nido*-carbaborane anions with metal halides is also a method of preparing *commo*-metallacarbaboranes

(equations 8–10). In equation (8), there is competition between the formation of the *closo*- and *commo*-germacarbaboranes.

$$nido\text{-}[C_2(SiMe_3)_2B_4H_4]^{2-} + GeCl_4 \xrightarrow{\text{THF, }0\,^\circ\text{C}} closo\text{-}GeC_2(SiMe_3)_2B_4H_4 + commo\text{-}Ge\{C_2(SiMe_3)_2B_4H_4\}_2 \quad (8)$$

$$2nido\text{-}[C_2B_9H_{11}]^{2-} + SiCl_4 \xrightarrow{\text{Reflux in }C_6H_6} commo\text{-}Si(C_2B_9H_{11})_2 \quad (9)$$

$$2nido\text{-}[C_2B_9H_{11}]^{2-} + EuI_4(THF)_2 \xrightarrow{\text{THF}} [1,1\text{-}(THF)_2\text{-}commo\text{-}Eu(C_2B_9H_{11})_2]^{2-} \quad (10)$$

4.2 Use of Thallium(I)-containing Carbaboranes

In Section 2.5, the special nature of $[TlC_2B_9H_{11}]^-$ was described. The Tl(I) center can be replaced by a variety of p-, d-, and f-block metal atoms, e.g., equations (11–16). The use of Tl(I)-containing carbaboranes for the synthesis of other metallacarbaboranes is of general reaction type {M} + {TlCB}. Reactions of $[X][TlC_2B_9H_{11}]$ (e.g., X = Tl or PPN) with metal halides proceed with loss of thallium(I) halide. Equation (11) shows a designed route to a *commo*-samaracarbaborane by the displacement of two THF ligands from *closo*-$Sm(THF)_4C_2B_9H_{11}$ by a dicarbollide ligand. The reaction also involves a redox change: Tl(I) to Tl(0) and Sm(II) to Sm(III). The product of the reaction of $[TlC_2B_9H_{11}]^-$ with CuCl and PPh_3 depends on the reaction stoichiometry. For a cluster anion : copper(I) ratio of 1:1, the reaction proceeds according to equation (13). With a 1:2 ratio, a second Cu atom is introduced as an exo-polyhedral unit (**33**), with two of the cluster B–H hydrogen atoms stabilizing the structure by forming B–H–Cu_{exo} bridging interactions.

$$[PPN][TlC_2B_9H_{11}] + closo\text{-}Sm(THF)_4C_2B_9H_{11} \longrightarrow [PPN][(THF)_2\text{-}commo\text{-}Sm(C_2B_9H_{11})_2] + Tl + 2THF \quad (11)$$

$$Tl[TlC_2Me_2B_9H_9] + GeCl_2 \longrightarrow closo\text{-}GeC_2Me_2B_9H_9 + 2TlCl \quad (12)$$

$$[TlC_2B_9H_{11}]^- + CuCl + PPh_3 \longrightarrow closo\text{-}[(PPh_3)CuC_2B_9H_{11}]^- + TlCl \quad (13)$$

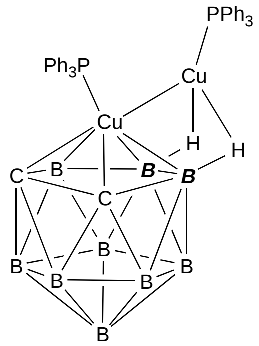
$$Tl[TlC_2B_9H_{11}] + PdCl_2(TMEDA) \longrightarrow closo\text{-}Pd(TMEDA)C_2B_9H_{11} + 2TlCl \quad (14)$$

$$2[TlC_2B_9H_{11}]^- + CoCl_2 \longrightarrow commo\text{-}[Co(C_2B_9H_{11})_2]^{2-} \xrightarrow{\text{Oxidation}} commo\text{-}[Co(C_2B_9H_{11})_2]^- \quad (15)$$

$$[TlC_2B_9H_{11}]^- + Ph_3PAuCl \longrightarrow [(Ph_3P)AuC_2B_9H_{11}]^- + TlCl \quad (16)$$

4.3 Neutral Carbaborane with a Metal Fragment

Syntheses of metallacarbaboranes from neutral carbaborane precursors, that is reaction type {M} + {CB}, are



B = BH, C = CH, ***B*** = B

(**33**)

exemplified in equations (17–20). Reaction conditions often involve thermolysis or photolysis. Capping a *nido* cluster to form a skeletally related *closo* cluster proceeds with the extrusion of ligands if the cluster-electron count is to remain constant. In equation (17), the structure of *nido*-$C_2B_4H_8$ is derived from an eight-electron pair pentagonal bipyramidal cluster (Figure 2). Reaction of *nido*-$C_2B_4H_8$ with $Fe(CO)_5$ results in the addition of an $Fe(CO)_3$ unit to the open face of the *nido* cluster. The $Fe(CO)_3$ unit provides two electrons to cluster bonding; in order to retain the pentagonal bipyramidal skeleton, the carbaborane responds to the addition of the metal fragment by eliminating H_2.

Metal fragment addition with *nido* to *closo* cluster change:

$$nido\text{-}C_2B_4H_8 + Fe(CO)_5 \xrightarrow{\Delta} closo\text{-}Fe(CO)_3C_2B_4H_6 + H_2 + 2CO \quad (17)$$

Metal fragment insertion into a *closo* cluster:

$$nido\text{-}C_2B_4H_6 + Fe(CO)_5 \xrightarrow{\Delta} closo\text{-}Fe(CO)_3C_2B_4H_6 + 2CO \quad (18)$$

Metal fragment-for-BH unit substitution in a *closo* cluster:

$$closo\text{-}C_2B_{10}H_{12} + CpCo(CO)_2 \longrightarrow closo\text{-}CpCoC_2B_9H_{11} + 2CO \quad (19)$$

Metal fragment insertion into a *nido*-cluster:

$$nido\text{-}C_2B_8H_{12} + Cp_2Ni \longrightarrow nido\text{-}CpNiC_2B_8H_{11} + C_5H_6 \quad (20)$$

The insertion of a two-electron cluster fragment into a *closo*-carbaborane cluster can result in the expansion of the cluster framework. Thus, in equation (18), the insertion of an $Fe(CO)_3$ fragment into the octahedral cluster *closo*-$C_2B_4H_6$ yields a pentagonal bipyramidal metallacarbaborane. On the other hand, fragment substitution may be preferred to fragment insertion. This is particularly true for the icosahedral skeleton. Reaction 19 shows the substitution of a CpCo for an isolobal BH unit. This type of fragment replacement is called *subrogation*. Finally, equation (20) illustrates the insertion of

a metal fragment into a *nido* cluster; the CpNi unit is a source of three electrons and one H atom is lost from the precursor in order to retain an even electron count for the cluster.

4.4 Metallaborane with an Alkyne

An important method for the synthesis of carbaboranes is the reaction of a borane cluster with an alkyne. However, an analogous reaction of a metallaborane cluster with an alkyne is not commonly used to prepare metallacarbaborane clusters. Equation (21) illustrates one example.

$$nido\text{-2-(CpCo)B}_4\text{H}_8 + \text{C}_2\text{H}_2 \longrightarrow nido\text{-2-(CpCo)C}_2\text{B}_3\text{H}_7 \quad (21)$$

Reactions between a metallaborane and alkyne are not always predictable. For example, *nido*-1,2-$(Cp^*Rh)_2B_3H_7$ catalyzes the cyclotrimerization of alkynes rather than undergoing insertion of the alkyne into the cluster cage.[52]

4.5 Aggregation of Metal Atoms, Borane, and Alkynes

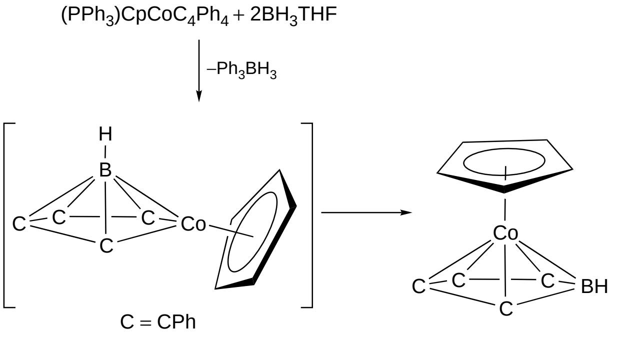
Metal-atom vapor synthesis techniques have been successfully applied to the preparation of metallacarbaboranes, that is, reaction type {M} + {C} + {B}. A disadvantage is that product distribution tends to be nonspecific, for example, when Co metal is vaporized by electrical heating and cocondensed at −196 °C with cyclopentadiene, B_5H_9, and the alkyne MeC≡CMe, 1-(CpCo)-2,3-Me_2-2,3-$C_2B_4H_4$, 1,7-$(CpCo)_2$-2,3-Me_2-2,3-$C_2B_3H_3$, and 1,7-$(CpCo)_2$-2,5-Me_2-2,5-$C_2B_5H_5$ are formed in low yield. If B_6H_{10} is used instead of B_5H_9 as the borane precursor, the products are 3-(CpCo)-1,2-Me_2-1,2-$C_2B_5H_5$, 2,5-$(CpCo)_2$-6,7-Me_2-6,7-$C_2B_6H_8$, and 2,4-$(CpCo)_2$-6,7-Me_2-2,4–6,7-$C_2B_6H_6$.

4.6 Borane with an Organometallic Complex

The method of metallacarbaborane synthesis that involves the combination of {MC} + {B} fragments is not commonly used. However, the designed synthesis shown in Scheme 1 works well. The reagent BH_3·THF is a source of boron for the metallacarbaborane product, and is also able to abstract phosphine from the organometallic precursor. Monoborane (BH_3) is a Lewis acid and forms adducts with Lewis bases; PPh_3 displaces THF from BH_3·THF and is transferred from $(PPh_3)CpCoC_4Ph_4$ to form PPh_3·BH_3, leaving an active {$CpCoC_4Ph_4$} fragment, which can interact with a second mole of borane.

4.7 Construction of Stacked Complexes

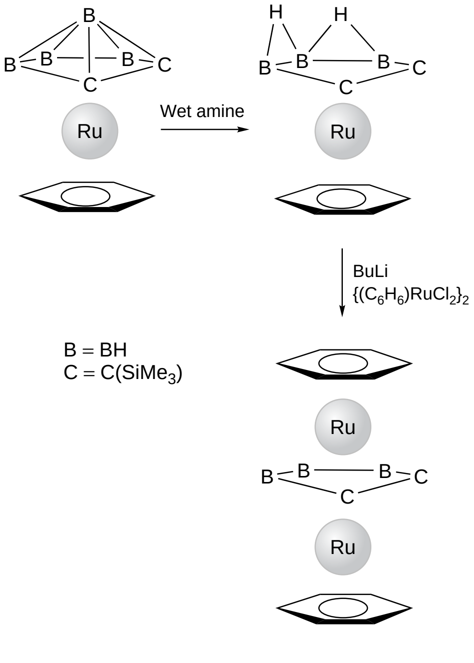
Work directed at preparing and characterizing stacked complexes has been developed since the late 1980s, and the syntheses are carefully controlled.[39,51] The principles of the approach are outlined below, but may be summarized as an example of the method. The archetypal sandwich compound is ferrocene,



Scheme 1

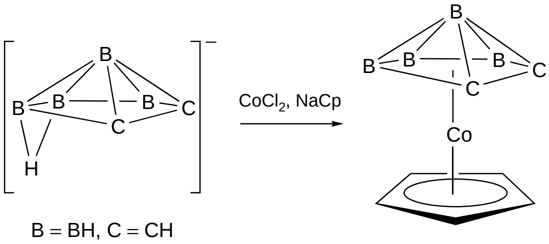
in which two coparallel C_5H_5 rings sit on either side of Fe. Both the Cp^- and $[C_2B_3H_5]^{2-}$ ligands are sources of 6π electrons and both have similar frontier orbitals. Similarly, the *nido* cluster $[2,3\text{-}C_2B_4H_6]^{2-}$ can present an open C_2B_3 pentagonal face to a metal center. Organometallic sandwich complexes utilize organometallic π ligands other than Cp^-, for example, benzene can act as a 6π-electron ligand. These and other chemical building blocks can be used to assemble stacks with alternating metal and organic or carbaborane units. Extension of these principles could lead to three-dimensional networks.[43]

In the simplest type of reaction, a double-decker sandwich is prepared as shown in equation (22). The next step in the assembly of a stack might be the removal of the BH apex from a $(\eta^n\text{-}C_nH_n)M(2,3\text{-}R_2\text{-}2,3\text{-}C_2B_4H_4)$ complex, where typically $n = 5$ and M = Co, Ni, or $n = 6$ and M = Ru, Fe (first step in Scheme 2). The decapping of $(\eta^6\text{-}C_6H_6)Ru(2,3\text{-}(SiMe_3)_2\text{-}2,3\text{-}C_2B_4H_4)$ is accompanied by double protonation of the newly



Scheme 2

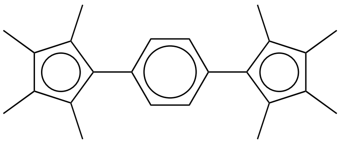
exposed C_2B_3 face. The two protons (present as B–H–B bridges) can be removed by treatment with a base such as *n*-BuLi; the dianion so formed reacts with an organometallic metal halide, adding a new metal-containing unit to the stack, and yielding a triple-decker sandwich complex. This general strategy can be adapted to generate a variety of multiple stacks.



B = BH, C = CH

(22)

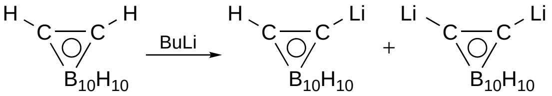
Linking stacks together can be achieved by incorporating ligands with pendant arms into the first stack, which are themselves potential ligands, for example (**34**). One of the results of this strategy is the formation of (**21**).



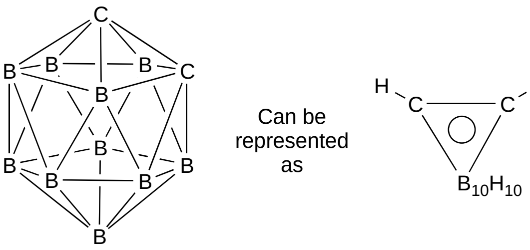
(**34**)

4.8 Use of Lithiated Carbaboranes

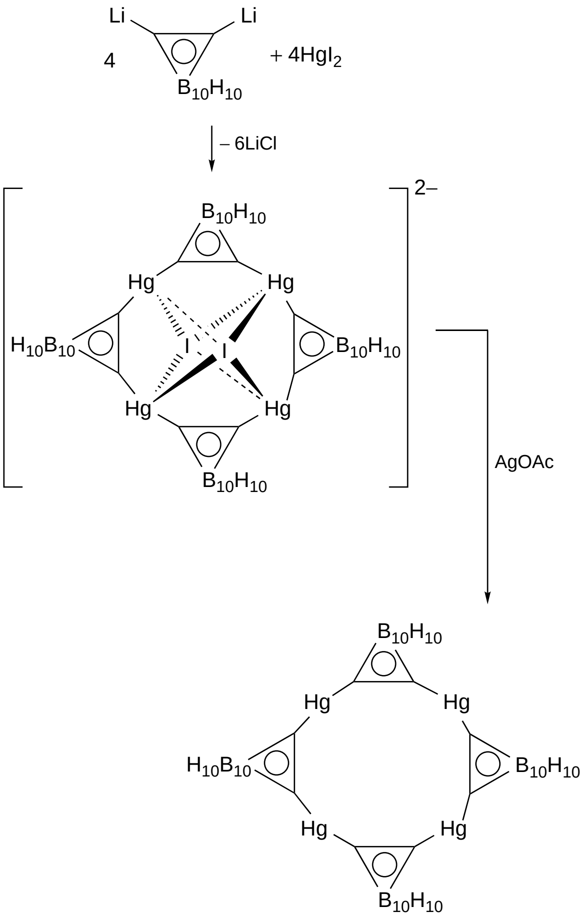
The carbon-bound hydrogen atoms in *closo*-1,2-$C_2B_{10}H_{12}$ (**35**) are acidic, and lithiation occurs readily (equation 23). The monolithiated cluster disproportionates to a mixture of 1,2-$C_2B_{10}H_{12}$ and 1,2-Li_2-1,2-$C_2B_{10}H_{10}$. Protection of one C site can be achieved by using a *t*-$BuMe_2Si$ group; the cluster can be deprotected with [*n*-Bu_4N]F. Lithiated derivatives are used to prepare a range of C-substituted derivatives.[53]



(23)



B = BH, C = CH
(**35**)



(**30**)

Scheme 3

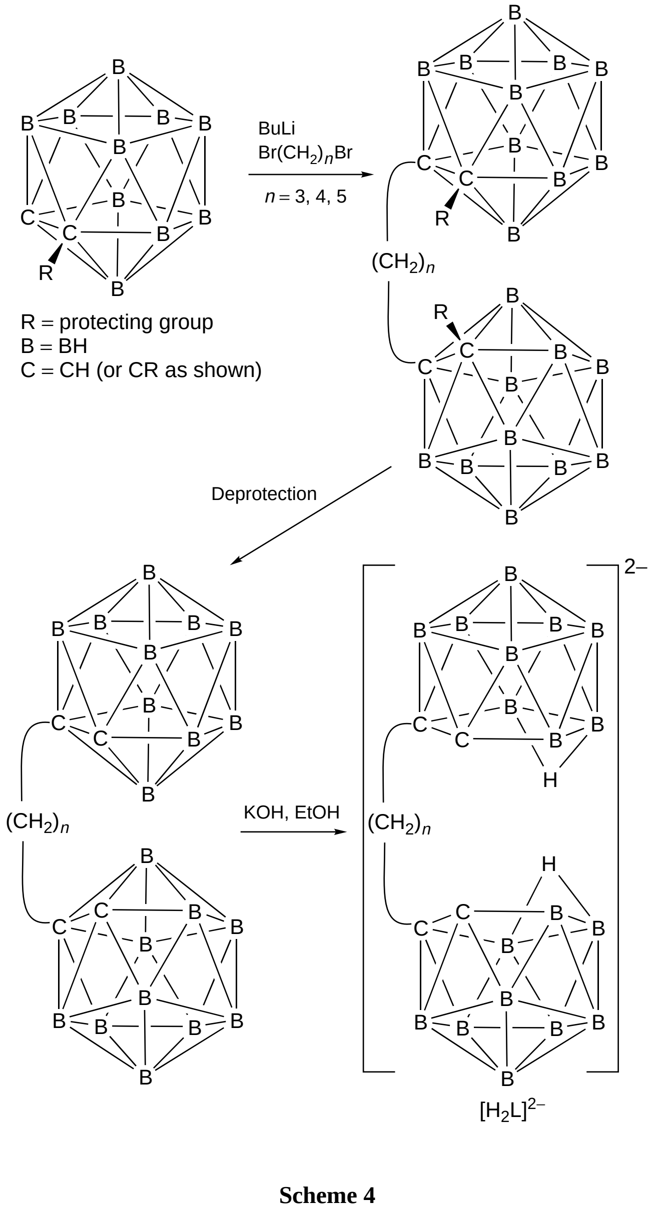
The reaction of lithiated derivatives of 1,2-$C_2B_{10}H_{12}$ with mercury(II) halides is a route to organomercury complexes with Hg–$C_{carbaborane}$ bonds.[54] An interesting example is shown in Scheme 3; 1,2-Li_2-1,2-$C_2B_{10}H_{10}$ reacts with HgI_2 to give $Li_2[Hg_4(C_2B_{10}H_{10})I_2]$. When LiI is removed, a cyclic tetrameric complex, which is described as a macrocyclic Lewis acid, is produced.

4.9 *commo*-Clusters

commo-Metallacarbaborane clusters in which the two dicarbollide ligands are connected by a bridging unit can be prepared by introducing the bridge after the *commo* cluster has been synthesized. For example, (**18**) is prepared by the reaction of $K[Co(C_2B_9H_{11})_2]$ with CS_2 and HCl in the presence of aluminum chloride. Alternatively, VFC (see Section 2.2), are prepared by first assembling a ligand consisting of two carboranyl ligands that are strapped together. The strap can either be a B ··· B or C ··· C link, where B or C is a B- or C-substituted site on one carboranyl unit.

The protected monosubstituted derivative 1-(t-BuMe$_2$Si)-1,2-$C_2B_{10}H_{11}$ is the starting point for the synthesis of ligands of type $[H_2L]^{2-}$ shown in Scheme 4. The length of the strap is critical if $[H_2L]^{2-}$ is to be a precursor to *commo*-metallacarbaboranes of type $[ML]^-$. Scheme 4 illustrates a sequence used to link together two dicarbollide ligands via a C $\cdots$ C link. Ligand $[H_2L]^{2-}$ interacts with a variety of first-row transition metal(III) ions (M^{3+}), for example, Co^{3+}, Cr^{3+}, with concomitant deprotonation of the two *nido* cages to give $[ML]^-$. The pyrazole-containing ligand present in complex (**19**) is synthesized from *closo*-$C_2B_9H_{11}$ and $[C_3H_3N_2]^-$.

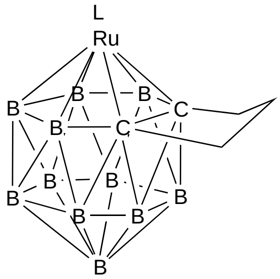
The development of preparative routes to ligands such as $[H_2L]^{2-}$ in Scheme 4 has been a breakthrough in the controlled synthesis of the VFC group of *commo* complexes, which have potential biological uses (see Section 8).



Scheme 4

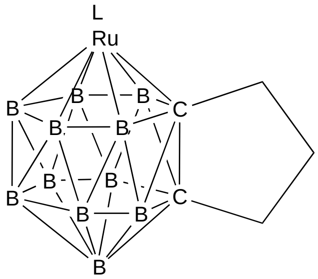
4.10 Clusters with More than 12 Vertices

Although the chemistry of metallacarbaborane clusters with $\leq$12 vertices is extremely well established, that of larger, single-cage compounds is a more recent development. Preparative routes to dicarbon metallacarbaboranes of the platinum group metals having 11, 12, or 13 vertices have been reviewed.[55] Metal capping of *nido*-[7,9-$R_2C_2B_{10}H_{10}]^{2-}$ is a general route to 13-vertex metallacarbaboranes. The *nido* precursor is produced by reduction of *closo*-1,2,-$R_2C_2B_{10}H_{10}$, but this step always results in a separation of the carbon atoms in the cluster cage (the ''carbons-apart'' product). Tethering the C_2 unit to a C,C′-bridging substituent allows the ''carbons adjacent'' product to be isolated (Scheme 5). The ''carbons-apart'' and ''carbons-adjacent'' species exhibit different redox properties, with the dianion in Scheme 5 being further reduced by Li metal to the corresponding tetraanionic *arachno* cluster. By altering the length and flexibility of the organic bridge, it is possible to gain control over the final positions of the two carbon atoms in the reduced product.[56] A significant achievement has been the use of the carbon-tethered *nido* or *arachno* clusters in reactions with $RBCl_2$ to prepare the first examples of 13- or 14-vertex carbaboranes, respectively.[57,58] Advances in the syntheses of metallacarbaboranes with 13 vertices (MC_2B_{10}, MC_4B_8, $M_2C_2B_9$, $M_2C_3B_8$, $M_3C_3B_7$) or 14 vertices (MC_2B_{11}, $M_2C_2B_{10}$, $M_2C_4B_8$) have been reviewed.[56,59] Most recently, reduction of the carbon-tethered 1,2-μ-$(CH_2)_3$-1,2-*closo*-$C_2B_{11}H_{11}$ by Na and subsequent reaction of the reduced, open cage with [(p-cymene)$RuCl_2]_2$ has given rise to the isomeric, 15-vertex clusters (**36**) and (**37**).[60]



B = BH
L = p-cymene

(**36**)

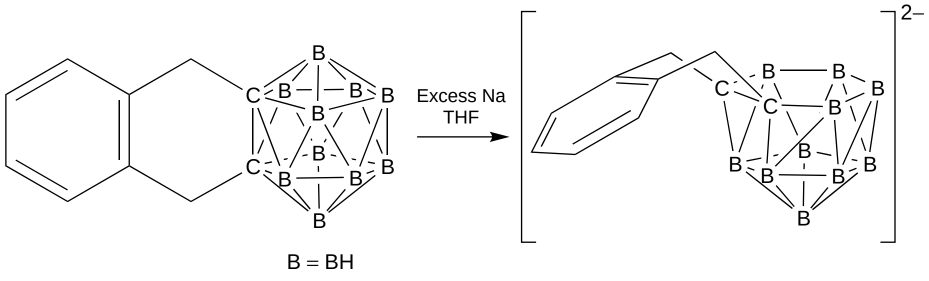


B = BH
L = p-cymene

(**37**)

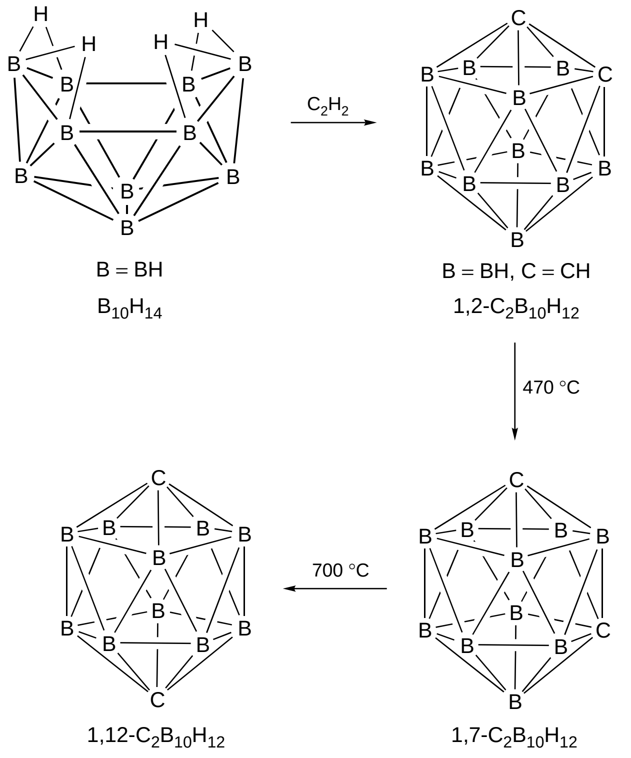
5 SKELETAL ISOMERISM

Of the polyhedra in Figure 1, only the octahedron and icosahedron possess equivalent vertices. *closo*-$[B_{12}H_{12}]^{2-}$ contains only one B environment and the introduction of one C atom in place of B generates $[CB_{11}H_{12}]^-$ for which there is only one structure. Introduction of two C atoms to



Scheme 5

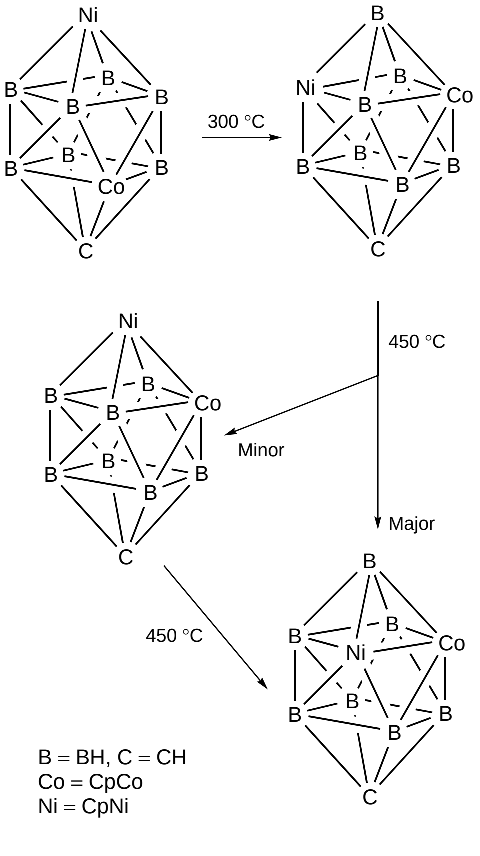
give $C_2B_{10}H_{12}$ leads to three possible isomers: 1,2-, 1,7-, and 1,12-$C_2B_{10}H_{12}$ (equation 24).



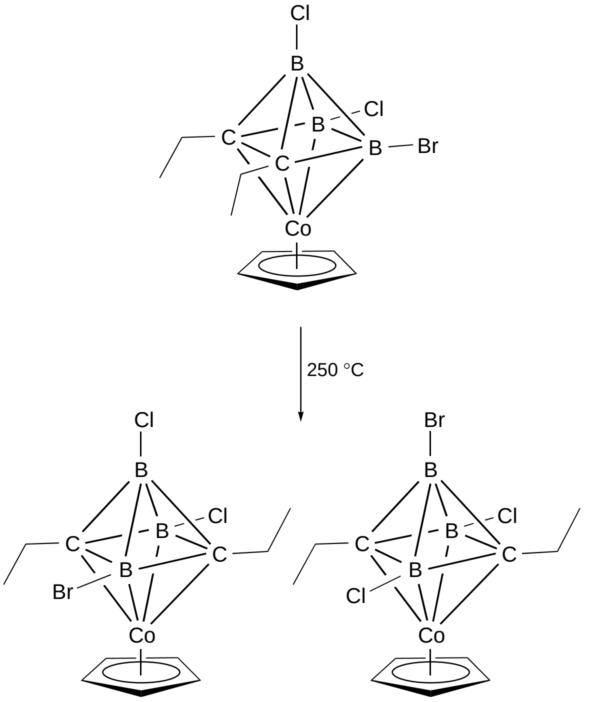
(24)

Introducing a metal atom into the carbaborane framework increases the number of possible isomers. In the synthesis of a metallacarbaborane, the kinetic product may not necessarily be the thermodynamically preferred isomer, for example, in the synthesis of $CpCoC_4Ph_4BH$, the first isomer to be formed rearranges spontaneously to the thermodynamically favored one (Scheme 1). An understanding of the mechanisms for polyhedral rearrangements among metallacarbaboranes remains relatively undeveloped, but proposals usually involve nondissociative processes. General preferences follow the guidelines that (i) carbon atoms prefer sites of low *connectivity*, (ii) carbon atoms tend to be apart from one another (but see Section 4.10), (iii) metal atoms show a tendency for sites of relatively high connectivity, and (iv) a metallacarbaborane cluster tends to exhibit some degree of symmetry. However, these are guidelines, not rules. In (**5**), for example, all four guidelines are met: the Ru atom occupies the unique site of the octadecahedron with connectivity six, while the two C atoms are mutually apart (a ‘‘carbons-apart’’ isomer) and are in sites of connectivity four.

Examples of thermal skeletal isomerization are as follows. The 11-electron pair cluster *closo*-$Cp_2CoNiCB_7H_8$ (Scheme 6) has a structure based upon a bicapped square antiprism (Figure 1). This polyhedron has two distinct types of vertex: (i) two apical sites each of which has a connectivity of four within the cage and (ii) eight equatorial or square antiprism sites each of which has a connectivity of five within



Scheme 6



Scheme 7

the cage. After thermolysis, the metal atoms end up in the sites of higher connectivity and the carbon atom remains in a site of low connectivity.[61]

When 1-(CpCo)-2,3,-$C_2B_9H_{11}$ is heated between 400 and 700 °C, six isomers are obtained in which the carbon atoms have migrated around the cage positions.[62] Thermal rearrangements of $(CpCo)_2C_2B_nH_{n+2}$ ($n = 6{-}8$) lead to isomeric products,[63] and an *exo–nido* → *closo* skeletal rearrangement is observed when *exo–nido*-5,6,10-$(Cl(PPh_3)_2Ru)$-5,6,10-(μ-H)$_3$-10-H-7,8-$C_2B_9H_8$ is heated in benzene under reflux conditions.[64,65] In the rearrangement of icosahedral [3,1,2-$(CO)_2(C_3H_5)Mo(PhC_2B_9H_{11})]^-$ to the carbons-apart isomer [3,1,9-$(CO)_2(C_3H_5)Mo(PhC_2B_9H_{11})]^-$, a nonicosahedral intermediate has been isolated; the rearrangement is facile, occurring at room temperature, apparently to relieve steric crowding.[66] A final example involves the little-studied six-membered *closo*-MC_2B_3 cage. When heated to 250 °C, *closo*-1,2,3-Cp*Co($Et_2C_2B_3$-4,6-Cl_2-5-Br) rearranges as shown in Scheme 7, while heating *closo*-1,2,3-Cp*Co($Et_2C_2B_3Br_3$) leads to a single ''carbons-apart'' isomer.[67]

6 ELECTROCHEMISTRY

The discussion of the electrochemical properties of metallacarbaboranes involves the compounds that are best subdivided into clusters and stacked complexes.

$$[\text{Co–Co}]^{2+} \leftarrow [\text{Co–Co}]^{+} \rightleftharpoons [\text{Co–Co}] \rightleftharpoons [\text{Co–Co}]^{-} \rightleftharpoons [\text{Co–Co}]^{2-}$$

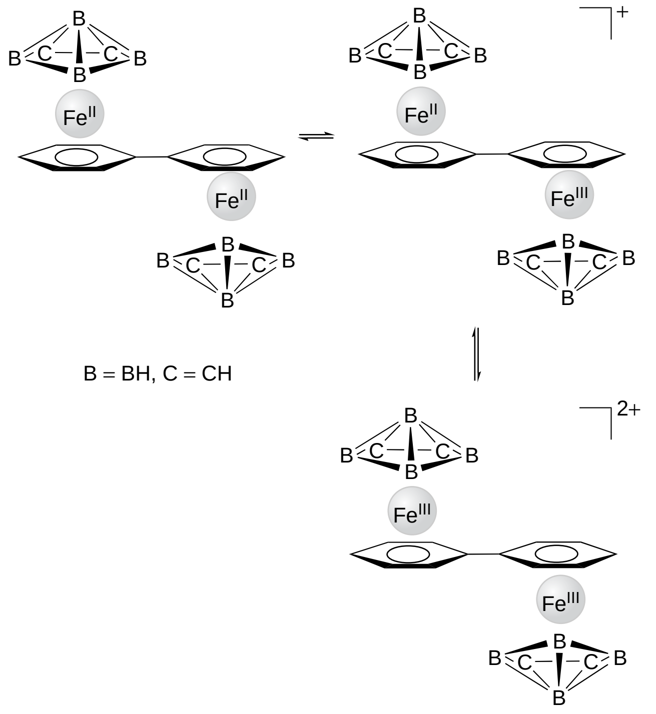
Scheme 8

Electrochemical data for a wide range of metallacarbaborane clusters have been collected together in several reviews.[68–70] For metallacarbaboranes containing transition metal atoms, the measured redox couple is usually assigned to the process $M^{n+} + e^- \rightarrow M^{(n-1)+}$. However, this may be a formal designation since the bonding in a metallacarbaborane cluster is delocalized. Some general conclusions[68] are as follows: (i) if the carbon atoms are adjacent to the transition metal atom, the reduction process for the cluster occurs more easily than when the carbon atoms are more remote from the metal atom; (ii) metallacarbaborane clusters containing an $MC_2B_{10}H_{12}$ core exhibit lower reduction potentials than clusters with an $MC_2B_9H_{11}$ core for a common metal, M; and (iii) when more than one metal is present in a metallacarbaborane cluster core, the metals influence one another.

Electrochemical studies of sandwich complexes have also included multiple stacked systems.[5,7,68] In triple-decker complexes such as (**20**), a series of diffusion-controlled reversible one-electron redox processes is observed. Thus, for (**20**) (CMe replaced by CEt), the processes are summarized in Scheme 8 in which [Co–Co] represents the core of the triple-decker sandwich complex. It is the metal atoms (not the sandwich layers) that are the centers for the redox changes; however, the reduced or oxidized species are stabilized by the ability of the multiple-sandwich structure to delocalize electronic charge. Detailed studies of $(4\text{-MeC}_6H_4CHMe_2)Ru(Et_2C_2B_3H_3)Ru(4\text{-MeC}_6H_4CHMe_2)$ (Ru–Ru) and $CpCo(Et_2C_2B_3H_3)Ru(4\text{-MeC}_6H_4CHMe_2)$ (Co–Ru) by voltammetric, coulometric, electron paramagnetic resonance (EPR) spectroscopic, and optical spectroelectrochemical methods have been used to illustrate that there is complete delocalization of charge in the cations $(Ru–Ru)^+$ and $(Co–Ru)^+$. This is encouraging for the application of the stacked complexes in the construction of electroactive polymers.[71] A redox series involving a linked stack with iron centers is shown in Scheme 9. Related studies with Co- and Fe-containing systems have been reported.[72,73] The alkyne-coupled clusters in (**22**) exhibit double one-electron reductions followed by a single two-electron reduction. These results are interpreted in terms of significant electronic communication between the four metal centers.[42]

7 REACTIVITY

It is extremely difficult to generalize about the reactivity patterns of metallacarbaborane clusters. Some properties are



Scheme 9

outlined below, but the reader is directed to the literature for details of the reactions of specific compounds.[4–6,12–17]

7.1 Metal Exchange Reactions

The use of thallium(I) metallacarbaboranes in the synthesis of a range of other metal-containing clusters (equations 11–16) is well documented. The exchange of lithium in 1,2-Li_2-1,2-$C_2B_{10}H_{10}$ and 1-Li-$C_2B_{10}H_{11}$ for selected metals (Section 4.8) provides routes to metal derivatives in which the metal atom is bonded externally to the carbaborane cage via a C–M σ bond. The exchange of other metal atoms is less general. One example is shown in equation (25), but the Co-for-Sn exchange competes with the insertion of Co into the cluster.

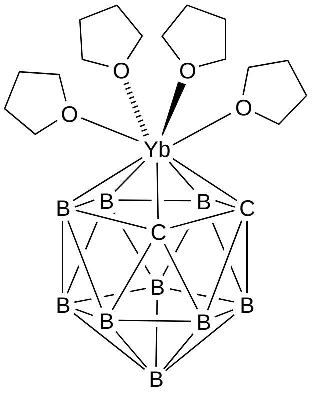
$$\textit{closo}\text{-1-Sn-2,3-}C_2Me_2B_4H_4 + CpCo(CO)_2 \xrightarrow{\text{Gas phase}} \textit{closo}\text{-}CpCoC_2Me_2B_4H_4 + \textit{closo}\text{-}CpCoSnC_2Me_2B_4H_4 \quad (25)$$

7.2 Ligand Substitution at the Metal Atom

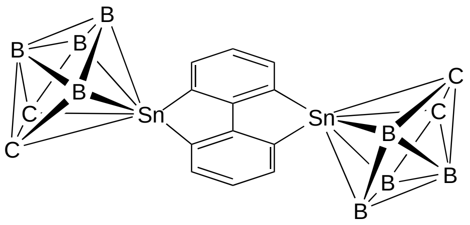
For transition metal–containing metallacarbaboranes, reactions at the metal center with no concomitant change to the cluster core are possible. The simplest type of reaction is ligand substitution. In equation (26), the three carbonyl ligands (each a two-electron donor) are replaced by a π-bonded benzene ring (a six-electron donor). When the net electron count for the cluster remains unchanged, there is no change in the skeletal geometry of the cluster.

$$\textit{closo}\text{-Fe(CO)}_3C_2B_9H_{11} \xrightarrow{h\nu, C_6H_6} \textit{closo}\text{-Fe}(\eta^6\text{-}C_6H_6)C_2B_9H_{11} \quad (26)$$

As an example of simple ligand replacement, the THF ligands in $(THF)_4YbC_2B_9H_{11}$ (**38**) can be displaced by MeCN or DMF. Metallacarbaboranes containing naked p-block metal atoms can function as Lewis acids forming adducts with Lewis bases, for example, the reaction of 1-Sn-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_4$ with 2,2′-bipyridine gives complex (**25**). When a dinucleating ligand such as 2,2′-bipyrimidine is used, the metallacarbaborane clusters may be linked together as in (μ-L){1-Sn-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_4$}$_2$ (**39**).



(**38**)



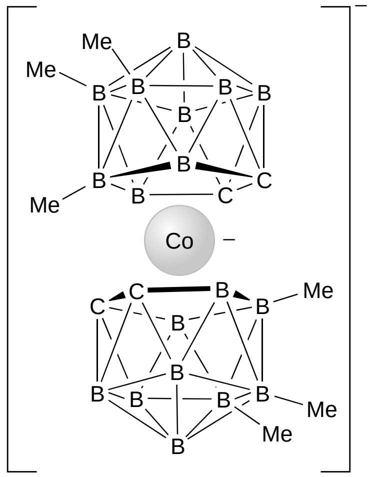
(**39**)

7.3 C and B Derivatization

For C-derivatized metallacarbaborane clusters, the substituents attached to the cage carbon atoms are usually introduced into the carbaborane precursor. Examples have been given earlier in equations (4), (5), (8), and (12), and Scheme 4.

Electrophilic substitution reactions are used to introduce B substituents into metallacarbaboranes. For example, the electrophilic bromination of 1-(CpCo)-2,3-$C_2B_8H_{10}$ gives a mixture of 10-Br-1-(CpCo)-2,3-$C_2B_8H_9$ and 4-Br-1-(CpCo)-2,3-$C_2B_8H_9$. In the presence of $AlCl_3$ and at

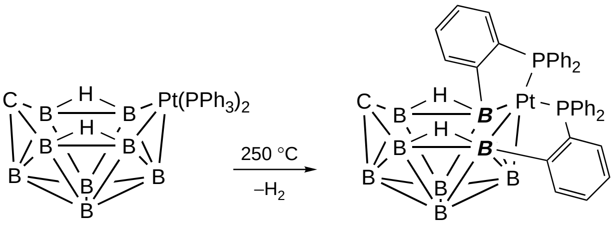
higher temperatures, 4,5,6,10,11-Br_5-1-(CpCo)-2,3-$C_2B_8H_5$ is produced. Similarly, the bromination of 1-(CpFe)-2,3-$C_2B_9H_{11}$ occurs at room temperature to give the 8-bromo derivative; with an $AlCl_3$ catalyst, the 8,9-dibromo and 8,9,12-tribromo derivatives are formed. This substitution pattern is consistent with the electron distribution in the polyhedral cage. Friedel–Crafts acetylation of 1-(CpCo)-2,3-$C_2B_9H_{11}$ occurs at the 8-position; other organic substituents can be introduced in an analogous manner. The introduction of multiple B-Me groups is illustrated in the formation of (**40**) by reaction of the parent anion with ICl followed by MeMgBr.[74]



B = BH (or BMe as shown), C = CH

(**40**)

Cycloboronation (similar to an *orthometalation* reaction in organometallic chemistry) occurs in a range of iridaborane, platinaborane, iridacarbaborane and platinacarbaborane. The reaction involves the activation of an ortho C–H bond in a phenyl substituent of a triphenylphosphine ligand attached by the metal (equation 27).[75] The result is the elimination of H_2 and the formation of a B–C bond within a five-membered MPC_2B ring. Other examples include the formation of [10-(PPh_3)-2,6:2,9-(μ-S_2CH)$_2$-2-(o-$Ph_2PC_6H_4$)-*closo*-2-IrB_9H_5-1][76] and the cycloboronation of thiobenzoates, resulting in five-membered Ni–S–C–O–B rings.[77]



(27)

B = BH, ***B*** = B, C = CH_2

An unusual example of migration of an Me_3N substituent from a cluster-C atom to an adjacent B atom is observed when Li_2[7-NMe_3-*nido*-7-$CB_{10}H_{10}$] reacts with [$Mo(CO)_3(NCMe)_3$] to give a molybdenacarbaborane intermediate which, following oxidation and addition of [$(PPh_3)_2N$]Cl, gives [N$(PPh_3)_2$][2,2,2-$(CO)_3$-2-X-3-NMe_3-*closo*-2,1-$MoCB_{10}H_{10}$] (X = Br or I).[78]

7.4 Alkylidyne Derivatives and Those with Bridging Carbene or Carbyne Ligands

Metallacarbaborane clusters incorporating an M(≡CR) unit (e.g., M = W, Mo) have been studied in depth by Stone and coworkers.[79–81] The $[C_2R_2B_9H_9]^{2-}$ ligand can replace a Cp^- (or $C_5R_5{}^-$) ligand in, for example, CpW(≡CR)$(CO)_2$. In the presence of H^+ (e.g., $HBF_4{\cdot}OEt_2$), cluster coupling via CR bridge formation has led to a number of dimetallic derivatives. Grimes and coworkers[82] have reported the linkage of [Cp*Co($Et_2C_2B_3H_5$)] sandwich units by alkynyl and diethynylphenylene connectors; the linking groups are attached to the Cp* ligands and to the C_2B_3 rings. For example, *nido*-[{(C_5Me_4(C≡CH))}Co($Et_2C_2B_3H_5$)] can be converted to 1,4-[*nido*-($Et_2C_2B_3H_5$)Co{(C_5Me_4(C≡C))}]$_2C_6H_4$.

Reactions between small metallacarbaboranes and organic substrates, more generally, have been reviewed.[43]

8 APPLICATIONS

The potential applications of metallacarbaboranes discussed below are selective; Grimes' recent look at metallacarbaboranes in the new millennium includes a range of potential applications.[43] Of particular significance is the development of biological/medicinal applications.

A number of metallacarbaborane clusters are effective catalysts. The Rh(III) cluster 3,3-$(PPh_3)_2$-3-H-3-Rh-1,2-$C_2B_9H_{11}$ was the first example of this type of cluster to exhibit high reactivity as a homogeneous catalyst.[83] It catalyzes the hydrosilylation of PhCOR (R = Me, Et, Me_2CH) with Me_2PhSiH, and the isomerization of unsaturated alcohols to aldehydes and ketones; 3,3-$(PPh_3)_2$-3-H-3-Rh-1-Ph-1,2-$C_2B_9H_{10}$ behaves similarly. The complexes 3,3-$(PPh_3)_2$-4-py-3-Rh-1,2-$C_2B_9H_{10}$ and 3-PPh_3-3-CO-4-py-3-Rh-1,2-$C_2B_9H_{10}$ are hydroformylation catalysts and the former catalyzes the hydrosilylation of alkenes (e.g., styrene) and alkynes (e.g., PhC≡CH). 3,3-$(PPh_3)_2$-3-H-3-Rh-1,2-$C_2B_9H_{11}$ and related clusters exist as a mixture of isomers that are in equilibrium in solution (equation 28). In the *closo* form, the Rh(III) center is coordinatively saturated. In the *exo–nido* form, Rh(I) is coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*); it is this form of the cluster that

is catalytically active.

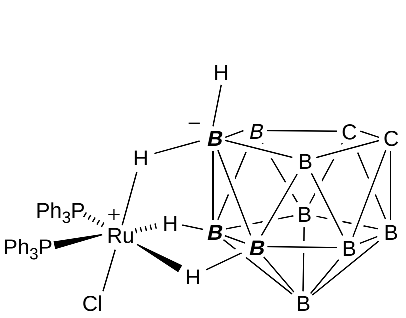
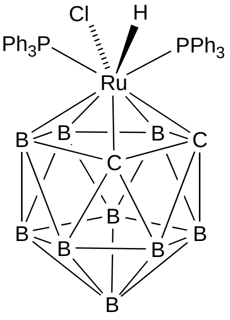
(28)



B = BH, C = CH, ***B*** = B

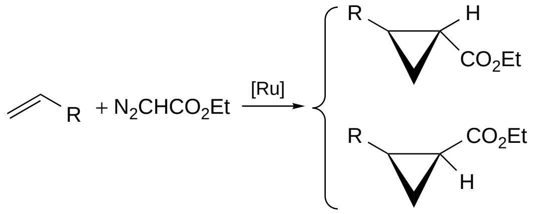
(**41**)



B = BH, C = CH

(**42**)

The *exo–nido* and *closo* cage ruthenium clusters $RuCl(PPh_3)_2(C_2R_2B_9H_{10})$ (R = H or Me) (**41**) and (**42**), respectively, exhibit a high activity as cyclopropanation catalysts, for example, in the reaction between ethyl diazoacetate and alkenes (equation 29). During cyclopropanation, an *exo–nido* → *closo* rearrangement should occur. [(7-PPh_2-8-R-7,8-$C_2B_9H_{10}$)$Rh(PPh_3)_2$] (R = H, Me) and [(7-PPh_2-8-Me-7,8-$C_2B_9H_{10}$)Rh(cod)] are also active in the cyclopropanation of alkenes with diazoacetates.[84]



(29)

Silver phosphines in association with [1-*closo*-$CB_{11}H_{12}$]$^-$ and [1-*closo*-$CB_{11}H_6Br_6$]$^-$ are highly active Lewis acid catalysts for some hetero-Diels–Alder reactions. Very low catalyst loadings are required (0.1 mol%) and turnover frequencies of 4000 h^{-1} are observed.[85] The complexes [$(PPh_3)_2Rh(nbd)$][*closo*-$CB_{11}H_{12}$] and [$(PPh_3)_2Rh(nbd)$][*closo*-$CB_{11}H_6Br_6$] have been tested using cyclohexene, 1-methylcyclohexene, and 2,3-dimethylbut-2-ene for their catalytic activity (under ambient conditions) in internal alkene hydrogenation.[86] Further examples of metallacarbaborane catalytic activity have been reviewed by Grimes.[43] The complex $(Ph_3P)_2Ir(H)_2$(*closo*-$CB_{11}H_6Br_6$) catalyzes the hydrogenation of cyclohexane and can be recycled up to five times without decomposition; related results for ethene are summarized in Scheme 10.[87] The effects of the halogen substituent and of the steric demands of the phosphine have been detailed.[88]

Group 4 metallocenes with constrained geometries are highly active catalysts. The replacement of one or two $[C_5R_5]^-$ ligands by *nido*-$[C_2B_9H_{11}]^{2-}$ ligands (see (**3**)) gives a means of modifying metallocene catalysts.[89,90] Examples include (**43**), which is proposed as the active catalytic species in the hydrogenation of internal alkynes to (*Z*)-alkenes.[91] Complex (**44**) incorporates a *nido*-C_2B_4 cage and this complex catalyzes the polymerization of ethene to high molecular weight polymers under ambient conditions.[92] The catalytic activity of single-walled carbon nanotube-supported nickellacarbaboranes has also been explored.[93]

The application of metallacarbaborane clusters as radiometal carriers for radioimmunodiagnosis and radioimmunotherapy has been explored, with ''VFCs'' (see Sections

2.2 and 4.9) being central to these studies.[36,94,95] It is necessary to provide a radiometal-containing system (the metallacarbaborane) that is suitably functionalized to enable conjugation to monoclonal antibodies. The dicarbollide ligand present in complex (**19**) can encapsulate a radiometal atom (e.g., ^{57}Co) to form a particularly stable metallacarbaborane *commo* cluster. The first examples of direct labelling of proteins with ^{121}At using a *nido*-carbaborane, a ''VFC'', or *closo*-decaborate(2-) clusters were reported in 2007.[96] Salts of $[1\text{-CpFe-2-Me-2,3,4-}C_3B_7H_9]^+$ and the complex 1-CpFe-2-Me-2,3,4-$C_3B_7H_9$ have been found to be effective cytotoxic agents against human and murine tumor cell lines; the agents act by inhibiting the *de novo* purine synthesis of L-1210 cells, thus reducing DNA and RNA syntheses.[97] 1-Cp-1-Br-2-Ph-1,2,3,4-$VC_3B_7H_9$ and *commo*-Nb-1-Cl-(4-Me-1,2,3,4-$NbC_3B_7H_9)_2$ are also cytotoxic agents; the vanadium-containing complex exhibits significant activity against the growth of cultured human solid tumors.[98] The tantalum and niobium-containing species $CpTaCl_2(Et_2C_2B_4H_4)$, $CpNbCl_2(Et_2C_2B_4H_4)$, $Cp^*TaCl_2(Et_2C_2B_4H_4)$, $CpTaCl_2\{(Me_3Si)_2C_2B_4H_4\}$, and $CpTaCl_2(Me_2C_2B_4H_4)$ are active against suspended tumors, and result in cell death in a number of tissue culture lines including murine L1210 lymphoid leukemia.[99] Metallacarbaborane-containing nucleoside conjugates with thymidine, 2′-*O*-deoxyadenosine, 2′-*O*-deoxyguanine, or 2′-*O*-deoxycytidine[100,101] provide building blocks for the synthesis of, for example, iron(III) and cobalt(III)-containing dinucleotides (**45**). The synthetic pathway to (**45**) generates a series of synthons for the preparation of bioinorganic DNA/metallacarbaborane conjugates.[102] Related mononucleotide conjugates may function as electrochemical tags, and are proposed as labels for electrochemical coding of DNA.[103]

Technetium and rhenium coordination chemistry associated with the introduction of ^{99m}Tc into radiotherapy and radioimaging agents is of active current interest, and the application of *nido*-carbaborane ligands has recently been explored. Microwave heating assists the formation of rhenium η^5-carbaborane complexes in aqueous solution, and similar conditions are effective at the tracer level for the preparation of ^{99m}Tc complexes.[104]

The ability of $[3,3'\text{-M}(1,2\text{-}C_2B_9H_{11})_2]^-$ ($M^{3+} = Co^{3+}$, Fe^{3+}, Ni^{3+}) to act as Cs^+ sensors in ion selective electrodes has been assessed. The related complexes $[3,3'\text{-Co}(1\text{-Me-}2\text{-}(CH_2)_nOR\text{-}1,2\text{-}C_2B_9H_9)_2]^-$ ($n = 3$, R = Et; $n = 3$, R = $(CH_2)_2OMe$; $n = 3$, R = $(CH_2)_3Me$; $n = 6$, R = $(CH_2)_3Me$) and $[3,3'\text{-Co}(1\text{-Ph-}1,2\text{-}C_2B_9H_{10})_2]^-$ and $[3,3'\text{-Co}(1,7\text{-}Ph_2\text{-}1,7\text{-}C_2B_9H_9)_2]^-$ act efficiently in ^{137}Cs, ^{90}Sr, and ^{152}Eu extraction.[105,106]

One challenge within the area of conducting electroactive polymers such as polypyrrole (PPy) is increasing the stability of the materials. By doping PPy with $[Co(C_2B_9H_{11})_2]^-$, the material becomes more resistant to overoxidation by 300–500 mV.[107]

9 FUTURE WAYS FORWARD

In addition to the areas already discussed in this article and, in particular, development of applications in biological, medicinal, and materials chemistry, several aspects are of current research interest. Section 4.10 introduced the steadily expanding area of single-cage metallacarbaborane clusters with more than 12 vertices. The role of carbaboranes and metallacarbaboranes within supramolecular chemistry[108] has been actively investigated in the last decade. One of the best-explored areas is that of multicluster mercuracarbaboranes, which act as macrocyclic Lewis acidic hosts for electron-rich (anionic or neutral) guests.[54]

Finally, small metallacarbaboranes containing the C_2B_4 unit have been the subject of much study in the last few decades. However, Hosmane has made a pertinent point: the area has depended on supplies of B_5H_9 from government surplus, which are no longer available.[109]

1 INTRODUCTION

The chemistry of boron–nitrogen compounds is extremely rich and varied, and much of the evolution of this field derives from attempts to obtain compounds both electronically and structurally comparable with well-known organic molecules.[1,2] In addition, a great deal of effort has been devoted to establishing reactivity parallels between the isoelectronic/isostructural organic and inorganic compounds. Some known isoelectronic/isostructural compound pairs are summarized in Figure 1.

Boron–nitrogen chemistry has been regularly reviewed as part of the Gmelin series.[3] In addition, regular coverage of B–N chemistry is found in annual or semiannual contributions to Coordination Chemistry Reviews (elements of group 3).[4] Summaries of new organoborane compounds containing B–N bonds also are found in the Journal of Organometallic Chemistry (article on the group 3 element chapter).[5] As a result, most of the illustrative chemistry summarized in this article appears in the original literature after 1984. The classes of B–N compounds described parallels the classification used in the Gmelin series. Where practical, parallels with isoelectronic organic chemistry are drawn. It is pointed out that the literature coverage in this article is not complete. Only

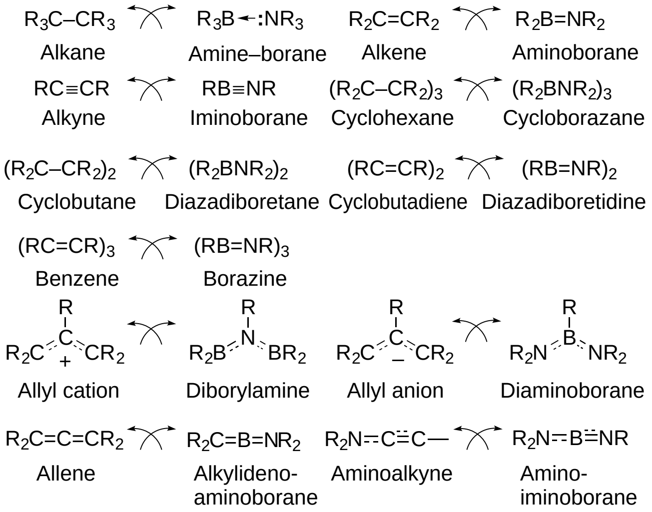

Figure 1 Some known isoelectrical/isostructural compound pairs

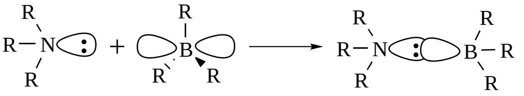
a selection of work that illustrates recent advances in each subfield has been presented. However, recent reviews were sought for each of the sections listed in the table of contents.

2 AMINE-BORANES

Amine-boranes are coordination complexes formed by combination of an amine Lewis base with a tricoordinate Lewis acid borane fragment (equation 1), and as noted in Figure 1, they are analogs of alkanes.



(1)

Their reactions have been studied extensively,[6] and a great deal is known about the factors that control the stability of the complexes in the gas phase and in solution. Nonetheless, studies of these compounds are popular, and new features are continuously revealed. For example, the structure of the simplest complex, H_3BNH_3, has been redetermined in the solid state, and the B–N bond distance confirmed to be relatively short at 1.564(6) Å.[7] This distance contrasts with the B–N distance of 1.672 Å found for the gaseous molecule by using microwave spectroscopy. These results and subsequent ab initio MO calculations for the molecule at several levels suggest that the molecular geometry is strongly dependent on environment. The MO calculations reveal a relatively flat potential surface in the bond distance range r_0(BN) approximately 1.55 to 1.70 Å, a figure mirrored by experimental studies that have shown common B–N bond distances of 1.55 to 1.75 Å.[6] Furthermore, it is found that,

starting from the gas-phase value, the B–N bond distance decreases with increasing solvent polarity (1.62 Å in hexane and 1.57 Å in water). This suggests that the short B–N distance found in the solid-state structure may arise from 'crystal medium effects'. Calculations of ^{11}B NMR shifts (IGLO) also suggest that variations in ^{11}B delta data with solvent may be less a result of solvent effects on nuclear shielding and more a result of structural changes induced in the molecule by the medium.

The thermal decomposition of H_3BNH_3 has been studied by ^{11}B NMR in aprotic solvents at temperatures above 80 °C.[8] Three reaction types were found. In etheral solvents, decomposition occurred by hydrogen loss with formation of cycloborazanes and eventually borazine, $(HBNH)_3$. In pyridine solution, base displacement took place with generation of pyridine·BH_3; in acetonitrile solution, hydrogen loss and solvent hydrogenation or hydroboration occurred. These results suggest that it may not be possible to study the reaction chemistry of the monomeric aminoborane H_2BNH_2 in solution prior to its undergoing condensation reactions. A triarylborane with orthohydrogen bonding groups was shown to strangely bind ammonia through all four of its atoms.[9] This was a rare example of a host-guest system[10] able to recognize ammonia.

The reactivity of BX_3 fragments toward bifunctional Lewis bases (e.g. $R_2ENR'_2$, $RE(NR'_2)_2$, and $E(NR'_2)_3$; E=P, As) are also of fundamental interest.[11] It is clear that a combination of substituent inductive effects, E$\cdots$N p_π–d_π electronic effects, as well as steric influences are responsible for the BX_3 coordination site selectivity and selected bond-breaking chemistry found in these complexes. The mechanism for hydrolytic decomposition of amine-borane complexes also continues to be of interest. A comparison of the hydrolysis of benzylamine-borane with the hydrolysis of various arylamine-boranes has been reported,[12] and the results are important for the selection of borane adducts as practical hydridic reagents in aqueous phase reductions.

Although tertiary amine-borane and aromatic amine-borane complexes are common, azo-boranes (**1**) and (**2**) were unknown until recently. Borane complexes (**3**) and (**4**) of 2,3-diazabicyclo[2.2.1]hept-2-ene and 2,3-diazabicyclo[2.2.2]oct-2-ene have now been isolated,[13,14] and in most other cases the azo-borane complex is stable in the presence of alkenic unsaturation. The Lewis acidity of methylene boranes has been recognized for some time, and satisfaction of the electron deficiency in these species has been considered to occur by nonclassical (**5**) and classical (**6**) intramolecular interactions. It has now been reported that intermolecular Lewis acid-base complexes (**7**) of these unique species can also be formed.[15] The strong Lewis acid $(CF_3)_3B$ can only be isolated with a base such as ammonia. While the B–N bonds are extremely strong, the N–H groups undergo a wide range of interesting reactions. For example, $(CF_3)_3B–NH_3$ forms $Cs[(CF_3)_3B–NX_2]$ (X=Cl, Br), when combined with the appropriate cesium hypohalite.[16]

Several amine-borane complexes have recently been reported that have potential applications. For example, borylated crown ethers (**8**) provide a host-guest environment for molecular recognition of primary amines.[17] There is also interest in the synthesis and study of pharmacological properties of boron analogs of isoelectronic/isosteric biologically important molecules. These include selected amino acid analogs (**9**)–(**11**) and boronated nucleosides and nucleotides (**12**) and (**13**).[18–23] Studies have shown that amine carboxyboranes (amine·BH_2X) may be useful as treatments for cancer, osteoporosis, and inflammation.[24] A technique to break strong amine-borane bonds involves methanolysis catalyzed by palladium or Rainey nickel.[25]

3 AMINOBORANES

Aminoboranes have the general formula $R_2B{\cdots}NR'_2$, and they are the isoelectronic analog of alkenes. The boron and nitrogen atoms are formally three-coordinate, and the electron deficient and coordinatively unsaturated boron atom in monomeric molecules is stabilized by sterically bulky groups and by electron donation from the amido group. When these steric and electronic influences do not provide sufficient stabilization for the boron atom, the fragment typically forms cyclic aminoboranes, for example, $(R_2BNR_2)_2$ and $(R_2BNR_2)_3$. The factors influencing this chemistry have been systematically studied. Extensive reviews of aminoborane chemistry appeared in 1970,[26] 1980,[27] and in 1991 Noth briefly summarized some recent work from his group.[28] Recent emphasis on these molecules has centered on the development of precursors for formation of low-coordinate fragments, for example, amino-iminoboranes, $R_2N–B{=}NR$, and amino-phosphanylidene boranes, $R_2N{\cdots}B{=}PR$. The subfield of amino-iminoboranes will be discussed in Section 4, while selected advances in other aspects of aminoborane chemistry are discussed here.

Historically, aminoboranes have typically been prepared by XY elimination reactions between borane BX_3 and amine NY_3 reagents (equation 2) and by salt elimination reactions (equation 3). Dehydrocoupling catalyzed by rhodium has recently been discovered as a convenient, clean route to aminoboranes.[29–31] Many seemingly straightforward elimination reactions of haloboranes with NH_3 and primary and secondary amines have been examined.[27] In many cases, oligomeric products are obtained, and in some cases the desired aminoborane products are difficult to separate from organoammonium salt by-products. In other cases, the expected amino substitutions could not be achieved in good yields owing to sluggish elimination reaction kinetics. As a result, a significant effort has been given to the development of silane and stannane elimination pathways by utilizing silylamine and stannylamine reagents.[28] For example, stannazane cleavage of $Cl_{3-n}Me_nSiN(SnMe_3)_2$ with excess BCl_3 gives bis(dichloroboryl)silylamines (equation 4), while reactions of equimolar amounts of $RN(SnMe_3)_2$ and $Me_3SiN(SnMe_3)_2$ with various boron halides give monoborylated amines (equations 5 and 6). These reagents are very useful for subsequent elimination reactions involving further N–Sn or B–X bond breaking. This includes the formation of borazine derivatives (equation 7).

$$X_3B + NY_3 \xrightarrow{-XY} X_2B{=}NY_2 \qquad (2)$$

$$X_3B + LiNY_2 \xrightarrow{-LiX} X_2B{=}NY_2 \qquad (3)$$

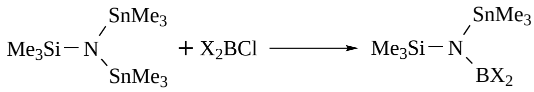
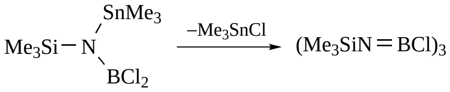
(5)



(6)

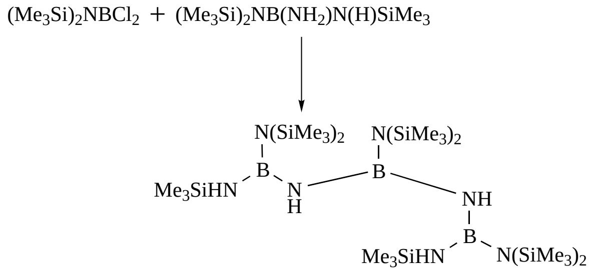


(7)

The related reaction chemistry of the B-silylaminoborazine $[(Me_3Si)_2NBNH]_3$ with HCl has been examined as a means to produce condensed polyborazine materials.[32] The reaction of BCl_3 and $(Me_3Si)_3N$ at 23 °C gives the expected aminochloroborane (equation 8), but in surprisingly low yield; at higher temperatures, methylation of the boron center occurs (equation 9). This result points out the potential limitations of this chemistry. In related studies directed at developing boron nitride precursors, Paciorek[33] examined routes to several silylaminoborane open-chain compounds through Me_3SiCl elimination reactions (equations 10 and 11).

$$(Me_3Si)_3N + BCl_3 \longrightarrow (Me_3Si)_2N–BCl_2 \qquad (8)$$

$$(Me_3Si)_3N + BCl_3 \xrightarrow{\Delta} MeBCl_2 + N(SiMe_2Cl)_x(SiMe_3)_{3-x} \qquad (9)$$

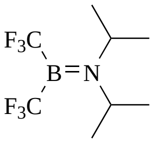


(10)

$$3(Me_3Si)_2NB(NH_2)NH(SiMe_3) + BCl_3 \cdot NEt_3 \longrightarrow B[N(H)B[N(SiMe_3)_2][N(H)SiMe_3]] \qquad (11)$$

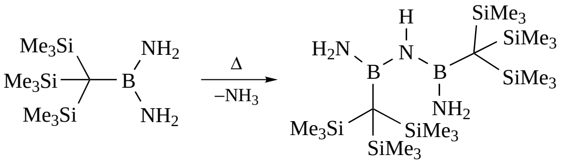
Several novel, new aminoboranes with electronically or sterically demanding substituents have been reported.

For example, trifluoromethyl aminoboranes $(CF_3)(Cl)BNEt_2$, $(CF_3)(Br)BNEt_2$, $(CF_3)_2BNEt_2$, and $(CF_3)_2BN(i\text{-Pr})_2$ have been obtained from the reactions of Cl_2BNEt_2, Br_2BNEt_2, and $Br_2N(i\text{-Pr})_2$ with a mixture of CF_3Br and $P(NEt_2)_3$ in CH_2Cl_2.[34] The trifluoromethyl groups should provide a highly electron-deficient B atom, which in turn should enhance B=N π bonding. Consistent with this reasoning, a crystal-structure determination for $(CF_3)_2BN(i\text{-Pr})_2$ (**14**) reveals a short B–N bond distance of 1.37(1) Å.



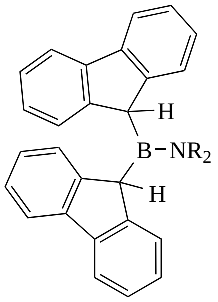
(**14**) B–N = 1.37Å

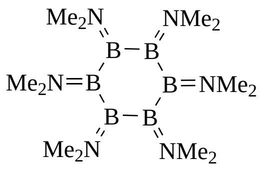
The tris(trimethylsilyl)methyl, $(Me_3Si)_3C$, substituent is a sterically bulky group, and can be used in the formation of low-coordination number environments at boron. Eaborn[35] has reported the synthesis of the diaminoborane (**15**) from aminolysis of $(Me_3Si)_3CBCl_2$. This compound is unusual since most other bis(amino)boranes without organic groups on nitrogen readily undergo decomposition with loss of ammonia and ring or oligomer formation. Compounds of comparable stability include $HB(NH_2)_2$, which is stable in the gas phase or in liquid NH_3 but decomposes with NH_3 loss in the liquid state, and $B(NHAr^*)(NH_2)_2$, which is thermally stable. Compound (**15**) can be sublimed in vacuo at 80 °C, but sublimation is accompanied by formation of (**16**) (equation 12). This compound is the first example of a bis(aminoboryl)amine without N-organyl substituents. Known analogs with N-alkyl or -aryl substituents typically decompose with formation of cyclic products.[36]



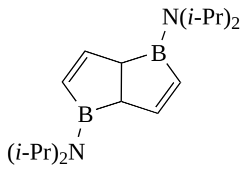
(**15**) (**16**) (12)

The fluorenyl fragment should also provide considerable steric protection, and to this end, bis(fluorenyl)aminoboranes (**17**) have been prepared by reaction of R_2NBCl_2 with fluorene deprotonated by potassium or by combination of R_2NBCl_2 (R=Et, *i*-Pr, *i*-Bu, *s*-Bu) with $LiC_{13}H_9$.[37] This result contrasts in its outcome in an important way with related reductions involving R_2NBCl_2. For example, it has been observed that reduction of $(Me_2N)_2BCl$ with Na/K alloy leads to a series of acyclic $Bn(NMe_2)_{n+2}$ ($n = 2–5$) compounds containing B–B bonds. Noth[28] and Baudler[38] further observed the formation of several cyclic and cage subvalent B^I compounds including



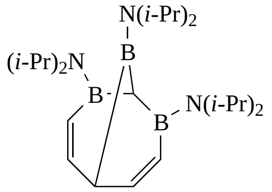


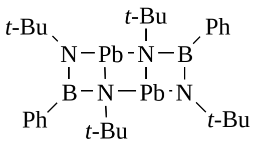
(**17**) (**18**)



(**19**)

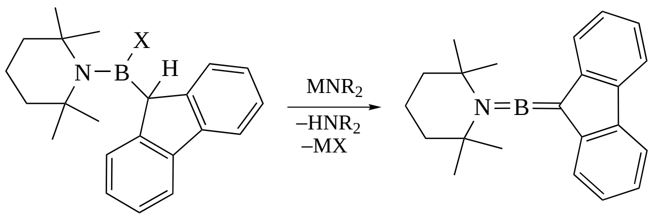
$B_6(NMe_2)_6$ (**18**). Paetzold[39] has subsequently discussed the occurrence of subvalent group 13 species, and it is clear that transient carbenoid R_2NB species should have considerable reactivity toward various unsaturated organic fragments. Meller[40] has exploited this theme to prepare several subvalent boron species, and much of that work has been briefly reviewed.[40] For example, the tetrahydroborolo[3.2-b] borane (**19**) and triborabicyclo[3.3.1]nona-3,6-diene (**20**) were obtained in reaction with benzene. That care must be exercised over the generality of these systems is illustrated by the fact that Na/K reduction of $F_2BN(Me)(i\text{-}Pr_2C_6H_3)$ in DME gave a complex mixture of products including some that contained methoxylated borane fragments. Finally, in a related system, the combination of $PbCl_4$ with $Li_2PhB(N\text{-}t\text{-Bu})_2$ gave a 1,3-diaza-2-plumba-4-boracyclobutane (**21**).





(**20**) (**21**)

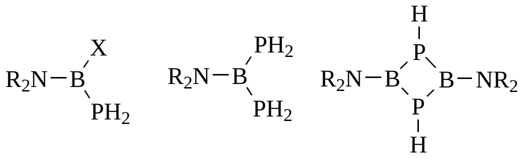
It was noted that the bis(fluorenyl)aminoboranes (**17**) are relatively stable compounds. The corresponding monofluorenyl aminohaloboranes (**22**) can also be prepared, and they serve as a source of the alkylidenylaminoborane (**23**).[41,42] The compound (**23**) was the first of a family of alkylideno aminoboranes, $R_2N{=}B{=}CR'_2$ that can be considered to be allene or aminoalkyne analogs. These compounds, containing two-coordinate boron, are kinetically stabilized by sterically



(**22**) X = Cl, Br (**23**)

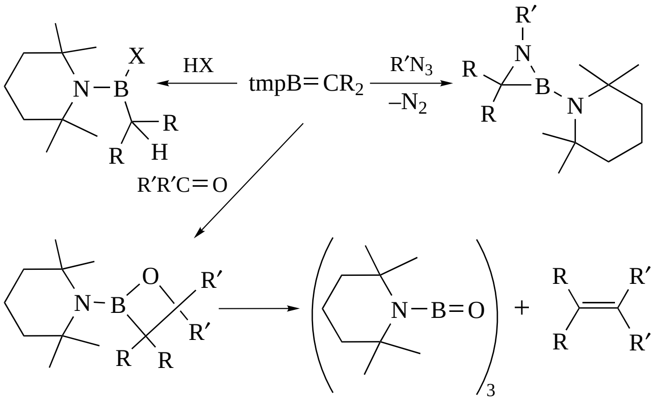
demanding substituents R and R′ and by π electron donation from the amino group to the coordinatively unsaturated boron center. The tmp (t-Bu)$_2$N, and (t-Bu)(Me$_3$Si)N groups serve well in this role; however, the (Me$_3$Si)$_2$N group does not. In the last case, the incipient (Me$_3$Si)$_2$N=B=fluorenyl compound spontaneously dimerizes. Despite kinetic stabilization, the B=C bond in the fluorenyl aminoboranes is highly reactive (Scheme 1) toward polar addition reactions as well as [2 + 2] and [2 + 3] cycloadditions.[41–43] In addition, transition metal reagents TiCl$_4$, Fe$_2$(CO)$_9$, Fe(CO)$_5$, CpCo(CO)$_2$, CpMn(CO)$_3$, and (C$_6$ H$_6$)Cr(CO)$_3$ have been observed to react with (**23**) (Scheme 2).[44–46]

The reactivity of two related alkylideno aminoboranes, i-Pr$_2$N=B=C(SiMe$_3$)$_2$[47,48] and tmp=B=C(SiMe$_3$)$_2$,[48] has been extensively studied. The chemistry displayed is similar to that depicted in Scheme 1, and additional reaction patterns are summarized in Scheme 3.

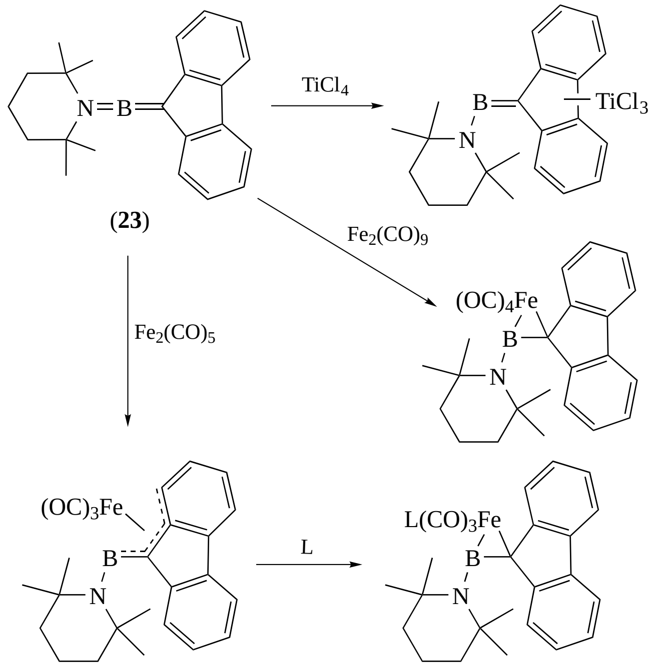


(**24**) (**25**) (**26**)

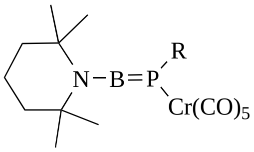
Aminoborane fragments R$_2$NB have recently been reported to stabilize a variety of phosphanyl species where the



Scheme 1



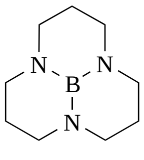
Scheme 2

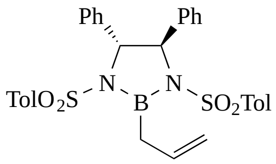


(**27**)

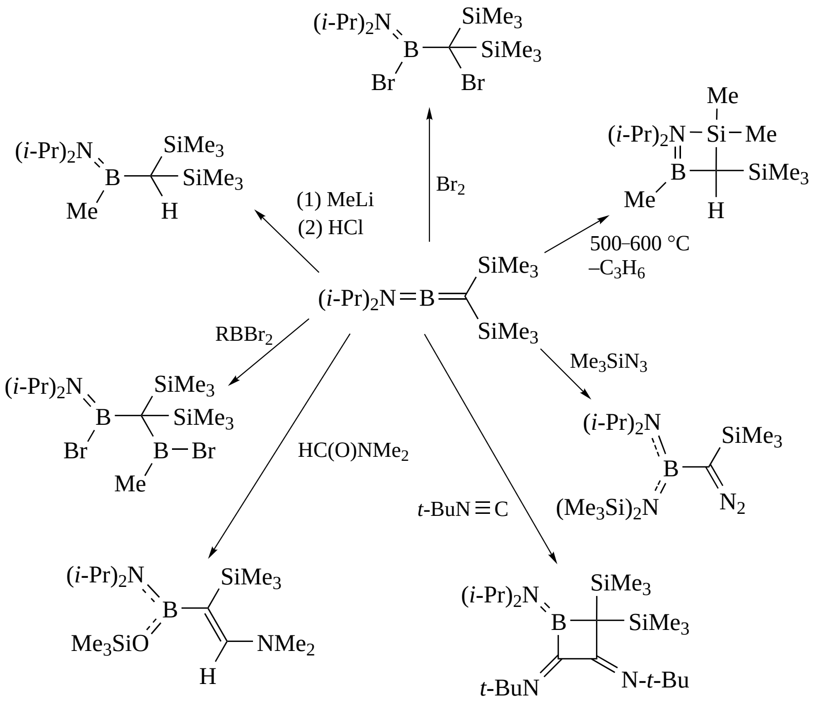
phosphorus atom carries H, SiMe$_3$, or organyl fragments.[49] This includes the formation of boryl phosphanes (**24**), boryl bis(phosphanes) (**25**), diazadiphosphetidines (**26**), cage species,[50] and the first stabilized phosphanylidene borane fragment (**27**) having a formal P=B double bond.[51] Some of the reaction chemistry of one phosphanylborane is summarized in Scheme 4.

Finally, several years ago, Richman[52] reported the formation of a boron inclusion compound (**28**) that alternatively could be considered to be a tris(amino)borane. Practical applications have been found for several aminoboranes. For example, an aminoborane reagent (**29**) has been reported to be useful in enantioselective addition of allyl to aldehydes.[53]

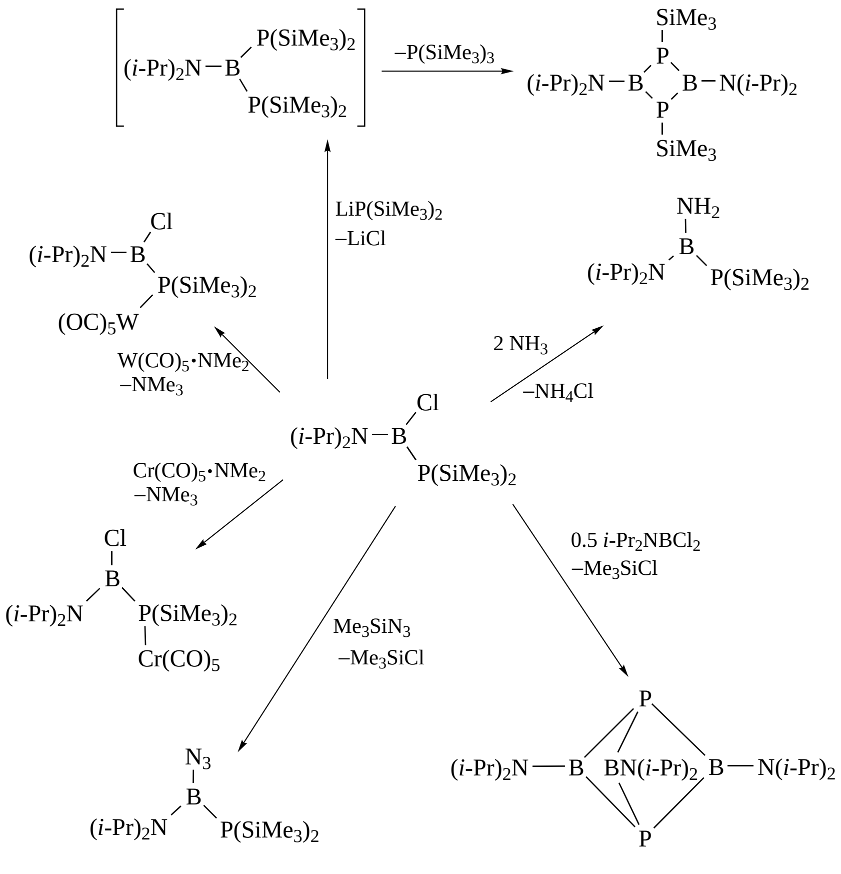




(**28**) (**29**)



Scheme 3



Scheme 4

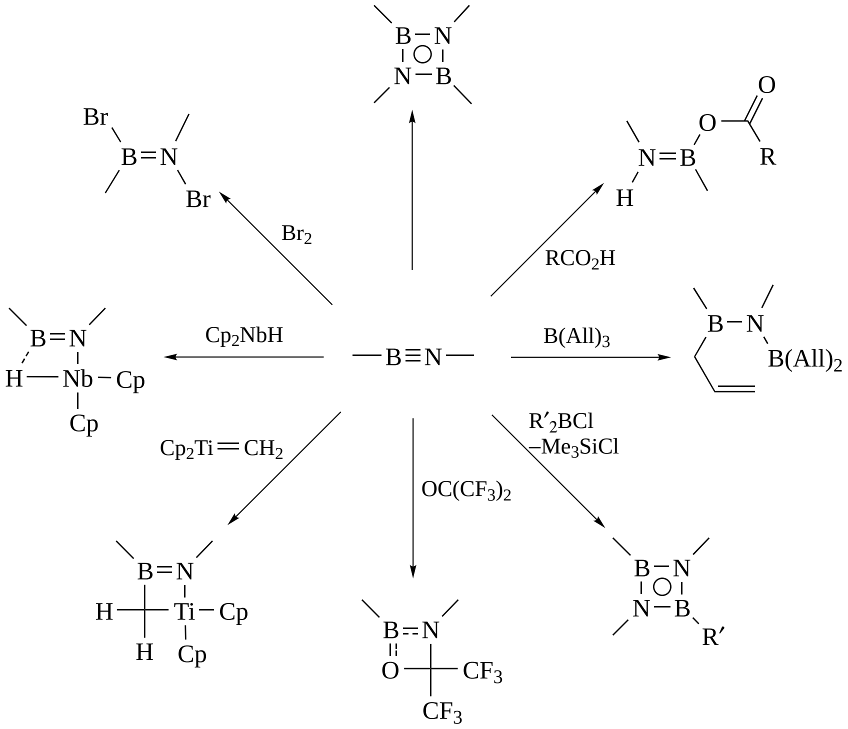
4 IMINOBORANES

Unlike aminoboranes, which have had a lengthy development history, the acetylene analogs diorgano-iminoboranes (R–B≡N–R) and amino-iminoboranes (R_2N⋯B≡NR′) were first reported in 1979 and 1983, respectively. The boron atom is two-coordinate, electron deficient, and coordinatively unsaturated. Consequently, it is expected that, in order to isolate these species, some amount of kinetic stabilization will be required through steric and/or electronic effects. Without stabilization it would be expected, and is observed, that these fragments cyclodimerize or cyclotrimerize. Despite their late arrival in the development of boron–nitrogen chemistry, the synthesis, structure, and reaction chemistry of –B≡N–species has been pursued and consequently reviewed.[1,2,54,55] A good description of the π bonding[56] and aromaticity[57] in these and related systems is available.

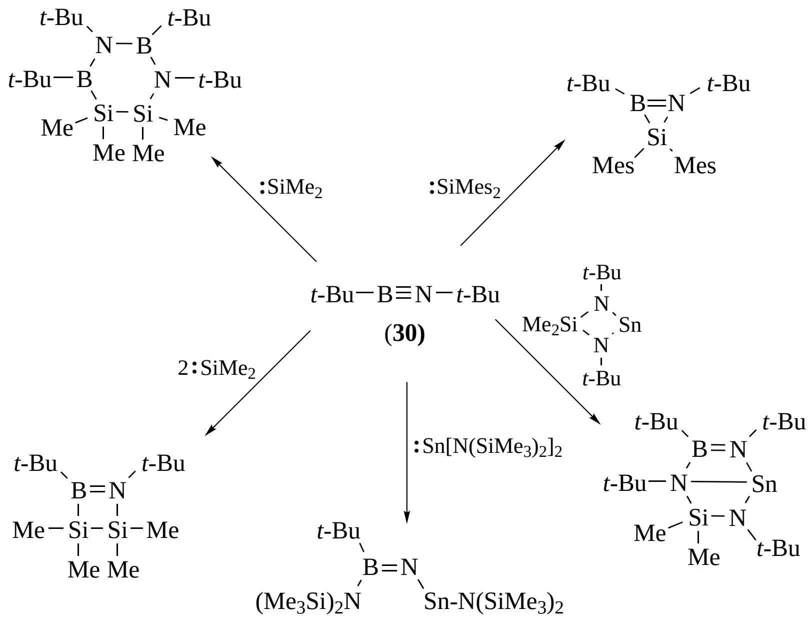
Iminoboranes have typically been prepared from appropriate organo aminoboranes, R(X)BN(Y)R′, that are designed to undergo (1) chemically induced elimination of XY, (2) thermally induced elimination of XY, or (3) thermally induced rearrangement (or from an aminoborane oligomer by thermally induced ring opening). Examples for each of these general methods have been described.[1,55] It has been noted that the bond distances, stretching frequencies, and force constants for alkynes and iminoboranes are closely comparable, and the dipole moments for various –B≡N–species are less than 1.0 D. These experimental data, as well as theoretical analyses of several –B≡N–species, are consistent with a relatively nonpolar electronic structure with a slight $\delta+$ charge on the B atom and $\delta-$ on the N atom.

Most nonpolar alkynes are relatively stable at 23 °C and are not highly reactive. Polar alkynes, on the other hand, are often unstable at 23 °C, and they participate in a host of chemical reactions. Although their polarity is generally small, iminoboranes tend to be reactive unless they are very sterically constrained. The general reaction types found include (1) lone pair donation from the imino nitrogen atom; (2) cyclodimerization giving diazadiboretidines (cyclobutadiene analogs), cyclotrimerization giving borazines (benzene analogs), or cyclotetramerization giving cyclooctatetraene analogs; (3) 1,2-addition of HY and XY with the more electronegative fragment Y bonded to the B atom; (4) insertion reactions; and (5) various cycloaddition reactions. A few general results are summarized in Scheme 5, and ample additional examples are provided in the recent review literature.[1,2,54,55]

It should be stressed that in some cases, for example, chloroboranations, alkylideno-iminoboranes give different product types when compared to amino-iminoboranes. Some additional reactivity studies are summarized for *t*-BuB≡N-*t*-Bu (**30**) and tmpB≡N-*t*-Bu (**31**) in Schemes 6 and 7. Note that the outcome of silylene cycloaddition to (**30**) is dependent on the size of the organic fragment on the silylene,[58] and the addition of the cyclostannylene occurs

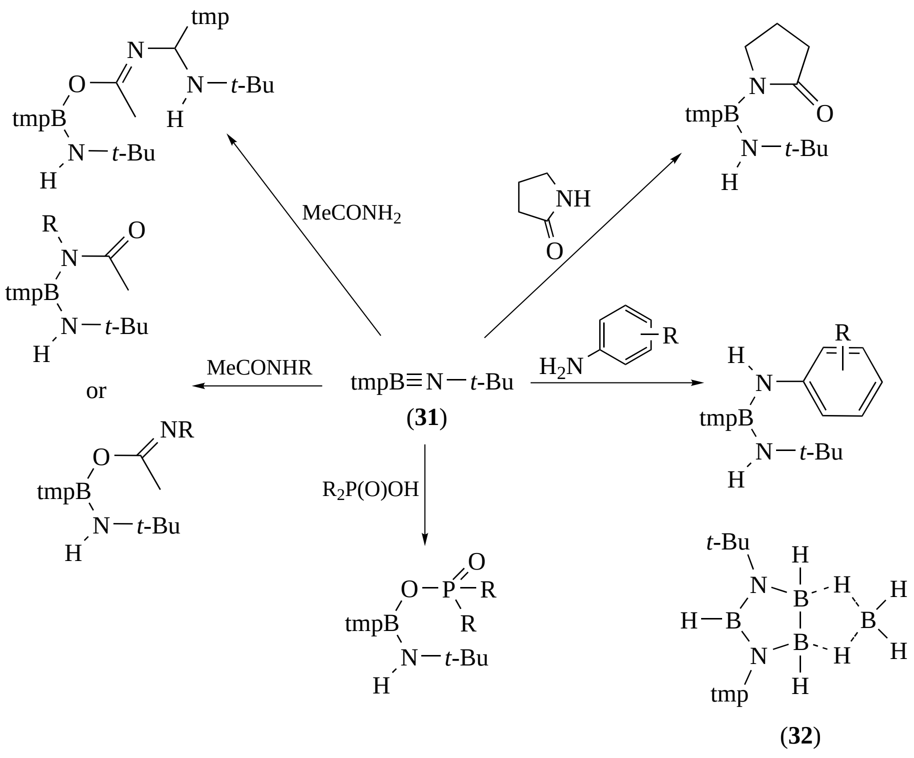


Scheme 5



Scheme 6

at the boron atom across a Sn–N bond.[59] The reaction of acetamide with (**31**) gives an O,N-diborylated acetimidic acid, while N-methylacetamide leads to N-borylated N-methylacetamide.[60] Pyrrolidone reacts with (**30**) to form a borylated lactam,[61] and phosphonic and phosphinic acids produce O-borylated phosphonates and phosphinates.[62] These reactions may in fact find some use in organic synthesis. Finally, Noth and coworkers[63] have explored the reactions



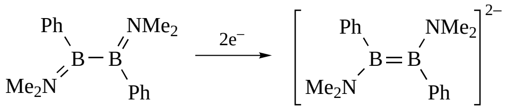
Scheme 7

of (**31**) with B_5H_9, $B_3H_7{\cdot}THF$, and $B_{10}H_{14}$. Pentaborane(**9**) is unreactive, but $B_3H_7{\cdot}THF$ hydroborates the B≡N bond, giving (**32**). More recently, it was shown that (**31**) combines with ECl_3 (E=Ga, In) to yield tmp=B=N(ECl_3)*t*-Bu.[64] Combination of *t*-BuB≡N-*t*-Bu amd $Cp_2M(H)Cl$ (M=Zr, Hf) leads to the compounds {*t*-BuB(H)=N(*t*-Bu)}MCp_2Cl where the iminoborane appears to be bound side-on in a manner analogous to alkynes.[65]

5 OTHER LOW-COORDINATE CONDITIONS

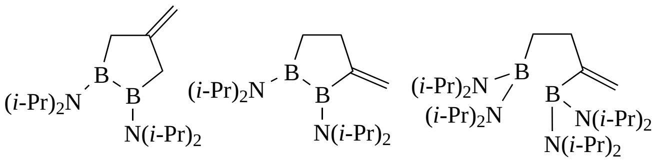
Compounds with B⋯N units in open-chain molecules, are known and summarized here. Power[66–68] has reported the synthesis of sterically hindered aminoboranes R(H)N=$BMes_2$ (R=Ph, Mes) and their lithium salts. Structure determinations for the aminoboranes and lithium salts reveal that the B and N atoms are planar, and the twist angle between the planes is small. As a result, it is expected that the anions $R\ddot{N}{=}BR_2^-$ should display weak sigma-bridging characteristics, and they should stabilize low-coordinate monomeric structures with relatively low-valent metal ions. This is indeed found to be the case as each of the complexes Li[Co(Cl)(L)$_2$], MnL_2, CrL_2, FeL_2, and NiL_2 is monomeric, confirming that the 'free' lone pair on nitrogen is strongly associated with B–N π bonding. In several cases, there appears to be a degree of interaction between the metal and the ipso carbon atom of the Mes substituent on boron. Power[68] has also reported formation of a diboryl amine $(Mes_2B)_2NH$, and its lithium amido salt, which is related to allene and borinium cations $[R_2NBNR_2]^+$. Schmid[69] has reported the formation of several interesting amino vinylboranes, $Me_2N(R)B{-}CH{=}CH_2$ (**33**), and these ligands form (alkene)Fe(CO)$_4$ complexes as well as (butadiene)Fe(CO)$_3$ analog complexes, as summarized in Scheme 8.

Extending this 1,3-butadiene analogy to an all BN backbone composition, Power[70] reports the synthesis of diboron species $R(R'_2N)BB(NR'_2)R$. A structure determination for a compound with R=Ph, R′=Me shows that the π interaction is localized between the B⋯NMe_2 groups, the B⋯B bond is long, and the N-B-B planes are twisted out of coplanarity by approximately 60 degrees. Subsequent reduction of this species produces a dianion $[Ph(Me_2N)B{\cdots}B(NMe_2)Ph]^{2-}$. Its structure shows that the B_2N_2 array is planar and the B–B bond is shortened, but this occurs at the expense of B=N π overlap, as evidenced by elongation of the B–N bond distances. This is consistent with the valence bond representation shown in equation (13).

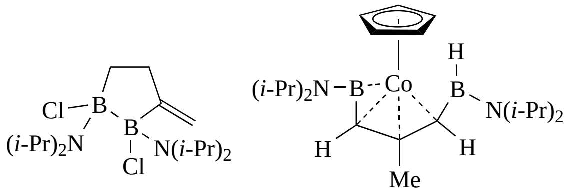


(13)

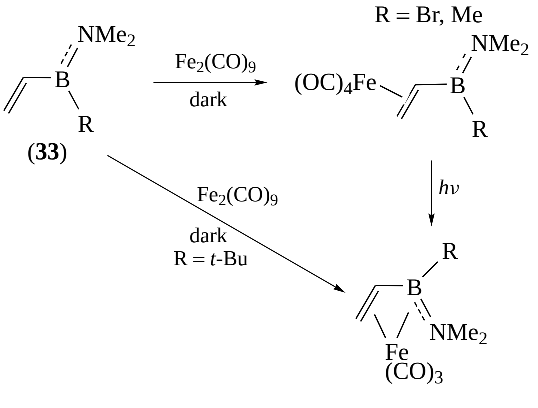
Siebert[71] has recently reported the syntheses of two related diborolanes (**34**) and (**35**), as well as two diborylamines (**36**) and (**37**). Reaction of (**34**) with $CpCo(C_2H_4)_2$ leads to formation of (**38**). The open-chain ligand can be considered as a B-heterobutadiene.



(**34**) (**35**) (**36**)



(**37**) (**38**)

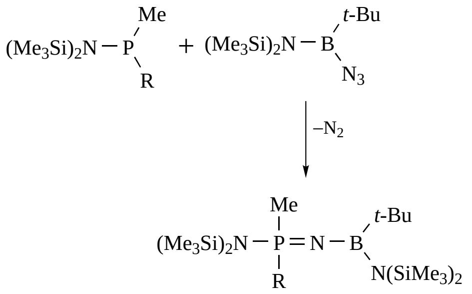


Scheme 8

6 PSEUDOHALOBORANES

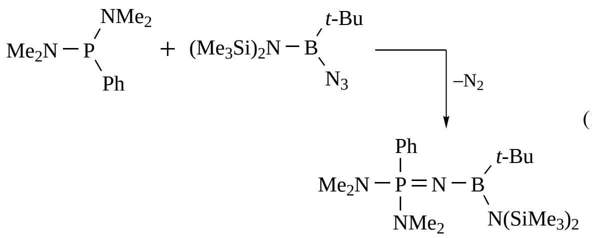
As described by Paetzold,[1,72] azidoboranes have played an important role in the synthesis of iminoboranes and various boron–nitrogen heterocycles discussed elsewhere in this article. As a result, there is continuing interest in these reactive reagents. Neilson[73] has reported the synthesis of the stable azidoborane $(Me_3Si)_2N(t\text{-}Bu)BN_3$ by treatment of a chloroborane precursor with Me_3SiN_3. This reagent was then used to oxidize (silylamino)phosphines by the Staudinger reaction (equation 14) to (borylimino)phosphoranes (**39**). Similar chemistry is found for three-coordinate aminophosphines (equation 15). It is interesting to note that the two-coordinate methylene- and iminophosphines also undergo oxidation to

give three-coordinate P^V centers (see (**40**); equation 16).

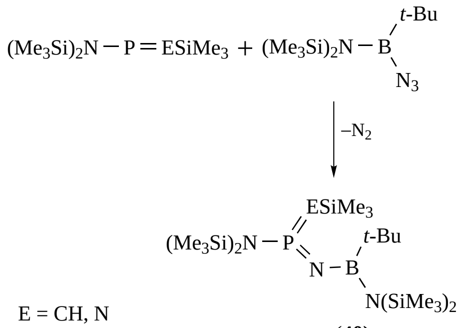


(14)

(**39**)



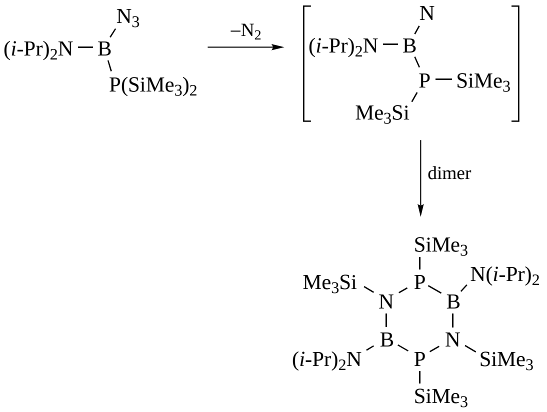
(15)



(16)

(**40**)

The reaction of i-$Pr_2NB(Cl)P(SiMe_3)_2$ with Me_3SiN_3 gives a stable azido borane i–$Pr_2NB(N_3)P(SiMe_3)_2$,[49] which when heated in vacuo at 80 °C produces nitrogen. The incipient nitrene dimerizes accompanied by silyl group migration from phosphorus to nitrogen (equation 17). The $(P–B–N)_3$ ring has a boat conformation, and the decomposition pathway resembles that reported for R_2BN_3 species that produce borazines $(RBNR)_3$.[1] In contrast, use of the C_6F_5 group in a similar reaction allows for the structurally characterized diamer $[(Ar)_2B(N_3)]_2$. X-ray diffraction studies have shown a B–N bond length of approximately 1.59 Å.[74] The bis-azido compound, $C_6F_5B(N_3)_2$, is readily prepared through a TMSCl elimination reaction. It can be isolated as the pyridine adduct, but in the absence of base, will trimerize in the solid state.[75] In a recent breakthrough for this chemistry, crystal structures of $[B(N_3)_3]_x$·L (L = quinoline, X = 1 and L = pyrazine, X = 2) and $[B(N_3)_4]^-$ (isolated as the 2,2,6,6-tetramethylpiperidinium salt) were reported. B-N_{quin} was found to be 1.619(2) Å and B–N_α was found to be approximately 1.52 Å in the quinoline derivative. $[B(N_3)_4]^-$ demonstrated variable B–N distances, depending on whether the γ-nitrogen was involved in hydrogen bonding (B–N of 1.529(7)–1.549(6) Å for the nonhydrogen-bonded groups and 1.509(8)–1.535(8) Å for the hydrogen-bonded groups). The dissociation enthalpy for a pyridine complex of $[B(N_3)_3]$ was calculated to be 10 kcal·mol^{-1}.[76]

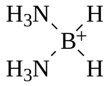


(17)

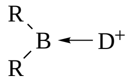
The gas-phase molecular structures of Me_2BN_3 and Me_2BNCO have been determined by electron diffraction.[77] The BN_3 and BNCO units are planar and bent. MO calculations for the B-azido compound reproduce the observed bent structure, but they predict a linear structure for the B-isocyanato analog.

7 CATIONIC SPECIES

Examples of tetra-coordinate boronium ions (**41**) have been known for many years.[78] The quest for low-coordinate, neutral borane compounds also stimulated interest in the formation of three-coordinate borenium ions (**42**) and two-coordinate borinium ions (**43**).[78–80]



(**41**)



(**42**)

(**43**)

The cations are typically prepared by (1) boron-halogen bond heterolysis (for example, by displacement of Br^- by pyridine to form $[BF_2(py)_2]^+$),[81] (2) electrophilic attack on BN bonds, (3) nucleophilic displacement, or (4) metathesis (for example, by silanol elimination from the chelate $B(OSiPh_3)$ with trific acid to acid to form $[LB(thf)]^+OTP^-$).[82] The cationic B center is stabilized by amino substituents, which π donate to boron, and by bulky substituents. The formation of cations with electrophilic reagents in fact suggests that some previously studied reactions of boranes may proceed through cationic intermediates as opposed to neutral coordination complexes. For example, $Ph_2B(ClO_4)$ catalyzes aldehyde condensations.[83] Although it has a polar covalent B–O bond in nitromethane (having a ^{11}B NMR shift of 46 ppm),[84] it

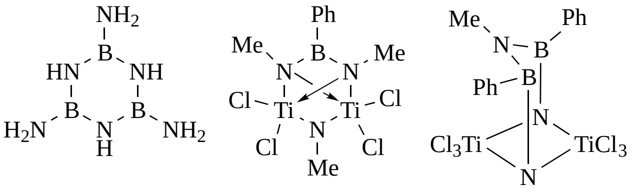
is likely to be cationic in the presence of the aldehyde. Borenium salts are obtained from n-$Bu_2B(O_3SCF_3)$ and 9-BBN(O_3SCF_3) when combined with sterically demanding bases, while neutral acid-base complexes are obtained with less demanding bases. Neutral complexes are also obtained with n-Bu_2BCl and 9-BBNCl. Several adducts of $R_2BCl{\cdot}L$ produce borenium ions when combined with $AlCl_3$ or $GaCl_3$. Similarly, $SbCl_5$ abstracts Cl^- from Ph_2BCl in CD_3NO_2 to form a transient cation having a ^{11}B NMR shift of 20 ppm.[85]

8 BORAZINES

Borazines, $(RBNR)_3$, can be considered to be cyclotrimers of parent iminoboranes, RB≡NR.[86–88] In general the compounds are relatively stable, and as a result they can be obtained through many routes. In fact, they are often undesired side-products or decomposition products. The simplest borazine, $(HBNH)_3$, is often referred to as inorganic benzene, a correspondence that is probably overemphasized. The compound displays D_3h symmetry with equivalent, relatively short B–N bond distances of 1.44 Å. The ^1H NMR data for substituted borazines suggest some degree of transannular electronic conjugation. However, reactivity patterns of borazine differ markedly from benzene. For example, borazine takes part in little electrophilic substitution chemistry, but does undergo many addition reactions. These observations suggest that borazine reaction chemistry is more dictated by B–N bond polarity than the π HOMO/LUMO character of the molecule. Needless to say, these divergent pictures have led to a number of experimental and theoretical studies of the electronic structure of borazine.[89,90] The current view appears to favor a picture in which the π system is highly polarized, but significantly resonance stabilized.

Borazine is often prepared by reaction of NH_4Cl and $LiBH_4$ or $NaBH_4$, or by thermal decomposition of $H_3B{\cdot}NH_3$. Trichloroborazine, $(ClBNH)_3$, is prepared by combination of BCl_3 and NH_4Cl. Both compounds undergo a variety of substitution reactions at boron. It is often straightforward to obtain complete substitution, for example, $(XBNH)_3$, but difficult to obtain mono- or disubstitution products, (XB) $(HB)_2(NH)_3$ and $(XB)_2$(HB) $(NH)_3$, in pure form. Many N-substituted borazines are obtained by using substituted amines or ammonium halides. Again, complete symmetrical substitutions, for example, $(HBNR)_3$ or $(ClBNR)_3$, are usually straightforward; however, incomplete or asymmetrical substitutions are difficult. The majority of available substitution possibilities have been summarized.[87]

The recent interest in boron–nitrogen-containing polymers has spurred some renewed interest in borazine preparations since these compounds are potential monomers. The direct reaction between $(ClBNH)_3$ and NH_3 produces an organic solvent insoluble polymer. In an attempt to control ammonolysis chemistry, the reactions of $(Me_2NBNH)_3$ with NH_3 have been examined,[91,92] and Kimura[92] has succeeded in isolating $(H_2NBNH)_3$ (**44**), which rapidly polymerizes with loss of NH_3.

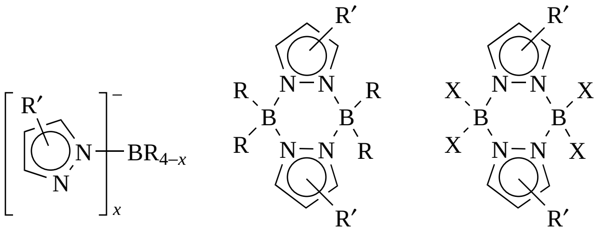


(**44**) (**45**) (**46**)

In a parallel area, and as part of the effort to develop polymers suitable for formation of ceramics and ceramic composites, Roesky[93] has reported formation of several metalloborazines. For example, reactions of $MeN[PhBN(Me)SiMe_3]_2$ with $TiCl_4$ produce nonplanar bicyclic rings such as (**45**) and (**46**).

9 PYRAZABOLES

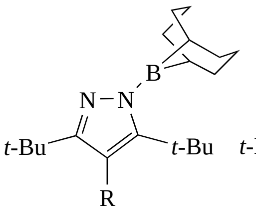
Pyrazaboles of the general types represented by (**47**) and (**48**) have been under study for a number of years, and the syntheses of numerous derivatives have been reviewed.[87,94,95] The compounds are relatively stable, and a significant body of C-atom organic substitution chemistry has been developed. In addition, the anionic character of (**47**) has made these species particularly attractive ligands for both metal and nonmetal cations. That topic is summarized in Section 10 of this article.



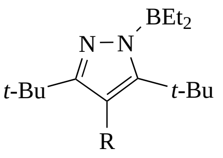
(**47**) (**48**) (**49**)

Niedenzu initiated studies of B-substituted analogs of (**47**) and (**48**) and various X = chloro, fluoro, alkyl, aryl, alkoxy, and amido derivatives of (**49**).[96] These compounds should be very useful for further synthetic transformations. Koster and coworkers[97,98] have examined the reactions of sterically congested pyrazoles with $(9H\text{-}9\text{-}BBN)_2$ and unique neutral, monomeric products with tricoordinate boron centers (**50**) are obtained. The compounds are stable toward dimerization. When bulky pyrazoles are allowed to react with activated trialkylboranes, for example, BEt_3 at 170 °C,

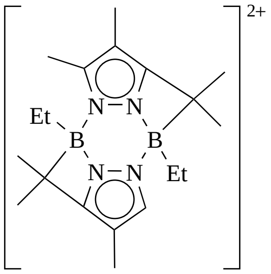
a monomeric pyrazoleborane (**51**) is obtained. At 220 °C the *t*-Bu group is likely to undergo beta-hydride elimination, and the alkene intermediate may undergo hydroboration with resultant formation of a C-borylated pyrazoleborane dimer (**52**).



(**50**)

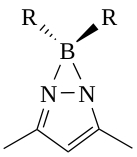


(**51**)

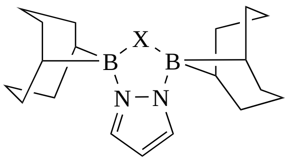


(**52**)

An IGLO NMR study and MO calculations have been used to show that the ground-state structures of compounds like (**50**) and (**51**) in solution as well as the solid state are as shown and not of the symmetrical bridging type (**53**). Nevertheless, the structure represented by (**53**) is likely to be involved in degenerate, fluxional isomerization processes.[99] Koster[100] has also prepared a series of compounds illustrated by (**54**) where X=O, S, Se. There has also recently been some success at preparation of new triazaboles.[101]



(**53**)



(**54**)

10 POLYPYRAZOLYLBORATE COORDINATION CHEMISTRY

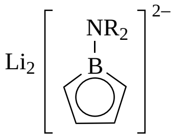
Ligands of the type (**48**) display a very large number of interesting coordination complexes with main group elements, transition metal cations, and *f*-element cations. This extensive chemistry has been thoroughly reviewed,[102–104] and only a few recent advances are summarized here for illustrative purposes. The $HB(pz^*)_3K$ ligand, in combination with PCl_3, gives rise to $[HB(pz^*)_3]PCl_2$ in which the ligand is likely to be bonded in a *trihapto* fashion to the P atom. Subsequent reaction with $Na_2Fe(CO)_4$ gives $[HB(pz^*)_3]PFe(CO)_4$, a complex containing a novel terminal phosphinidene ligand.[105] Parkin[106,107] has reported the use of other C-alkylated $HB(pz^*)_3K$ and $H_2(pz^*)_2K$ salts to form a new set of complexes with Al, Mg, and Be. Niedenzu[108] and Reger[109] have reported tin(II) complexes while using $H_2B(pz)^-$, $H_2B(pz^*)_2{}^-$, $B(pz)_4{}^-$, and $B(pz^*)_4{}^-$.

Many new transition metal complexes of these ligands continue to be prepared. The most interesting aspects of this chemistry are not so much the evolution of specific new ML, ML_2, and ML_3 compositions, but the purposes that the ligands serve or are suggested to serve. For example, poly(pyrazolyl)borate anions have been used to stabilize a 17-electron radical fragment, a seven-coordinate W^{II} complex, half-sandwich HB(pz*)MCl compounds, and to mimic a variety of natural bioinorganic coordination conditions.[110–112]

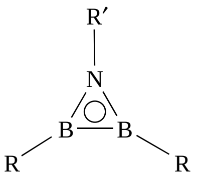
11 ADDITIONAL RING SYSTEMS

A variety of B–N ring systems have been prepared that do not easily fall into the general classes described previously. Some of these rings include other heteroatoms, some include carbon, and they range in size from three-membered to eight-membered. Some examples of cubane cages are also known. Examples of these systems have appeared in previous reviews.[3,86,87] Some representative new contributions in this area are summarized in this section.

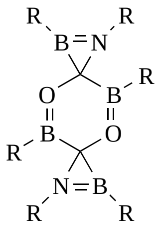
Borole dianions should be 6π-electron systems analogous to Cp^-, and one example (**55**) of this ring has been prepared with *exo* amino groups NR_2 (R=Me, Et, or *i*-Pr).[113] Metal complexes of the dianion have also been reported.



(**55**)



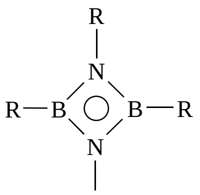
(**56**)



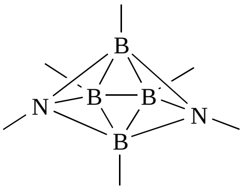
(**57**)

Several examples of azadiboridines (**56**) have been prepared,[114,115] and this ring with R=*t*-Bu reacts with CO to give (**57**) and with BuN_3 to give (**58**). The reductive reaction of *t*-BuB(Cl)-N(*t*-Bu)-B(Cl)*t*-Bu with Na/K that gives (**56**) with R=*t*-Bu also produces a novel diaza-*nido*-hexaborane (**59**).[116]

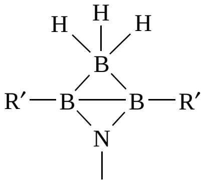
The reaction of several examples of (**56**) with $H_3B \cdot THF$ produces a novel four-membered bicycle represented by (**60**).[117]



(**58**)

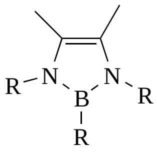


(**59**)

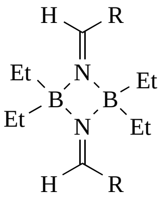


(**60**)

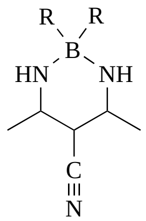
The substitution of B–N for a C=C unit in pyrrole gives a class of diazaboroles (**61**). Some of the most recent advances involving this ring, including π-complexes with the $Cr(CO)_3$ fragment and a potassium salt, have appeared.[118] The reactivity of four-membered diazadiboretene rings continues to be of interest, and a recent paper summarizes the variety of larger rings that can be prepared via insertion reactions on $(t\text{-BuNBR})_2$.[119] Koster and coworkers[120] explored in some detail the reactions of Et_3B, i-Pr_3B, and t-Bu_3B with a family of alkyl cyanides at 200 °C. A variety of heterocycles, including (**62**), (**63**), and (**64**), was produced, and the specific products obtained depended on the alkyl groups on the borane, the cyanide, and the reaction conditions. In another study, reactions of $(Me_2N)_2BR$ with dimethylurea were found to give bicyclic species of the general type represented by (**65**).[121]



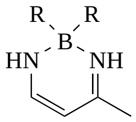
(**61**)



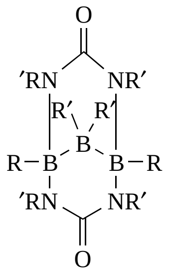
(**62**)



(**63**)



(**64**)



(**65**)

Finally, it is noted that some utility is being found for some of these apparently esoteric ring compounds. Oxozaborolidines and dioxaborolidines serve as enantioselective catalysts for ketone reductions, asymmetric allylations, Diels–Alder reactions, and aldol condensations.[122]

12 BORON NITRIDE

Extending the B–N/C–C analogies employed throughout this article, it is found that the allotropes of BN have a close correspondence with those of carbon. For example, the hexagonal form of BN forms a layered structure related to graphite, and the cubic form of BN closely resembles diamond. A number of properties for the two materials are similar but, interestingly enough, some properties are quite different. These differences include color, electrical properties, and optical properties. Practical interests in various forms of BN have spurred significant growth in boron–nitrogen monomer and polymer chemistry. A thorough review of BN appeared in 1990,[123] and aspects of the synthesis of BN from preceramic polymers were updated in brief reviews appearing in 1991[124] and 1992.[125] The present growth in this area should continue as new applications for the material are made possible by the availability of processible precursors and new synthetic techniques.

Within this section, it is appropriate to point out that there is interest in preparing isoelectronic B–N analogs of the newest form of carbon, C_{60},[126,127] and this offers a challenge to molecular chemists interested in this area of inorganic chemistry.

Boron nitride can be prepared by many routes such as CVD (NH_3 + organoborane),[128] pyrolysis of preceramic polymers derived from borazine,[129] and solid-state metathesis ($NaBF_4 + 3NaN_3$, for example).[130,131] The type of BN formed in these reactions parallels the materials that can be obtained from carbon. Thin films and coatings of BN have been studied extensively.[132] BN nanotubes can be prepared by CVD at 1100 °C using borazine (see Section 8) and catalytic NiB_2.[133] The tube formation is proposed to occur through a root-growth mechanism where growth occurs at the tube-catalyst interface. A low-temperature route (450–600 °C) to BN nanotubes using NH_4BF_4, KBH_4, and NaN_3 has recently been reported.[134] They have a diameter range of 60 to 350 nm. Hexagonal BN 'onions' and other structures can be prepared by combining BBr_3 with $NaNH_2$ and NH_4Cl at approximately 400 °C.[135] The materials were characterized by XRD, FT-IR, XPS, and EDXA spectra. Using activated carbon as a template, activated BN was synthesized with a specific surface area of 168 $m^2\,g^{-1}$, a total pore volume of 0.27 $cm^3\,g^{-1}$ and an average pore radius of 32.2 Å.[136] Spherical particles of 50 to 400 nm in diameter have been prepared through thermolysis of trimethoxyborane under an ammonia atmosphere.[137] BN fibers[138] and nanowires[139] are also known.

BN materials have many potential applications beyond use in ceramics. For example, the vacuum pyrolysis of poly(4,6-borazinylamine) produces highly microporous BN

with surface areas of 53 to 696 $m^2 g^{-1}$ and pore volumes of 0.036 to 0.39 $cm^3 g^{-1}$. Since BN has an inherently polar surface, porous BN should be an ideal gas adsorbent.[140] Indeed, BN nanotubes are capable of storing H_2 at ambient temperature.[141] Hexagonal BN can serve as a template for diamond synthesis.[142]

1 INTRODUCTION

The beginning of the chemistry of organoboron compounds dates back to 1859 when Frankland discovered triethylborane, Et_3B. While the subsequent availability of Grignard reagents provided facile access to organoboranes, a major breakthrough was the discovery of the hydroboration of alkenes as a convenient entry point to organoboron chemistry by Brown in 1956. Over the past decade the chemistry of organoboron compounds has developed from an area primarily of interest with regard to organic synthesis applications, where organoboranes play a pivotal role both as reagents and as catalysts, into a highly interdisciplinary research field.

Of particular significance in the chemistry of organoboranes is their behavior as Lewis acids, which is a result of the empty p-orbital of tricoordinate boron. Much recent effort has been devoted to the synthesis and development of highly Lewis-acidic organoboron compounds through introduction of fluorinated organic substituents. Boron can reach the desired octet configuration either through π-overlap with a substituent X or through formation of neutral or ionic Lewis acid Lewis base complexes (Figure 1). These interactions have been exploited in many of the applications of organoboron compounds. For example, overlap of the empty p-orbital on boron with organic π-systems leads to interesting luminescent and nonlinear optical properties. In addition, the selective coordination of nucleophiles D has opened a new avenue to sensor materials. Indeed it is this donor−acceptor interaction that allows organoboron compounds to act as efficient catalysts and cocatalysts in organic synthesis. Moreover, intramolecular donor−acceptor interactions are ubiquitous in the design of new heterocycles, and intermolecular interactions permit the (reversible) assembly of macrocycles and coordination polymers. Finally, organoborates, BR_4^-, have been studied extensively as weakly coordinating anions and are useful, for example, as battery components and cocatalysts in olefin polymerization.

This chapter reviews these new developments and strives to provide an overview of the current state of the highly interdisciplinary field of organoboron chemistry. The focus will be on the synthesis, structural aspects, properties, and applications of new organoboron compounds. Although reference to a few specific and particularly important applications in organic synthesis will be made, the broad applications of organoboranes as reagents in organic synthesis cannot be covered in the context of this review. However, there are ample recent reviews and texts that the interested reader is referred to (general;[1–4] organoboron reagents,[5–13] organoboron catalysts,[14–19] coupling reactions[20–23]). A separate chapter specifically devoted to boron−nitrogen compounds (*see* ***Boron–Nitrogen Compounds***) gives information on the important classes of amino-substituted organoboranes and organoborane amine adducts.

2 GENERAL SYNTHETIC METHODS

A brief overview of some of the most important synthetic routes to organoboranes, that is, (1) transmetallation reactions, (2) the boration of unsaturated compounds, and (3) C–H activation will be given. General aspects of these methodologies will be covered and illustrated with selected recent literature examples. While a large number of transformations are known that convert one boron compound to another, the diversity of these methods does not allow for full treatment in this context. Detailed information is given in several excellent comprehensive reviews that have been published.[1–3]

2.1 Organometallic Precursors

Transmetallation reactions represent an important method for the synthesis of organoboranes.[1–3] Organometallic

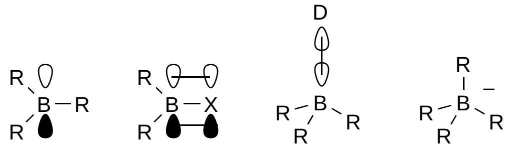

Figure 1 Schematic representation of common organoborane structures

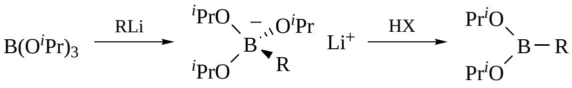
precursors are especially useful but not restricted to the synthesis of methyl, allyl, benzyl, alkynyl, and arylboranes, which cannot be made through hydroboration reactions. In general, an organometallic compound such as an organolithium species is treated with a borane BX_3 to yield the desired organoborane and a metal salt (equation 1).

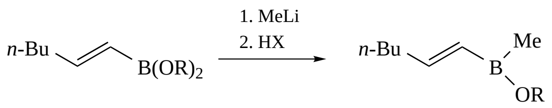
$$3R_nM + nBX_3 \longrightarrow nBR_3 + 3MX_n \qquad (1)$$

A large variety of organometallic reagents (M = Li, Na, K, Mg, Al, Si, Sn, Pb, Cu, Zn, Hg, Zr) are available for transfer of the organic substituent to boron, but organolithium (*see* ***Alkali Metals: Organometallic Chemistry***) and Grignard (*see* ***Alkaline Earth Metals: Organometallic Chemistry***) reagents are the most important and most readily available precursors. With organolithium reagents, the substitution occurs as a two-step process involving initial formation of a borate intermediate, from which the organoborane is typically liberated with an acid HX as shown in equation (2).

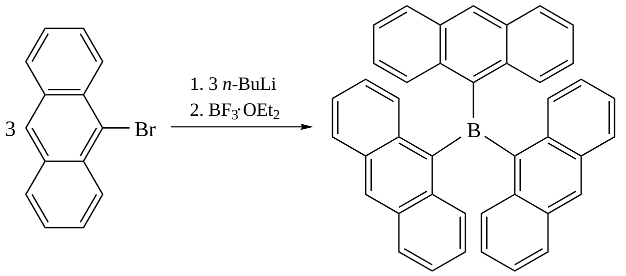


(2)

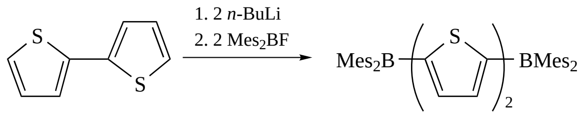
This procedure is the method of choice for the synthesis of boronic acids. Especially good selectivity is observed with $B(O^iPr)_3$ and $XB(NR_2)_2$ (X = Cl, Br) as the boron source. The method may also be applied to the synthesis of many diorgano- and triorganoboranes. Some recent examples of the formation of organoboranes from organolithium and organopotassium reagents, respectively, are shown in equations (3–6).[24–27]



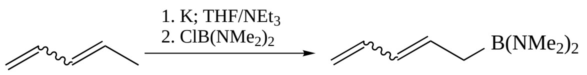
(3)



(4)

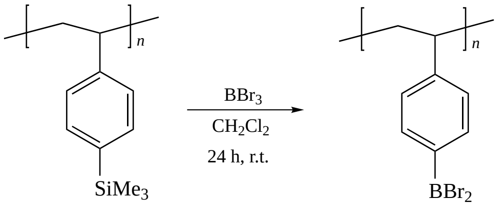


(5)

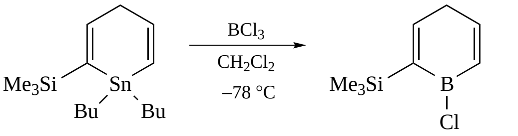


(6)

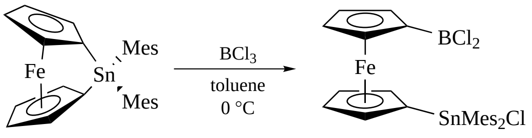
One drawback is that organolithium and Grignard reagents in certain cases are too reactive to produce the desired organoboranes with high selectivity. Indeed, depending on the type of boron derivative BX_3 used (X = F, Cl, Br, I, OR, NR_2, SR, H), a mixture of organoboron species RBX_2, R_2BX, R_3B, and borates $[R_4B]M$ may form. Another potential problem arises with the more reactive boron halides, BCl_3 and BBr_3, which tend to react with ethers that are typically employed as solvents for the formation of organolithium and Grignard reagents. Other less reactive reagents that are suitable for use in hydrocarbon or chlorinated solvents such as organosilicon (*see* ***Silicon: Organosilicon Chemistry***), organotin (*see* ***Tin: Organometallic Chemistry***), organozinc (*see* ***Zinc: Organometallic Chemistry***), organomercury (*see* ***Mercury: Organometallic Chemistry***), and organocopper (*see* ***Copper: Organometallic Chemistry***) species have therefore been developed and are widely applied.[1,2] These reagents are readily isolable, and can be purified and stored prior to use; importantly, in most cases they show very high selectivity. Some recently reported syntheses involving these organometallic precursors are shown in equations (7–18). For example, the high selectivity of silicon–boron exchange reactions (*ipso* borodesilylation) with aromatic compounds first reported by Haubold and Kaufmann has been exploited for the room temperature synthesis of fully functionalized dibromoboryl-substituted polystyrene (equation 7).[28] Tin–boron exchange reactions occur even more readily, as is nicely demonstrated in the synthesis of a boracycle from a stannacycle in the presence of a vinylic trimethylsilyl group (equation 8).[29] Remarkably high reactivity and good selectivity has been observed when the silicon or tin atom is incorporated into a strained cycle as shown for the ring-opening borylation of a strained ferrocenophane in equation (9).[30] It is interesting to note that cyclic organoboranes and organoborates themselves may serve as precursors to new bifunctional boranes via ring-opening reactions as illustrated in equation (10).[31]



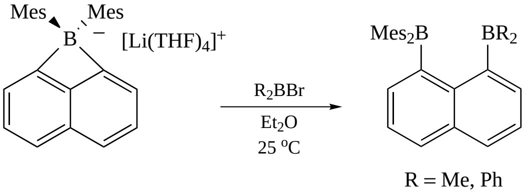
(7)



(8)



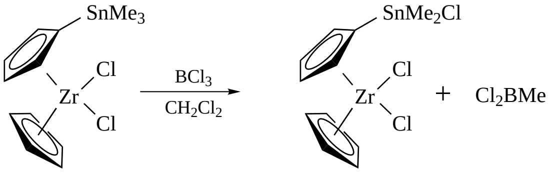
(9)



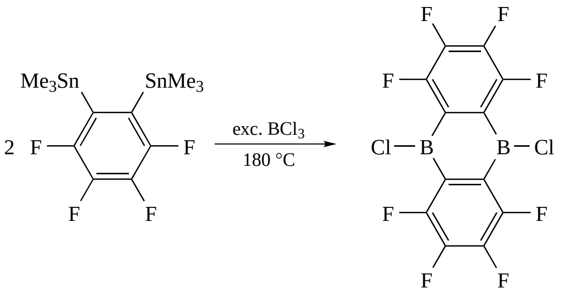
(10)

One of the limitations of silicon – and tin – boron exchange reactions for the synthesis of arylboranes is that preferred transfer of the alkyl substituents in $ArSiMe_3$ or $ArSnMe_3$ over the desired reaction of the silicon–aryl bond may occur in certain cases. Typically E–C(sp^2) (E = Si, Ge, Sn) and E–C(sp) bonds are more reactive in borylation reactions than E–C(sp^3) bonds.[32] However, it is well known that tin alkyls are reactive toward haloboranes, and it also has been shown that tetramethylsilane readily reacts with BBr_3 to produce Me_3SiBr and $MeBBr_2$.[33] Thus cleavage of methyl groups from species $ArEMe_3$ (E = Si, Sn) has, for example, been observed in the case of electron-deficient groups (Ar = C_6F_5) and with silylated and stannylated zirconocenes (equations 11 and 12).[34–36] This problem can generally be avoided if the homoleptic compound Ar_4Sn is readily available and is reactive toward boron halides. In other instances it has been shown that harsh reaction conditions and the use of excess borane can promote tin–boron exchange even in the presence of fluorinated aryl substituents in Ar^FSnMe_3 or $Ar^F{}_2SnMe_2$ (equation 13).[37]

$$C_6F_5SiMe_3 \xrightarrow{BCl_3} C_6F_5SiMe_2Cl + Cl_2BMe \quad (11)$$



(12)



(13)

Organomercury, organozinc, and organocopper reagents have been successfully employed in many cases, in which other more readily accessible reagents did not give satisfactory results. Some examples are illustrated in equations (14–16).[38,39] Reactions involving aluminum and zirconium–boron exchange (organozirconium chemistry: *see* ***Zirconium & Hafnium: Organometallic Chemistry***) have also been reported, and representative transformations are shown in equations (17) and (18). In particular, the commercially available trimethylaluminum is frequently used as a convenient methyl group transfer reagent.[40] Alkyl and vinylzirconium species, which are conveniently obtained via hydrozirconation or zirconocene coupling reactions, react smoothly with boron halides under zirconium–boron exchange.[41,42]

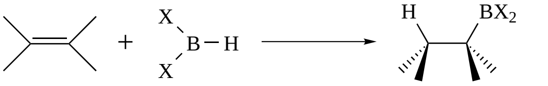
(18)

2.2 Hydroboration, Haloboration, Organoboration, Diboration

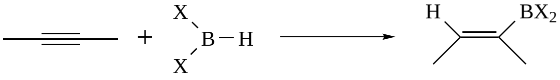
The discovery of hydroboration reactions by Brown has greatly advanced the field of organoboron chemistry, and this reaction remains one of the most important and versatile synthetic routes to organoboron compounds. Many excellent reviews and book chapters on this topic have appeared in the literature.[3–7] Thus, only a brief general introduction and

some representative recent examples of this chemistry will be provided here.

The hydroboration of olefins and alkynes is shown schematically in equations (19) and (20). In hydroboration reactions *cis*-addition of the borane X_2BH occurs across a double bond or a triple bond. Importantly, in almost all cases the boron atom preferentially goes to the sterically less hindered site. However, in the presence of strongly electron-withdrawing substituents such as fluorinated groups, Markovnikov addition products may be observed in considerable amounts.[43] The mechanism of hydroboration has been thoroughly studied and extensively reviewed.[1–3] For organoboranes such as 9-BBN-H (**4**) the first step is believed to involve dissociation of the dimeric borane $(R_2BH)_2$ into a monomeric species R_2BH, which then adds to the carbon–carbon double bond via a three-center π-complex that precedes the formation of a four-center transition state with no or little activation energy.[2]



(19)

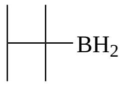


(20)

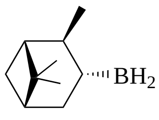
A large number of hydroboration reagents are available ranging from borane adducts $BH_3{\cdot}D$ (D = Me_2S, THF, NR_3, PR_3) to in situ generated haloboranes X_2BH. Organoboranes RBH_2 and R_2BH are also frequently used and often give higher selectivity in hydroboration reactions. Moreover, the use of chiral substituents on boron provides an opportunity for enantioselective catalysis.[5–7] Some of the most commonly used organoborane reagents are shown (**1–12**) and recent developments will be outlined in the following.

$MeBH_2$

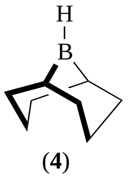
(**1**)



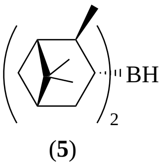
(**2**)



(**3**)

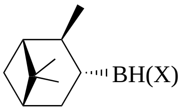


(**4**)



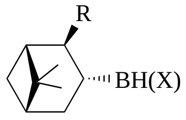
(**5**)

Chiral alkylhaloboranes RBHX that are even more efficient than typical organoboranes RBH_2 and R_2BH were developed by Brown. For instance, isopinocampheylhaloboranes (**6**; IpcBHX, X=Cl, Br) and related 2-organylapopinene



X = H, Cl, Br

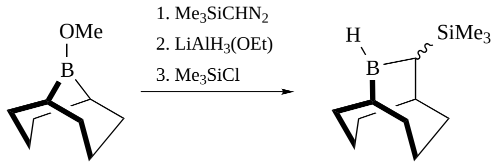
(**6**)



X = H, Cl, Br
R = Et, Pr, *i*-Pr, *i*-Bu, Ph

(**7**)

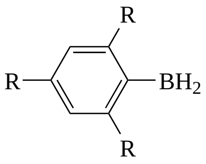
derivatives (**7**; RapBHX) show not only enhanced reactivity relative to $IpcBH_2$ (**3**), but also excellent selectivities in enantioselective hydroboration reactions.[44] A ring-expanded chiral bicyclic borane (**8**) was described by Soderquist.[45] Compound (**8**) was obtained in high yield through insertion of the diazomethane derivative Me_3SiCHN_2 into the boron–carbon bond of *B*-MeO-9-BBN (equation 21). The borane formed as a racemate, but was readily resolved through its pseudoephedrine complex. The enantiomerically pure boranes (**8**) showed very high stereoselectivity in various hydroboration reactions.[45]



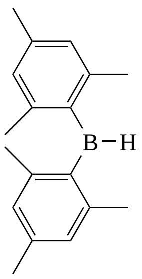
(21)

(**8**)

Arylboranes, $ArBH_2$ and Ar_2BH, have been studied as an alternative to alkylboranes in order to avoid potential problems related to retrohydroboration reactions. Moreover, further stabilization may be readily achieved by 2,6-disubstitution on the phenyl ring. Smith and Pelter reported the synthesis and properties of mesitylborane (**9**) and tripylborane (**10**).[46] Mesitylborane (**9**), which is obtained from Mes_2BH (**11**) and $BH_3{\cdot}THF$, shows not only better stability in solution compared to thexylborane (**2**), but also exhibits very high regio- and chemoselectivity in hydroboration reactions. Polymer-supported versions of these arylboranes have been developed.[47]

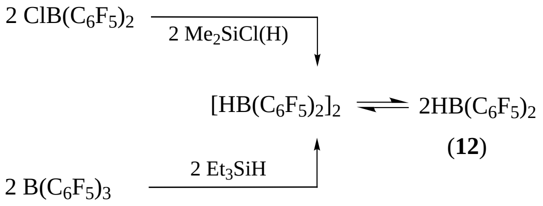


R = Me (**9**)
R = *i*-Pr (**10**)

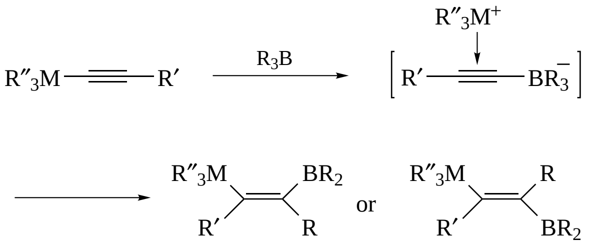


(**11**)

The fluorinated diarylborane $(C_6F_5)_2BH$ (**12**) and its hydroboration activity were studied by Piers.[48,49] This



Scheme 1



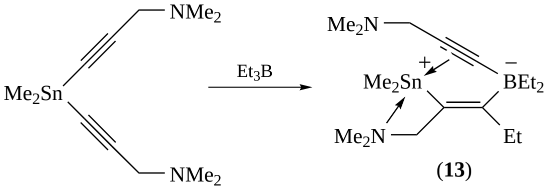
Scheme 2 1,1-Organoboration of alkynes

highly electrophilic borane can be synthesized through two different routes. While $ClB(C_6F_5)_2$ is readily converted to the desired borane (**12**) with $Me_2SiCl(H)$ as the hydrogen source, the chloroborane precursor itself is not readily available (Scheme 1). Thus, an alternative route to (**12**) from commercially available $B(C_6F_5)_3$ was developed. Borane (**12**) shows a dimeric structure in the solid state as confirmed by X-ray crystallography, but partial dissociation to the monomeric borane is observed in solution. Most interesting is the unusually high activity of (**12**) in hydroboration reactions, which provides a means to functionalize sterically hindered substrates that are not attacked by other more commonly used organoborane reagents. The higher reactivity of (**12**) was attributed to the highly electron-deficient nature of the boron center and partial dissociation into the monomeric borane in solution. A similar monomer–dimer equilibrium was also observed for Mes_2BH (**11**).[50] However, this sterically hindered reagent shows low reactivity toward alkenes and is therefore most favorably used in selective alkyne hydroborations.

Haloboration Reactions. The haloboration of carbon–carbon triple bonds provides another entry point for the synthesis of organoboranes.[2,13,51] A wide variety of haloboranes including BBr_3, 9-BBN-Br, and 9-BBN-I has been found to react with terminal alkynes to produce (Z)-2-halo-1-alkenylboranes.[13] The reaction occurs in a stereo-, regio-, and chemoselective fashion specifically with terminal alkynes and has been used to synthesize numerous substituted olefins and related compounds. Diboration reactions of alkynes with B_2Cl_4 are also well known. However, more convenient transition-metal-catalyzed procedures with the less reactive alkoxy substituted diboranes $B_2(OR)_4$ have recently been developed.

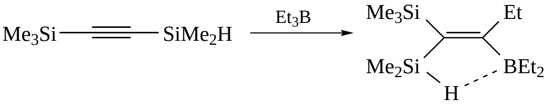
1,1-Organoboration Reactions. Alkynyl derivatives R''_3MCCR' of the group 14 elements (M=Si, Ge, Sn, Pb) react with organoboranes R_3B via 1,1-organoboration to give boron-substituted alkenes (Scheme 2).[52] In most cases, high yields and good selectivity are observed for products with the R_2B group and the group 14 element in *cis*-position at the carbon–carbon double bond.

Organoboranes typically used in these reactions are Et_3B, *i*-Pr_3B, and alkylated 9-BBN derivatives. Interestingly, multiple organoboration steps may take place with di-, tri-, and tetra-1-alkynyl element compounds. Intermediates such as the donor-stabilized zwitterion (**13**) have been identified and fully characterized (equation 22).[52]



(22)

A large number of intriguing new organoboron compounds including many unusual organoboron heterocycles have been synthesized through organoboration reactions.[52] As an example, the 1,1-organoboration of a silylalkyne is shown in equation (23). The vinylborane (**14**) thus produced shows the first Si–H–B bridge, which was confirmed by multinuclear NMR studies.[53]



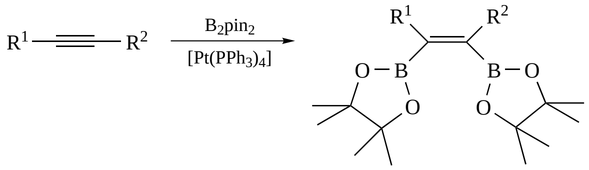
(23)

(**14**)

Catalyzed Boration Reactions. Since the initial report by Männig and Nöth on the rhodium catalyzed room temperature addition of HBcat to alkenes much effort has been devoted to the search for new catalytic hydroboration processes and other boration reactions (*see* ***Hydroboration Catalysis***).[7,54,55] The most intriguing aspect of transition-metal catalysis in boration reactions is that (1) chemoselectivity, (2) regioselectivity, and (3) stereoselectivity may be altered compared to uncatalyzed reactions. New methods for the catalytic addition of diboranes $R_2B–BR_2$,[56,57] B–S,[58] B–Si,[59] and B–Sn[60] moieties have greatly enhanced the scope and utility of catalytic boration chemistry. Moreover, cross-coupling of B–B and B–H compounds with organic halides and triflates provides a convenient one-step procedure for the synthesis of organoboron compounds from organic electrophiles.[55–57] For many of these catalytic processes, boryl–metal species have been identified as key intermediates.

The transition-metal-catalyzed diboration of alkynes can be directed to give highly selective *cis*-addition yielding 1,2-diborylated olefins (equation 24). Depending on the catalyst,

tetraborylated alkanes may also be observed. However, in the catalyzed diboration of alkenes not only 1,2-diborylated products, but also various other mono-, di-, and triborylated alkanes are often obtained depending on the specific conditions.[56] This behavior was traced back to competing β-hydroelimination pathways and has been exploited for the selective synthesis of 1,1-diborylated olefins.[61]



(24)

2.3 C–H Activation

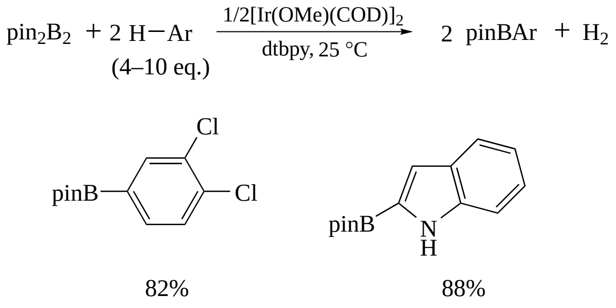
A new direct access to organoboranes via stoichiometric and catalytic C–H activation (*see* ***Alkane Carbon–Hydrogen Bond Activation***) has been developed over the past few years.[62] It is especially interesting that this methodology provides an opportunity to functionalize unreactive C–H bonds of hydrocarbons in a single preparative step thus combining economy, efficiency, elegance, and environmental benignity.[62] Most studies have been performed with diboranes such as $B_2(OR)_4$, but boranes $HB(OR)_2$ may also serve as a precursor.

Initial reports on the borylation of alkanes using isolated transition-metal–boryl complexes date back to 1995, when Hartwig showed that $Cp^*Re(CO)_2(Bpin)_2$ converts pentane to 1-borylpentane with high regioselectivity.[63,64] The catalytic C–H borylation of alkanes with $Cp^*Re(CO)_3$ using photochemical activation was demonstrated soon thereafter (equation 25).[65] Also, an efficient thermal process that involves the use of rhodium catalysts has since been developed (equation 26).[66] It is interesting to note that this methodology is not restricted to small molecules, but has recently been exploited for the direct side-chain functionalization of polyolefins.[67]

$$\mathrm{pin_2B_2 + H{-}R \xrightarrow[h\nu/CO]{Cp^*Re(CO)_3} pinB{-}R + pinBH} \qquad (25)$$

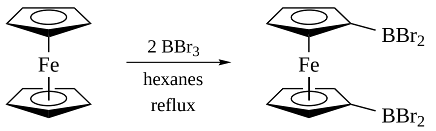
$$\mathrm{pin_2B_2 + 2H{-}R \xrightarrow[150\,^\circ C]{Cp^*Rh(\eta^4\text{-}C_6Me_6)} 2pinB{-}R + H_2} \qquad (26)$$

Highly electron-rich aromatic compounds are known to undergo direct electrophilic borylation reactions with the strong electrophiles BI_3, BBr_3, BCl_3, or $HB(C_6F_5)_2$ under thermal conditions.[68,69] As an example, the dibromoborylation of ferrocene in refluxing hexanes is shown in equation (27). Facile intramolecular borylation reactions have also been



Scheme 3 Borylation of arenes via C–H activation

reported.[70,71]



(27)

On the other hand, transition-metal catalysis provides an opportunity to regioselectively borylate even electron-poor aromatic compounds under mild conditions and in the presence of functional groups. The first example of transition metal–catalyzed aromatic C–H borylation was reported in 1993, when Marder found borylation of the solvent toluene during the preparation of the iridium–boryl complex $Ir(\eta^6\text{-}MeC_6H_5)(Bcat)_3$ from $Ir(\eta^5\text{-}C_9H_7)(cod)$ with catecholborane (catBH).[72] The first catalytic process has been reported by Smith, who used iridium complexes containing phosphine ligands.[73,74] Various rhenium and rhodium complexes have since been shown to catalyze the aromatic borylation with B_2pin_2 and HBpin, respectively. More recently, Miyaura and Hartwig have demonstrated the room temperature conversion of arenes to arylboranes with B_2pin_2 in the presence of the iridium complex $[Ir(OMe)(cod)]_2$ and the ligand di-*t*-butylbipyridine (dtbpy) as shown in Scheme 3.[57,75,76]

Marder reported that the alkyl C–H bonds in benzylic compounds are selectively borylated with a rhodium catalyst.[77] Aromatic borylation products were only observed as minor by-products. Similar results were obtained by Miyaura with Pd/C (equation 28).[78]

$$\mathrm{pin_2B_2 + 2PhCH_3 \xrightarrow[100\,^\circ C/16\,h]{Pd/C\ 3-6\,mol\%} \underset{74\%}{2pinBCH_2Ph} + H_2} \qquad (28)$$

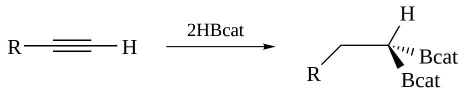
3 ALKYLBORANES

Trialkylboranes were the first organoboranes to be discovered by Frankland. Nevertheless, the crystal structure of trimethylborane, which is a gas at ambient temperature and

has a melting point of 112 K, has been determined only very recently.[79] In contrast to its heavier group 13 analogues, it consists of layers containing only extremely weakly interacting BMe_3 molecules. The shortest intermolecular B···H contact is 3.04 Å, which is well beyond the sum of the van der Waals radii of B and H (2.83 Å). Numerous higher alkylboranes have been prepared and are commonly encountered as intermediates in synthetic organic chemistry.[1,2,5,7,8,10,12,20,22]

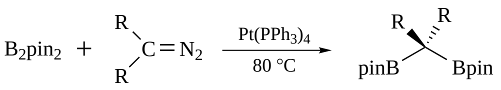
Perfluorinated analogs of trialkylboranes, tris(trifluoromethyl)borane ($B(CF_3)_3$; **15**) and its higher homologs, are still unknown although they have been the subject of a considerable research effort.[80] Many complexes of (**15**) on the other hand have been isolated.[81] Indeed, the B–N bond in amine adducts is extraordinarily stable and withstands even hydrochloric acid and concentrated solutions of KOH. However, the donor-free compound (**15**) could not be liberated. This is believed to be due to facile decomposition under elimination of difluorocarbene and formation of BF_3. The unusual organoboron carbonyl complex $(CF_3)_3B{\cdot}CO$ (**16**) has been prepared very recently.[82] This complex was obtained in high yield through solvolysis of the borate salt $K[B(CF_3)_4]$[83] in concentrated sulphuric acid and was found to be exceptionally stable. In contrast, $(C_6F_5)_3B{\cdot}CO$ needs to be generated in a CO matrix and is only stable at very low temperature. A rich chemistry has been developed with the aminoborane $(CF_3)_2BNMe_2$, which serves as a precursor to other trifluoromethylborane complexes $(CF_3)_2BR{\cdot}D$ (R=H, alkyl, aryl) and numerous heterocyclic compounds.[80]

Diborylated organoboranes with a BCB backbone such as (**17**) are usually prepared by double hydroboration of terminal alkynes (equation 29).[84] The treatment of the diborane B_2pin_2 with diazomethane derivatives provides an interesting alternative that allows for the synthesis of species pinB–CR_2–Bpin (**18**, R=H, Ph; equation 30), which are not accessible via hydroboration reactions.[85]



(**17**)

(29)



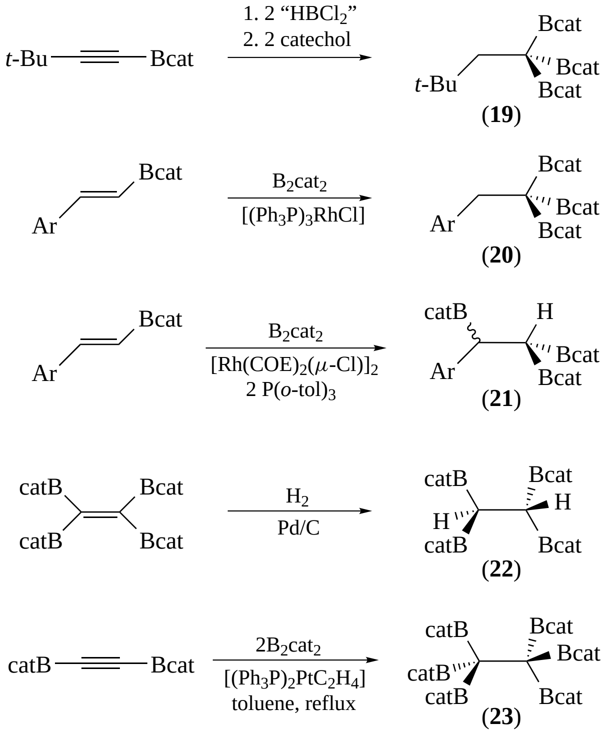
(**18**)

(30)

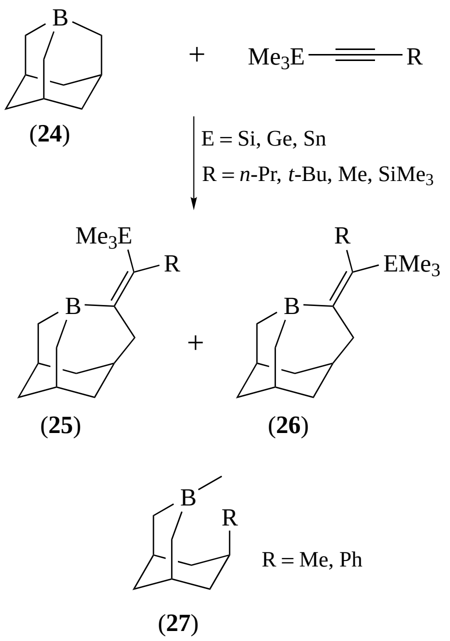
Compounds containing three or even four boryl groups attached to a single carbon atom are accessible through treatment of $RCCl_3$ with $ClB(OR)_2$ and lithium metal, a synthetic route that has been thoroughly studied by Matteson in the 1970s. Moreover, 1,1,2,2-tetraborylethanes are obtained in good yields from acetylene and B_2Cl_4. More recently, transition-metal-catalyzed hydrogenation, hydroboration and diboration reactions have been used to prepare triborylalkane, tetraborylethane, and hexaborylethane derivatives (Scheme 4, (**19–23**)).[86,87] Interestingly, depending on the catalyst, the diboration of vinylboranes with B_2cat_2 leads via sequential diboration and dehydroboration steps either to 1,1,1-triborylalkanes (**20**) or to 1,1,2-triborylalkanes (**21**).[88] 1,1,1-Triborylalkanes, 1,1,2,2-, and 1,1,1,2-tetraborylethane species have been proposed as intermediates in the reaction of borylated alkynes with excess Et_2BH (''hydride bath'') that eventually leads to the formation of small carboranes.[89–91] Indeed, isolated triborylmethane species with alkyl or halide substituents on boron have recently been shown to rearrange to small carboranes upon thermal treatment.[87]

Tetraborylmethane derivatives continue to attract interest as potential candidates for the stabilization of planar tetracoordinate carbon.[92] Species $C(B(OR)_2)_4$ containing alkoxy substituents on boron adopt classical structures. However, a planar tetracoordinate carbon environment has been suggested based on DFT calculations for compounds $C(BR_2)_4$ (R = alkyl), in which the CB_4 group is incorporated into a cage system thus leading to both 'electronic' and 'mechanical' stabilization.[93,94] The electronic structures of penta- and hexaborylated compounds containing planar pentacoordinate and hexacoordinate carbon have also been studied using theoretical calculations.[95,96]

Numerous cyclic organoboranes are known and only selected recent studies will be highlighted. 1-Boraadamantane (**24**), which is isoelectronic with the 1-adamantyl cation, is a peculiar trialkylborane since the three-coordinate boron atom normally prefers a trigonal planar environment, but



Scheme 4

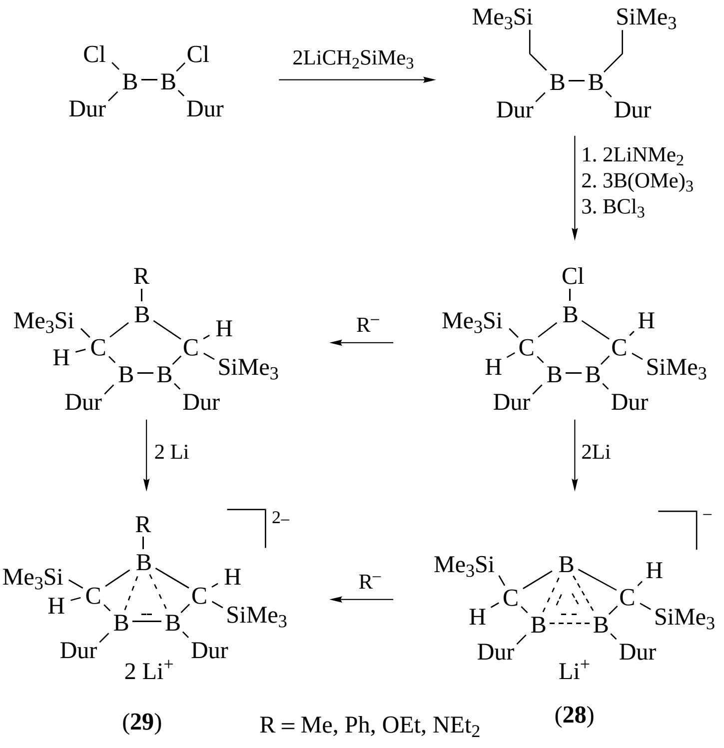


Scheme 5

occupies a bridgehead position with a tetrahedral geometry in (**24**). Consequently, (**24**) exhibits a markedly increased Lewis acidity when compared with other trialkylboranes. Several new ring-enlarged systems and multicyclic organoboron species have recently been obtained via 1,1-organoboration reactions.[97–99] For example, reaction of 1-boraadamantane with *n*-propyltrimethylsilylacetylene yields two isomeric ring-enlarged 4-methylene-3-borahomoadamantane species (**25** and **26**; Scheme 5).

In a different study, a series of substituted 3-borabicyclo[3.3.1]nonanes (**27**) have been prepared and investigated by X-ray crystallography. Intramolecular interactions between the empty *p*-orbital on boron and the substituent R were shown to play an important role in the stabilization of the chair-like conformation in these species.[100]

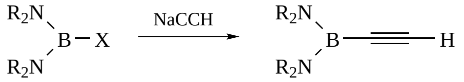
Cyclic organoboranes containing multiple boron atoms within the ring structure have been extensively studied as precursors to (multidecker) transition-metal complexes and to nonclassical organoboranes (*see* ***Boron: Metallacarbaboranes*** and ***Boron: Polyhedral Carboranes***). Earlier efforts have been thoroughly reviewed.[101–103] Recently, a series of triboracyclopentane derivatives were reported by Berndt and Schleyer (Scheme 6).[104] Reduction of these boracycles gave the nonclassical bishomoaromatic anions (**28**) and homoaromatic dianions (**29**). Related trishomoaromatic dianions obtained via reduction of 1,3,5-triboracyclohexane derivatives with lithium were studied by Siebert and Schleyer.[105,106]



Scheme 6

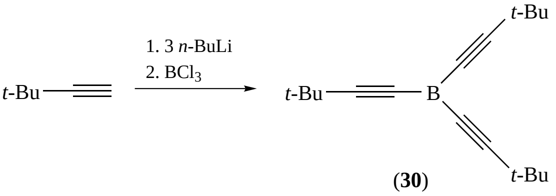
4 ALKYNYLBORANES AND VINYLBORANES

Borylated alkynes that are stabilized through Lewis base coordination or π-donation from electron-donating amino and alkoxy substituents on boron are well studied. Their synthesis typically involves either the reaction of a bis(dialkylamino)haloborane with an acetylide to form a diaminoborylacetylene (equation 31), or the treatment of stannylated alkynes with boron halides.[107–109] However, while alkynylboranes are readily available, in the absence of steric protection or electronic stabilization they tend to decompose thermally.

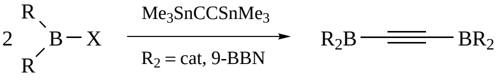


(31)

For instance, attempts at isolating donor-free alkynylboranes have been hampered by spontaneous polymerization. The first donor-free tris(alkynyl)borane, tris(3,3-dimethyl-1-butynyl)borane (**30**), has only recently been obtained by reaction of deprotonated 3,3-dimethyl-1-butyne with boron trichloride at $-78\,°C$ in pentane (equation 32).[110] The alkynylborane (**30**) was fully characterized by multinuclear NMR spectroscopy, mass spectrometry, and X-ray crystallography. The ^{11}B NMR signal of (**30**) shows a remarkable shift of $\delta = 48$, which is upfield from typical shifts of alkyl- and alkenylboranes. The crystal structure of (**30**) shows similar C–C bond lengths, but significantly shorter B–C bonds in comparison to those observed for the donor-stabilized complexes (**30**) D indicative of a small degree of $p_\pi - p_\pi$ interactions between the sp^2-boron atom and the sp-hybridized carbon. Weak π-overlap was further confirmed by *ab initio* calculations.[109] It is this π-interaction that has been exploited for the development of nonlinear optical (NLO) materials based on alkynylboranes as described in Section 7.1.[111]

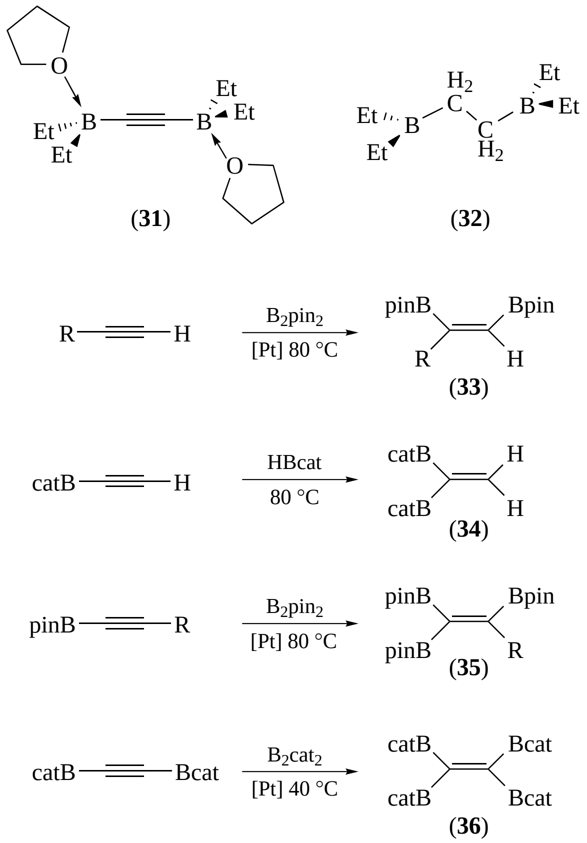


(32)



(33)

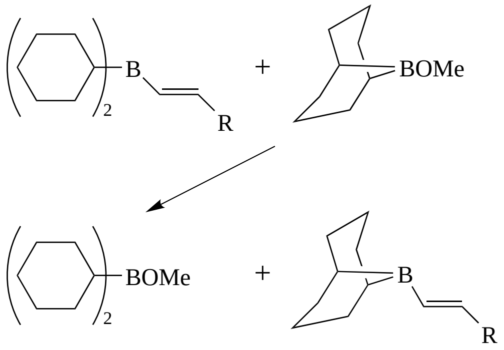
Tin–boron exchange reactions provide a convenient route to diborylated acetylene (equation 33).[107] Diborylalkynes show an enhanced Lewis acidity in comparison to diborylalkanes as demonstrated by the coordination of THF in (**31**), but a lack of binding to the related alkyldiborane (**32**). This effect has been attributed to the stronger inductive electron-withdrawing effect of sp-hybridized relative to sp^3-hybridized carbons.[32]



Scheme 7

Many different routes are available for the synthesis of vinylboranes and several of them are shown in Scheme 7. Hydroboration and diboration reactions of alkynes and borylated alkynes provide access to the full series of mono-, di-, tri-, and tetraborylated olefins.[56,57] 1,2-Diborylated olefins (**33**) are obtained via diboration of alkynes and 1,1-diborylated olefins (**34**) are accessible through hydroboration of borylalkynes. An alternative route to 1,1-disubstituted products involves the diboration of carbenoids formed in situ from vinylhalides and butyl lithium.[84] In certain cases, metal-catalyzed dehydrogenative borylation of olefins may be used.[61] Borylalkynes serve as precursors to triborylated (**35**) and tetraborylated (**36**) olefins. Thus, the sparingly soluble tetraborylethylene derivative (**36**) forms in good yield through platinum-catalyzed diboration of diborylacetylene in toluene at $40\,°C$ if the base-free catalyst $[Pt(cod)_2]$ is used.[112] If the reaction, however, is performed at higher temperature, further diboration of (**36**) leads directly to the hexaborylated ethane (**23**) shown above. Intramolecular B–O interactions were postulated for (**36**) based on HF-SCF calculations.[112]

Organometallic routes are frequently applied to the synthesis of vinylboranes.[84] Vinyltin and vinylzirconium reagents, for instance, serve as precursors for the preparation of vinylboranes, in which the boron centers are not electronically stabilized by oxygen or nitrogen substituents. Moreover,



Scheme 8

organoboration of silyl and stannylalkynes provides access to multiply functionalized olefins (see Scheme 2).[52,113,114] Vinylboranes may also be prepared via alkenyl transfer from boron to boron. This reaction, shown in Scheme 8, is particularly useful if the desired alkenylborane is not selectively formed in the hydroboration of alkynes.[115] Haloboration reactions and uncatalyzed diboration of alkynes with B_2Cl_4 allow for preparation of vinyldihaloboranes. The latter typically yields 1,2-diborylated products, but in the presence of silyl and germyl substituents 1,1-diborylated species are formed. In some cases, hydrozirconation of alkynylboranes and zirconocene coupling reactions also provide access to 1,1-diborylated olefins.[116]

The most important applications of borylated olefins and alkynes are certainly in the field of organic synthesis, where they play, for example, major roles as reagents in coupling reactions[20–22] and as dienophiles for Diels–Alder reactions.[117] Vinylboranes and alkynylboranes with bulky mesityl groups on boron have been investigated as nonlinear optical materials (see Section 7.1).[111] Moreover, 1,1- and 1,2-diborylated olefins containing electron-deficient boron centers have been extensively studied as bidentate hosts for the coordination of nucleophiles (see Section 7.2) and also serve as convenient precursors to various diboraheterocycles.[84] Finally, 1,1-diborylated olefins containing electron-withdrawing C_6F_5 groups on boron have been studied as bidentate Lewis acid activators for olefin polymerization and are further described in Section 7.3.3.[84,118]

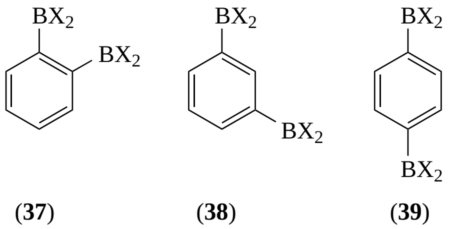
5 BORON ATTACHED TO UNSATURATED ORGANIC RINGS

5.1 Phenylboranes

Although direct borylation of arenes in specific cases is possible and metal-catalyzed C–H and C–X activation reactions provide new possibilities, most arylboranes are prepared from organometallic precursors. In particular, monoborylated arenes are conveniently obtained through reaction of organolithium or Grignard reagents with boranes BX_3 and have been well studied, and their importance in Suzuki cross-coupling reactions can hardly be overestimated.[20,22]

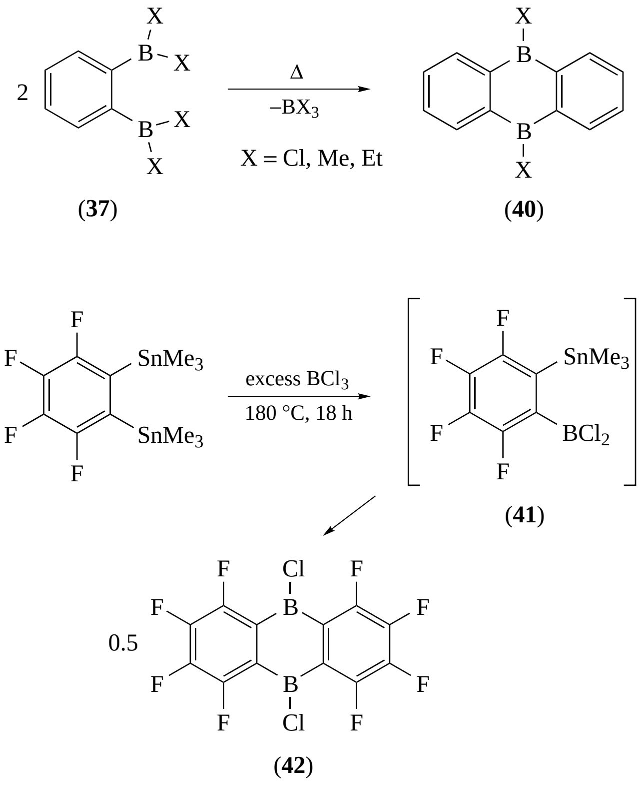
Triarylboranes Ar_3B continue to attract interest with regard to their stereodynamic behavior that is related to the propeller shape adopted by many triarylboranes containing bulky aryl groups. For instance, the *ortho*-substituted triphenylborane $(2\text{-}CF_3C_6H_4)_3B$, prepared from the corresponding organolithium compound and BCl_3, was studied by spectroscopic methods and MO calculations.[119] The X-ray crystal-structure analysis revealed a propeller-shaped structure of nearly C_3 symmetry, in which the three CF_3 groups are on the same side of the boron sp^2 plane. Two enantiomers crystallized separately and both enantiomers were found to be CD active in the solid state. However, in solution interconversion between the two isomers was observed by variable-temperature ^{19}F NMR spectroscopy. Related to the conformational flexibility of arylboranes is the question whether significant π-bonding occurs between the empty π-orbital on boron and the aromatic substituents. Based on crystallographic and NMR spectroscopic data, boron–carbon π-bonding is thought to be weak in the ground state of triarylboranes.[120] However, a greater π-contribution is evident in the excited state of triarylboranes and in the respective radical anions $[Ar_3B]^{-}$.[120] This effect has been exploited for the design of new photonic and electronic materials based on arylboranes, which are further discussed in Section 7.1.

Various derivatives of bis(boryl)benzene isomers (**37**), (**38**), and (**39**) are readily obtained through metathesis reaction of boron halides with the respective Grignard, trimethylsilyl, or trimethylstannyl reagents.[32,121] Especially the 1,2-disubstituted derivatives (**37**) have been studied extensively in molecular recognition and as activators in olefin polymerization (Sections 7.2 and 7.3.3), whereas species (**38**) and (**39**) have primarily been used for the design of new electronic materials (Section 7.1).



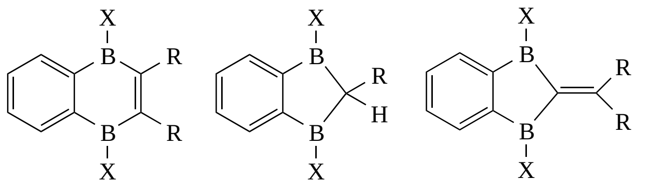
(**37**) (**38**) (**39**)

Thermolysis of 1,2-diborylated benzene species (**37**) (X=Cl, Me, Et) leads to cyclization with extrusion of BX_3 (Scheme 9).[32,122] The resulting diboraanthracenes (**40**) formally contain an antiaromatic central 6-membered ring.[32] Piers and Marks have independently developed perfluorinated analogs of diboraanthracene (**40**). Interestingly, borylation of $1,2\text{-}C_6F_4(SnMe_3)_2$ with BCl_3 leads directly to the perfluorinated diboraanthracene derivative (**42**) (Scheme 9).[37,123] Although the monosubstituted species



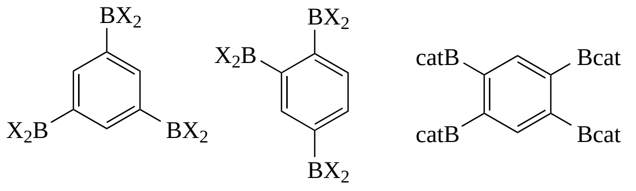
Scheme 9

1,2-$C_6F_4(SnMe_3)(BCl_2)$ (**41**) was detected initially, the expected diborylated intermediate 1,2-$C_6F_4(BCl_2)_2$ was not observed at any time during the reaction. It was suggested that the decreased nucleophilicity of the perfluoroaryl compounds disfavors the second electrophilic aromatic substitution step relative to coupling. The diborylated species $C_6F_4(BBr_2)_2$ can on the other hand be prepared from the mercurated precursor (1,2-$C_6F_4Hg)_3$ as shown in equation (14).[38] Perfluorinated arylboranes are further discussed in the context of their use as olefin polymerization activators in Section 7.3.3. Moreover, diboraanthracenes (**40**) and related diboracycles (**43**), (**44**) and (**45**) (X = Cl, Me, NMe_2), which are readily available through tin–boron exchange reactions, have been extensively studied as ligands for transition-metal complexes.[101]



(**43**) (**44**) (**45**)

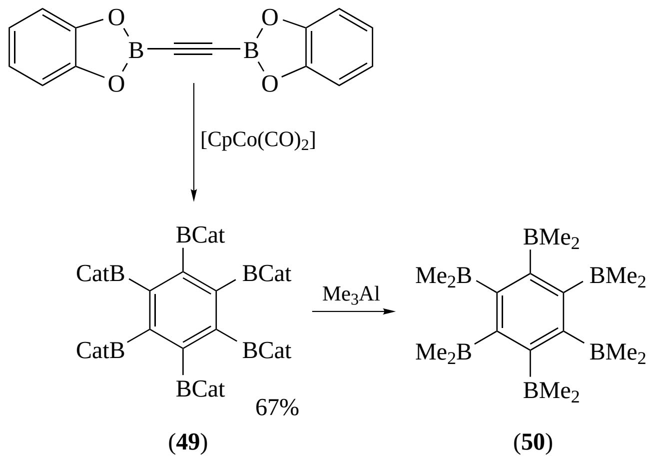
Only a few examples of higher borylated benzene derivatives (**46–50**) have been described. Okada used a Grignard methodology to prepare 1,3,5-tris(dimesitylboryl)benzene (**46**, X = Mes) in low yield and studied its conformational properties by variable-temperature NMR spectroscopy.[124] Silicon-boron exchange between 1,3,5-$C_6H_3(SiMe_3)_3$ and BI_3 provided 1,3,5-$C_6H_3(BI_2)_3$ (**46**, X = I) in somewhat higher yield of ca. 30%.[125] An alternative route to multiborylated benzene species was reported by Siebert, who applied the well-known cobalt-catalyzed cyclotrimerization of alkynes to dialkoxyborylacetylene derivatives $(RO)_2$B-CC-H.[109] A mixture of the 1,3,5- and 1,2,4-triborylated benzene derivatives (**46,47**) was obtained in yields of >50%. Subsequent treatment of the isomeric mixture with mesityl lithium and chromatographic workup gave compound (**46**) (X = Mes) in 49% yield.



(**46**) (**47**) (**48**)

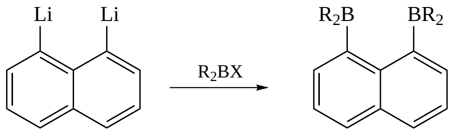
Siebert also used the cobalt-mediated cyclization of alkynes to synthesize the first tetraborylated and hexaborylated benzene compounds (**48–50**; Scheme 10). The boronate ester (**49**) which formed initially was converted into the intriguing base-free hexafunctional triorganoborane (**50**) with trimethylaluminum.[112,121]

The starting point for the synthesis of *peri*-borylated naphthalenes is 1,8-dilithionaphthalene, which may also be transformed into other useful reagents such as 1,8-distannylated and 1,8-dimercuriated naphthalenes.[31] Since the initial report of Katz on the unusual properties of 1,8-bis(dimethylboryl)naphthalene (**51**) as a 'hydride-sponge' new



Scheme 10

research has been devoted to the exploration of this class of bidentate Lewis acids (see also Section 7.2).[31] New derivatives such as the phenyl-substituted (**52**) and the amino-substituted species (**53**) have been synthesized (equation 34).[31] The latter form B_2N_2 four-membered rings when small substituents are attached to the amino groups.[126]

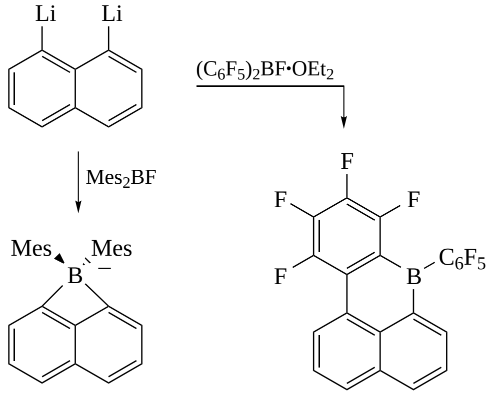


(34)

(**51**) R = Me
(**52**) R = Ph
(**53**) R = NR'_2

It is interesting to note that the reaction of 1,8-dilithionaphthalene with diorganoboron halides does not always lead to diborylated naphthalene species. The antiaromatic cyclic 16-π-electron system (**54**) and the strained four-membered ring (**55**) formed upon reaction of dilithionaphthalene with $(C_6F_5)_2BF{\cdot}OEt_2$ and Mes_2BF in diethyl ether, respectively (Scheme 11).[31,127] The boracycle (**55**) serves as a precursor to other 1,8-disubstituted naphthalenes through ring-opening reaction with electrophiles such as Ph_2BBr or Me_3SnCl (see equation 10).[128,129] Other extended π systems that have been borylated include biphenylene and anthracene.[25,130] The borylated derivatives are typically obtained from lithiated species via treatment with Mes_2BF.

The aromatic moiety in phenylboranes and phenylborates may serve as a 6-electron π donor ligand to transition-metal complexes. Half-sandwich complexes of chromium, $Mes_2[B(\eta^6\text{-Mes})Cr(CO)_3]$ (**56**), $MesB[\eta^6\text{-}MesCr(CO)_3]_2$ (**57**), and $B[\eta^6\text{-}MesCr(CO)_3]_3$ (**58**), containing trimesitylborane as a ligand have been prepared and structurally characterized.[131] The $Cr(CO)_3$ moieties interact weakly in the multinuclear systems (**57**) and (**58**) as shown by electrochemical studies. A more extensive exchange interaction was observed between vanadium centers in related trovacenylboranes $Mes_{3-n}B[(\eta^7\text{-}C_7H_7)V(\eta^5\text{-}C_5H_4)]_n$ (**59**).[132] Finally, tetraarylborates have been used for the generation of zwitterionic transition-metal complexes and of borato-bridged complexes, in which one or two aryl groups of the Ar_4B^- moiety bind to the metal.[133,134]



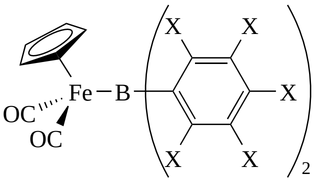
(**55**) (**54**)

Scheme 11

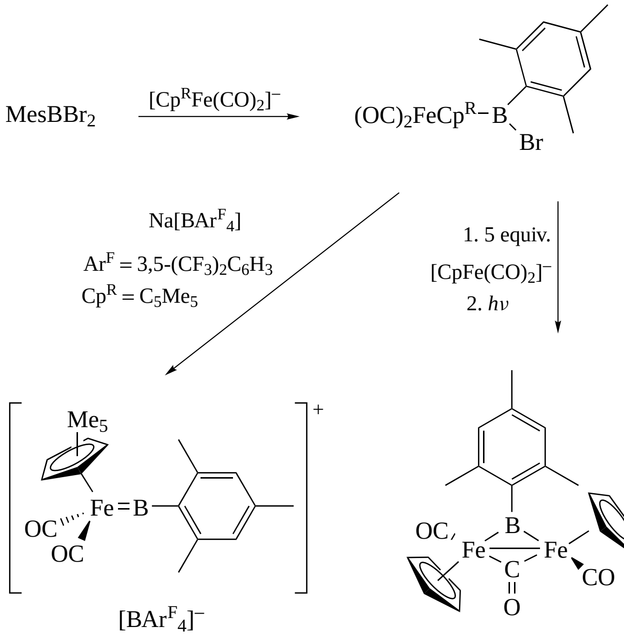
It is interesting to note in this context that arylboron transition-metal complexes with metal–boron bonds have recently been structurally confirmed. Transition-metal–boryl complexes have been of intense research interest, partly because of their involvement in the hydro- and diboration of carbon–carbon multiple bonds, but also owing to their importance in the stoichiometric and catalytic functionalization of alkanes and arenes under thermal and photolytic conditions *(see **Alkane Carbon–Hydrogen Bond Activation**)*.[135–138] While various borane and borylene complexes that feature amino substituents are known, only a few structurally confirmed arylborane complexes have recently been described.[138] Reaction of $[CpFe(CO)_2]Na$ with $BrB(C_6H_5)_2$ and $ClB(C_6F_5)_2$, respectively, led to attachment of diphenylboryl and bis(pentafluorophenyl)boryl groups to the $CpFe(CO)_2$ fragment in complexes (**60**) and (**61**).[139,140] The Fe–B distance in the perfluorinated derivative (**61**) (two independent molecules: 1.965(5) and 1.964(4) Å) is significantly shorter than that in the phenyl species (**60**) (2.034(3) Å). This effect has been attributed to the higher Lewis acidity of the boron center, which in turn results in increased π-overlap between boron and iron. The synthesis of the first terminal and bridging arylborylene complexes (**62**) and (**63**) has also recently been reported (Scheme 12).[141,142]

5.2 Cyclopentadienylboranes

The attachment of boryl groups to cyclopentadiene, indene, and fluorene has attracted much interest over the past decade owing to their utility as precursors to borylated transition-metal complexes, most notably those of group 4. The preparation of cyclopentadienylboranes from organolithium, Grignard, or organotin precursors with boron halides is well established. Cyclopentadienylboranes exist as three constitutional isomers, which can interconvert through sigmatropic rearrangements. Upon preparation at low temperature, the allylic isomer (**64**) is obtained initially. This isomer is fluxional as a result of fast sigmatropic migration of the BR_2 group if alkyl substituents are attached to boron. Upon warming to room temperature a mixture of the thermodynamically favored vinylic boranes (**65**) and (**66**) is formed via a [1,5] sigmatropic hydrogen shift.[143] The deprotonation of cyclopentadienylboranes was studied with the aim of developing convenient precursors for transition-metal complexes. Intriguingly, Herberich found that not only derivatives that are stabilized with amino groups on boron, but also those containing alkyl substituents are readily deprotonated if bulky amides such as LiTMP or cyclopentadienides MCp (M = Li, Na) are used as the

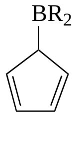


(60) X = H
(61) X = F

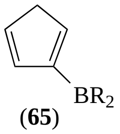


(**62**) (**63**)

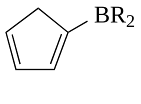
Scheme 12



(**64**)

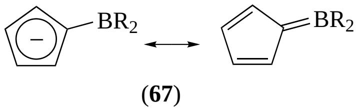


(**65**)



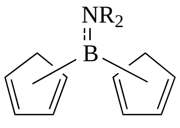
(**66**)

base.[143] The formation of the borylcyclopentadienides (**67**) was confirmed by X-ray crystallography. The crystal structures reveal a strong π-interaction between the Cp ring and the boron atom if alkyl groups are attached to boron. Borylindenides and borylfluorenides were prepared through similar routes.[144,145]

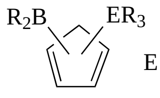


(**67**)

In many cases, deprotonation of the cyclopentadienylboranes is not necessary in order to form transition-metal complexes. For example, a large variety of bis(cyclopentadienyl)aminoboranes $Cp_2B(NRR')$ (**68**) and related compounds containing indenyl and fluorenyl groups were reacted directly with group 4 amides to give group 4 *ansa*-metallocene complexes.[146] Moreover, silylated and stannylated cyclopentadienylboranes (**69**) serve as efficient reagents in reactions with transition-metal halides.[147–149]



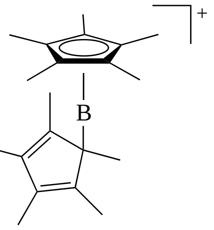
(**68**)



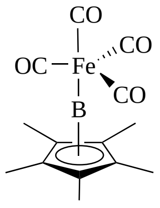
E = Si, Sn

(**69**)

It is interesting to note that boron may also be π-bonded to cyclopentadienyl groups. The decamethylborocenium cation $[Cp^*_2B]^+$ $[AlCl_4]^-$ (**70**) was studied by X-ray crystallography.[150] Compound (**70**) features one η^5-bonded and one η^1-bonded Cp* ring, both of which are essentially planar within the experimental error. The latter is localized and shows a strong bond alternation with average C_α–C_β and C_β–C_β bond distances of 1.339(5) Å and 1.476(6) Å, respectively. The different geometry in comparison to the ferrocene-like structure of the isovalent decamethylaluminocenium cation ($Cp^*_2Al^+$) was attributed to the higher electronegativity of boron and a stronger and more covalent B–C versus the Al–C σ-bond. A related η^5-bonded organoboron transition-metal complex (**71**) was obtained from reaction of $C_5Me_5BCl_2$ with $K_2[Fe(CO)_4]$.[151]



(**70**)

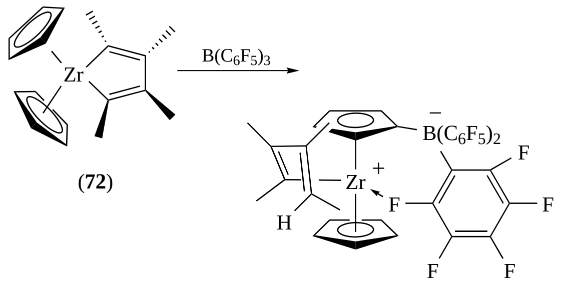


(**71**)

Transition-Metal Complexes of Cyclopentadienylboranes. The rich coordination chemistry of boryl and borate substituted cyclopentadienyl ligands has very recently been reviewed.[69] Group 4 and group 8 complexes have over the years been studied most thoroughly and selected examples of their chemistry and applications will be shown. The interested reader is referred to the review by Aldridge for a more detailed coverage that also includes various complexes of groups 5–7 and group 9.[69]

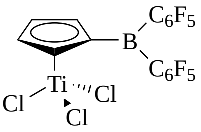
1. **Group 4 Complexes**. Borylated group 4 complexes have been primarily investigated with regard to their utility as single component olefin polymerization catalysts. The attachment of pendant boryl functionalities was envisioned to obviate the need for external Lewis acid activation (see Section 7.3.3).[152] There are only a few cases of direct borylation of group 4

metallocenes; one example is the reaction of $B(C_6F_5)_3$ with the zirconacycle (**72**) that led to attachment of the boryl group to the Cp ring under formation of a betaine complex (**73**; equation 35).[153] While many other betaines have been reported to form through similar reaction routes, in most cases the borate moiety is not directly attached to the Cp ring.[154–156]

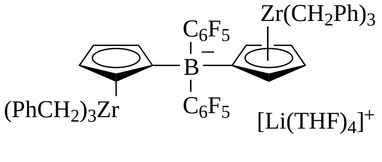


(**72**) (**73**) (35)

A more common method for the synthesis of ring-borylated cyclopentadienyl complexes takes advantage of the availability of cyclopentadienylboranes and related ligand precursors described above. This route has been pioneered by Jutzi and Seuferth, who prepared a series of half-sandwich complexes $(C_5H_3RBX_2)TiCl_3$ by dehalosilylation of $(C_5H_3RBX_2)SiMe_3$ (R=H, Me; X=Cl, Br, OEt, Me). Through similar methods, a number of cyclopentadienyl, indenyl, and fluorenyl complexes containing highly Lewis-acidic $B(C_6F_5)_2$ groups (**74**) as well as compounds with borate moieties (**75**) have been synthesized and studied as 'self-activating' single component olefin polymerization catalysts.[157] Several mono- and diborylated zirconocenes $(R_2BC_5H_4)(C_5H_5)ZrCl_2$ and $(R_2BC_5H_4)_2ZrCl_2$ (R=Me, Et, OEt, C_6F_5) have also been reported.[158]

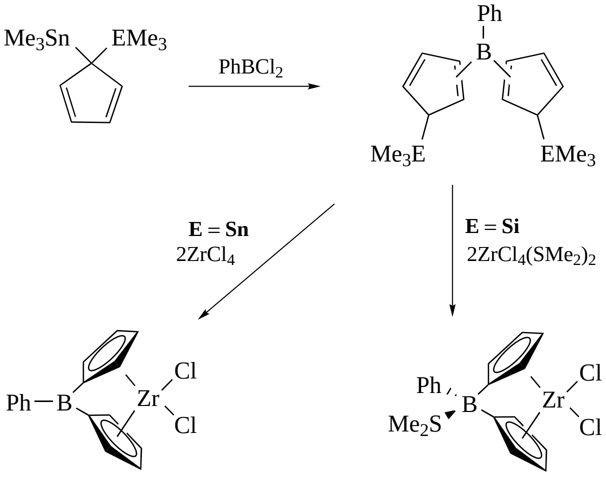


(**74**)



(**75**)

A structurally intriguing alternative design involves the incorporation of the boron center into the bridge of *ansa*-metallocenes.[146,159] First efforts toward this end have been reported independently by Rufanov and Shapiro (Scheme 13).[149,160] Both groups took advantage of the high selectivity of silicon–and tin–zirconium exchange reactions, thus avoiding the need to deprotonate the highly reactive bis(cyclopentadienyl)borane intermediate. Related boron-bridged indenyl complexes have been prepared through similar routes.[148,161] The boron-bridged zirconocene (**76**) has been characterized by NMR spectroscopy, and formation of the Lewis base complex (**77**) that contains

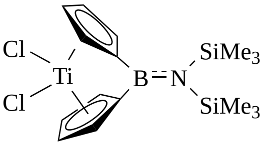


(**76**) (**77**)

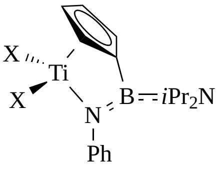
Scheme 13

a tetracoordinate boron center in the bridge has been confirmed by X-ray crystallography. The donor Me_2S is readily replaced by other ligands such as PMe_3. Moreover, (**77**) may be converted into borato-bridged compounds through treatment with organolithium or organoaluminum reagents.[162,163]

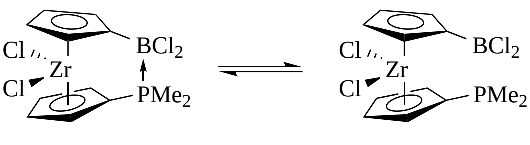
Boron-bridged titanocene and zirconocene complexes such as (**78**), in which an amino group stabilizes the boron center via boron–nitrogen π bonding are conveniently prepared through a one pot procedure starting from aminodihaloboranes.[146] Intriguingly, this approach also provides facile access to boron-bridged constrained geometry complexes (**79**).[146,164] Finally, the *ansa*-zirconocene (**80**), which operates based on the reversibility of donor–acceptor interactions, adopts a rigid structure in the bridged form, but is flexible in the open-chain form.[165] This type of conformational switch is of much interest for the development of 'smart' Ziegler Natta-type catalysts that produce polyolefins of well-defined architecture.



(**78**)

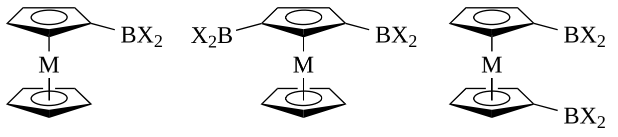


(**79**)

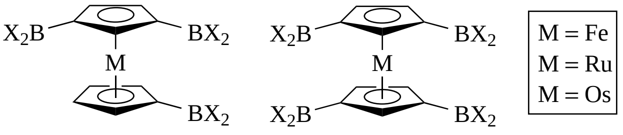


(**80**)

2. **Group 8 Complexes**. Ferrocenylboranes (**81–85**; M=Fe; X=F, Cl, Br, I, Me, Ph, C_6F_5, Mes, Fc, OR, NR_2) are the most thoroughly studied borylated metallocenes. Their synthesis via direct borylation of ferrocene has been extensively investigated since the original discovery by Siebert.[166–169] Depending on the reaction conditions mono-, di-, tri-, and tetraborylated ferrocenes form. The ferrocenyboranes (**81**), (**83**), and (**85**) were readily isolated, while species (**82**) and (**84**) were only spectroscopically confirmed as minor components in the product mixture. Multiborylated ruthenocenes and osmocenes were synthesized through direct borylation, and their structural features were compared with those of ferrocenylboranes.[167,169]



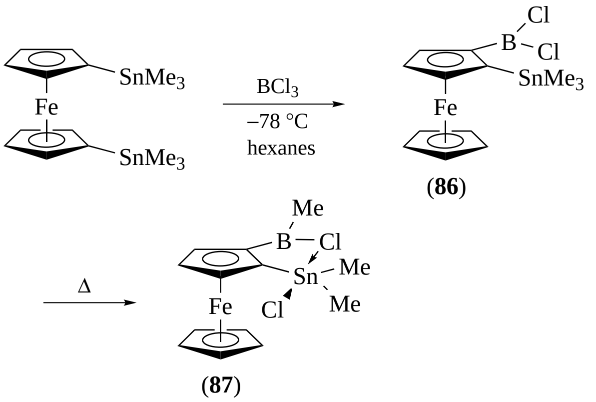
(**81**) (**82**) (**83**)



(**84**) (**85**)

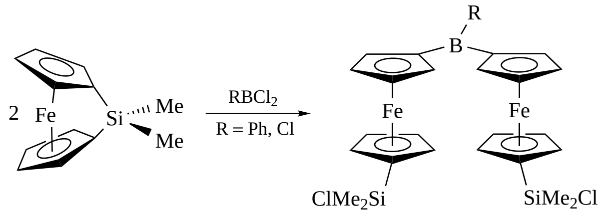
Metalated ferrocenes also serve as convenient precursors to ferrocenylboranes. Lithiated ferrocenes have been utilized for the preparation of ferrocenylboronates $FcB(OR)_2$ and 1,1′-fc$(B(OR)_2)_2$ and are especially suitable in the presence of *ortho*-directing donor-substituents.[69] The borylation of disilylated ferrocenes with excess BCl_3 on the other hand was reported to yield varying amounts of 1,3-diborylated product (**82**; M = Fe, X = Cl) in addition to the 1,1′-diborylated species (**83**; M = Fe, X = Cl).[170] In contrast, when 1,1′-distannylated ferrocenes were treated with equimolar amounts of boron halides, 1-stannyl-2-borylferrocenes (**86**) were formed as the major product rather than the expected 1-stannyl-1′-borylferrocenes (Scheme 14).[171] The 1-stannyl-2-borylferrocenes thus obtained underwent further thermal rearrangement to give heteronuclear bidentate Lewis acids (**87**). Interestingly, the boron-bound chloride substituent in (**87**) forms a bridge to the tin center, which consequently adopts an pseudotrigonal bipyramidal geometry as confirmed by X-ray crystallography and multinuclear NMR spectroscopy.

While only trace amounts of 1,1′-disubstituted products were observed in reactions of boron halides with 1,1′-distannylferrocenes, ring-opening addition reactions of boron halides with strained silicon- and tin-bridged [1]ferrocenophanes yielded 1-silyl-1′-boryl- and 1-stannyl-1′-borylferrocenes, respectively, in very high yield and under mild conditions.[30] This ring-opening reaction was exploited for the preparation of diferrocenylboranes (**88**; equation 36)



Scheme 14

and related multinuclear ferrocenyl assemblies as well as for the incorporation of ferrocenylborane units into polymer structures.



(**88**)

(36)

The structural features and spectroscopic properties of ferrocenylboranes are highly intriguing, especially the interaction of the electron-rich iron atom with strongly Lewis-acidic boron-substituents, which is evident from a tilting of the BX_2 group out of the Cp plane toward the iron center (Figure 2). The bending of the individual boryl groups has been

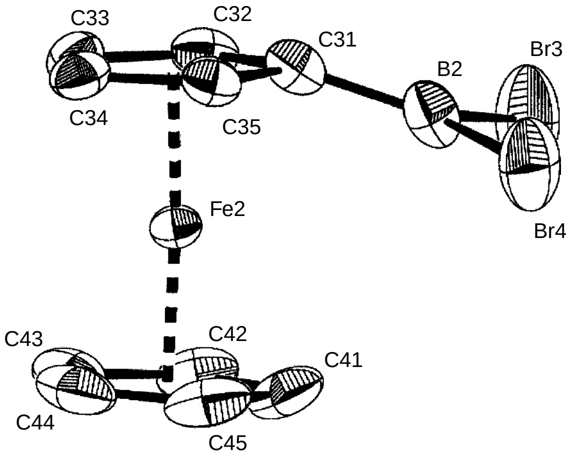


Figure 2 X-ray structure of $FcBBr_2$. (Reprinted with permission from Ref. 172. © 1996 American Chemical Society)

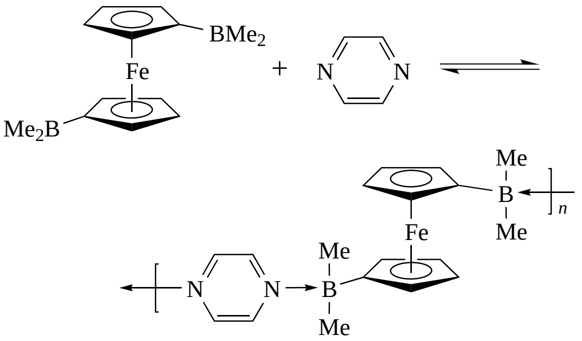
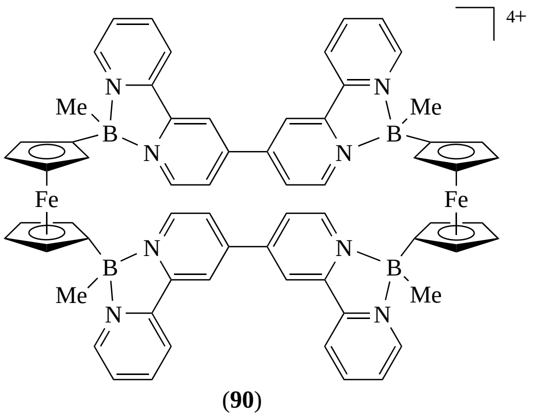
shown by X-ray crystallography to decrease with increasing number of boryl groups.[167,169] Thus, the degree of iron–boron interaction correlates with the number of Lewis-acidic boryl groups attached to the Cp rings; this conclusion was further supported by DFT calculations.[172] The interactions between the metal center and the boryl group increase in the order Fe < Ru < Os.

Piers investigated ferrocenylboranes containing pentafluorophenyl substituents as potential cocatalysts in Ziegler–Natta polymerization.[173,174] The bifunctional borane (**83**) (M = Fe, X = C_6F_5) was found to effect methide abstraction from Cp_2ZrMe_2 under mild conditions. However, significantly reduced polymerization activity was observed with the monoborylated species (**81**) (M = Fe, X = C_6F_5). This effect was rationalized by a stronger degree of interaction with the electron-rich iron center, which lowers the Lewis acidity of the boron center.

Borylated ferrocenes have been exploited by Wagner as building blocks for the assembly of macrocycles and coordination polymers (Scheme 15).[175] Treatment of the diborylated ferrocene 1,1′-fc$(BMe_2)_2$ with the bifunctional aromatic amines pyrazine and 4,4′-bipyridine, respectively, led to spontaneous and reversible formation of (**89**) and related ferrocenylborane polymers.[176,177] The polymeric nature of these materials in the solid state has been confirmed in some cases by single-crystal X-ray crystallography and in others by powder diffraction studies.[178] However, in solution, equilibration and partial dissociation occurs at elevated temperature. Intriguingly, the polymers are intensely colored as a result of charge transfer interactions between the electron-rich iron center and the electron-poor borylated heterocycles.[178] A number of related macrocycles such as (**90**) have been reported.

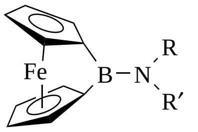


(**89**)

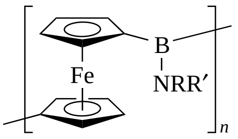


(**90**)

Scheme 15 Coordination polymers and macrocycles from ferrocenylboranes

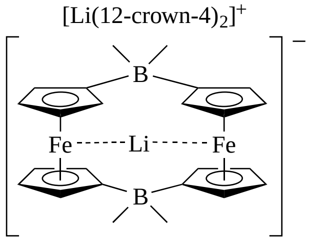


(**91**)

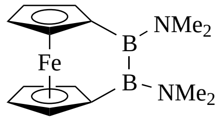


(**92**)

The first boron-bridged [1]ferrocenophane (**91**) was discovered by Manners and Braunschweig.[179,180] This highly strained organoborane shows a tilt-angle between the two Cp rings of 35.2°, the largest reported thus far for a [1]ferrocenophane. As a result of the strain energy, the boracycle (**91**) readily underwent ring-opening reactions, and low–molecular weight polymer accompanied by cyclic oligomers (**92**) (n = 2,3) formed upon thermolysis at 180–200 °C. The related diborata[1.1]ferrocenophane (**93**) was obtained by Wagner through a different route involving treatment of dilithioferrocene with the diborylated ferrocene 1,1′-$(fcBMe_2)_2$ in the presence of 12-crown-4.[181] The diborate (**93**) tightly binds one lithium counterion in the ferrocenophane cavity. Electrochemical studies suggest that the lithium ion is only released after oxidation of the ferrocenophane.

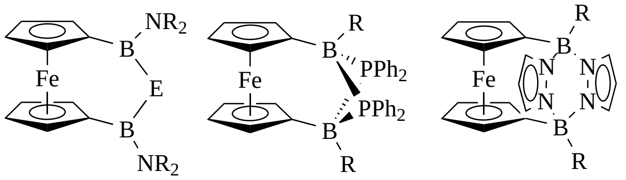


(**93**)



(**94**)

The first dibora[2]ferrocenophane (**94**) was prepared from 1,1′-dilithioferrocene and 1,2-dichlorobis(dimethylamino)diborane. A dynamic process due to motion of the cyclopentadienyl rings between staggered and eclipsed conformations was revealed by low-temperature NMR spectroscopy.[182] A number of 1,3-dibora[3]ferrocenophanes with B–E–B bridges (**95**; E=O, S, Se, Te, NR) were reported.[183] Moreover, Wagner used diborylated ferrocenes for the synthesis of doubly bridged switchable *ansa*-metallocenes (**96**) and (**97**), in which the bridges are created and



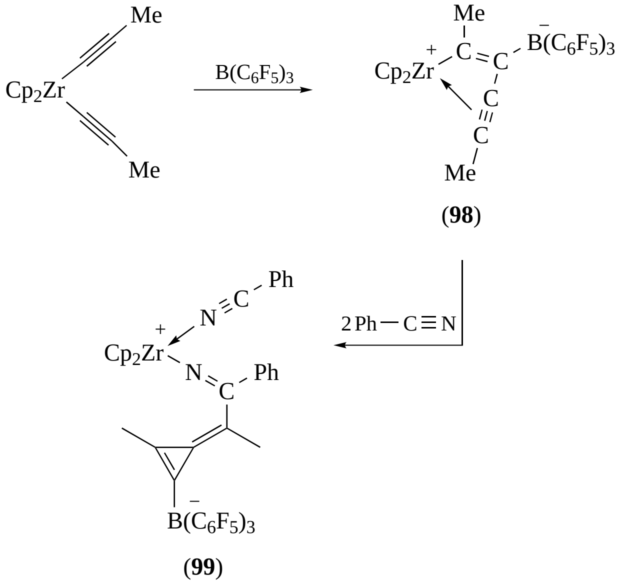
(95) (96) (97)

reopened via reversible formation of donor–acceptor bonds.[184–187]

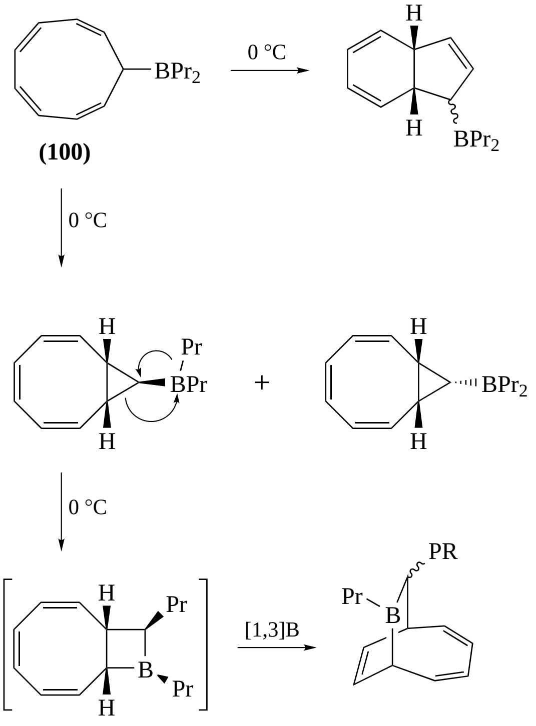
5.3 Boron Attached to Other Unsaturated Cyclic Compounds

Boron substituents have been attached to a variety of other unsaturated rings; some selected examples are summarized herein. Cyclopropenyliumborates (**99**) and related zwitterionic species were prepared by Erker (Scheme 16).[188] These compounds are believed to form through initial abstraction of an alkynyl ligand from $Cp_2Zr(alkynyl)_2$ followed by insertion of the borate moiety of (**98**) into the remaining Zr–C(alkynyl) bond. Subsequent rearrangement leads to a three-membered ring species that is trapped by nitriles or isonitriles yielding (**99**).

Borylated derivatives of the larger cycles cycloheptatriene, cyclooctatetraene, and cyclononatetraene have been studied with regard to their interesting fluxional behavior and tendency to rearrange to a variety of other cyclic species.[189,190] For instance, cyclononatetraenylborane (**100**) was obtained through reaction of cyclononatetraenyl lithium with Pr_2BCl at −35 °C.[191] A combination of dynamic NMR techniques and *ab initio* calculations showed that



Scheme 16

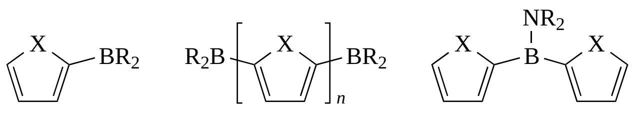


Scheme 17

[1,3]-dialkylboryl shifts are facile and slightly favored over [1,2]-shifts for (**100**).[190] At 0 °C a number of rearrangement reactions take place leading to various other ring systems (Scheme 17).

5.4 Boron Attached to Heterocyclic Arenes

The formation of borylated heterocyclic compounds has attracted much interest with regard to their use as starting materials for cross-coupling reactions, the possible formation of interesting macrocyclic species, and their applications in optoelectronic materials. Several synthetic routes are available for the borylation of the five-membered heterocycles thiophene, furan, pyrrole, and related compounds (**101–103**;



(**101**) (**102**) (**103**)

X = S, O, NR). Lithium–, silicon–, or tin–boron exchange provide facile access to the desired borylated species. On the other hand siloles and stannoles (X = Si, Sn) with organoboron substituents in the 3-position are conveniently prepared via organoboration reactions.[52] Another new

approach involves aromatic C–H activation as described in Section 2.3.

If the heterocycle contains a strongly basic site and a Lewis-acidic boryl group is attached, dimerization or oligomerization through donor–acceptor bonding occurs (see also the formation of ferrocene macrocycles described in Section 5.2). Thus, 2-diethylborylpyridine exists as a dimer (**104**), whereas 3-diethylpyridine adopts a tetrameric structure (**105**).[192,193] An isomeric species (**106**), which formally contains a borate anion and a boronium cation center was also reported.[194] Similar isomeric structures were discovered in the case of imidazaboles (**107**) and (**108**).[195,196] Diborylated bipyridine derivatives (**109**; R = NMe_2, 2-thienyl) were also studied. While amino substituents stabilize a monomeric structure through π bonding to boron, the thienyl derivative (**109**; R=Th) is believed to adopt an oligomeric structure.[197]

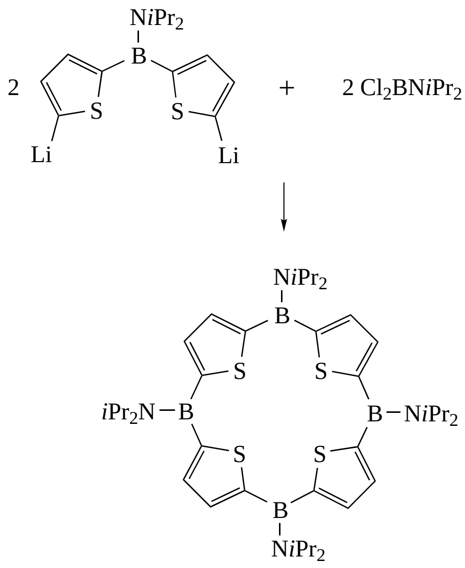
(**109**)

Corriu, Douglas, and Siebert reported the synthesis and structure of the tetraboratetrathiaporphyrinogens (**110**)[198,199] and of a number of related diboraporphyrinogens.[200] The macrocycles were obtained in good yield by treatment of dilithiated dithienylboranes with haloboranes Cl_2BNR_2 (Scheme 18). Signs of ring delocalization were not observed for (**110**) since the boron atoms are stabilized by π interaction with the amino groups. The macrocycle is thus colorless and the ring system is nonplanar as shown by X-ray crystallography. A number of other macrocycles in which the boron–carbon bonds are not an integral part of the cyclic structure were reported.[201]



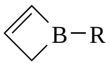
(**110**)

Scheme 18

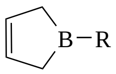
6 BORON AS PART OF UNSATURATED ORGANIC RINGS

The incorporation of boron into unsaturated rings has attracted much attention. Five-membered boroles (**114**) and six-membered boratabenzenes (**115**) are among the most prominent and most thoroughly studied systems containing one boron atom as part of the ring.[102,103] Related benzannulated systems such as borafluorene and boraanthracene have also been thoroughly investigated. Other fairly common organoboron rings of smaller and larger ring sizes are the borirenes (**111**), the boracyclobutenes (**112**), the boracyclopentenes (**113**), and the seven-membered borepin rings (**116**). Especially intriguing is the question of whether significant interactions exist between boron and the organic π-systems. The presence of such π-overlap in turn has implications on the aromatic or antiaromatic nature of these species.[120]

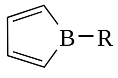
(**111**)



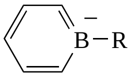
(**112**)



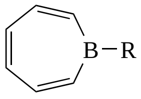
(**113**)



(**114**)

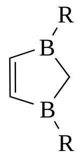


(**115**)

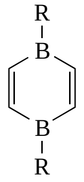


(**116**)

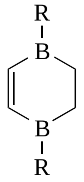
Among organoboron rings with multiple boron centers the five-membered (**117**) and six-membered diboracycles (**118** and **119**) and related benzannulated compounds are commonly studied systems, and a variety of other di- and triboracycles have also been developed.[102] These unsaturated rings have been investigated extensively as ligands to transition metals, which has led for example to the development of various multidecker sandwich complexes.[101,103] Many other cyclic organoboranes containing additional heteroatoms other than boron and carbon (i.e. N, O, S, etc.) and systems with B–B bonds are also known, but will not be covered here. In the following sections some recent developments in the chemistry and applications of borole (**114**), boratabenzene (**115**), and borepin (**116**) species will be highlighted.



(**117**)



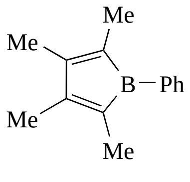
(**118**)



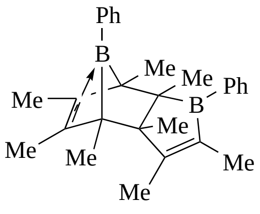
(**119**)

6.1 Boroles and Related Five-membered Boracycles

While the chemistry of borole complexes is well established, free 1H-boroles are highly reactive 4-π-electron systems and only a few sterically protected and benzannulated derivatives have been isolated.[102,103,120] The perphenylated species C_4Ph_4BPh is conveniently prepared from the stannacycle $C_4Ph_4SnMe_2$ and $PhBCl_2$. Preparation of the borole C_4Me_4BPh with the smaller methyl substituents attached to the ring was attempted through reaction of the zirconacycle $C_4Me_4ZrCp_2$ with $PhBCl_2$. However, the Diels–Alder dimer (**121**) rather than the borole (**120**) was obtained.[120] Diels–Alder reactions of boroles with olefins and acetylenes are very common. The high reactivity for Diels–Alder chemistry is attributed to a relatively high-energy HOMO and low-energy LUMO for the borole ring. Borole-amine adducts are more stable and may even be obtained through degradation of certain borole transition-metal complexes.[103] The unusual electronic structure of boroles has been studied theoretically.[202]

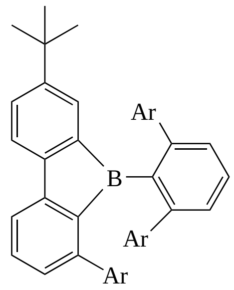


(**120**)

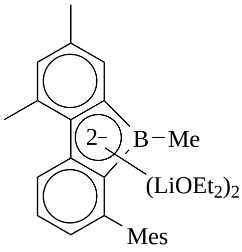


(**121**)

Although 9-borafluorenes may be regarded as benzannulated borole derivatives, their chemistry and physical properties are quite different from those of C_4Ph_4BPh. A convenient route to 9-borafluorenes involves reaction of 2,2′-dimercurated biphenyl with boron halides.[102] The sterically encumbered 9-borafluorene (**122**; Ar = 4-t-BuC_6H_4) was recently synthesized by reaction of 2,6-(4-t-$BuC_6H_4)_2C_6H_3Li$ with the borane source $H_2BCl(Me_2S)$.[203,204] This borafluorene shows bright yellow luminescence, but addition of pyridine leads to quenching of the fluorescence.[203] In contrast, the tetraphenylborole is blue-colored with $\lambda_{max} = 570$ nm and forms a light yellow pyridine complex.[120] The pyridine complex of (**122**) was studied by single-crystal X-ray crystallography. A long boron–nitrogen distance of 1.638(4) Å in comparison to other organoboron–pyridine complexes suggests formation of a weak adduct. Indeed, the colorless complex partially dissociates in hydrocarbon solvents to give bright yellow fluorescent solutions. Yamaguchi and Tamao exploited the luminescent behavior of 9-borafluorenes for the design of a fluorescent fluoride sensor.[205] A perfluorinated analog has been studied as an activator for olefin polymerization.[206]



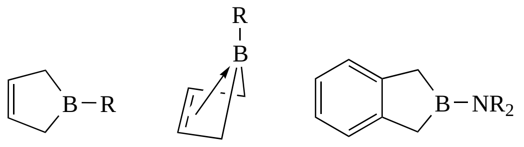
(**122**)



(**123**)

The 9-Borafluorenide dianion (**123**) was obtained upon reduction of the bulky borane $2,6\text{-}Mes_2C_6H_3BX_2$.[207] Formation of the borole ring is believed to occur via initial formation of a monovalent boranediyl species $2,6\text{-}Mes_2C_6H_3B$ that subsequently undergoes an intramolecular insertion into one of the C–C bonds in *ortho*-position of the phenyl group. A similar 9-boratafluorene was generated by reduction of (**122**) with lithium powder.[203,204]

2,5-Dihydro-1H-boroles (3-borolenes) serve commonly as precursors to borole complexes.[103,208] The 2,5-dihydro-1H-boroles either display a classical structure with a planar ring (**124**) or adopt a nonclassical structure with a folded ring skeleton and an interaction between the empty p_z orbital at boron and the π orbital of the olefinic double bond (**125**). Theoretical calculations on the parent compound C_4H_6BH show that the two structures are very close in energy with a difference of less than 1 kcal mol^{-1}.[209] Generally π-donor substituents such as amino and phenyl groups on boron stabilize the classical structure.[210] 2-Boraindans (**126**) and a number of other bicyclic systems have been reported.[211]



(**124**) (**125**) (**126**)

Treatment of 3-borolenes or 2-boraindans with bulky lithium amides yields the dilithiated aromatic borolide dianions, which are applicable as ligand precursors for transition-metal complexes. Many borole complexes including a number of unusual multidecker sandwich complexes and mixed-metal clusters have been described.[102,103,212] An unexpected new entry into the synthesis of borole complexes has been recently discovered. Bochmann found that attack of $B(C_6F_5)_3$ at a zirconium bound diene leads to a pentafluorophenylborole complex through successive C–H activation steps.[213]

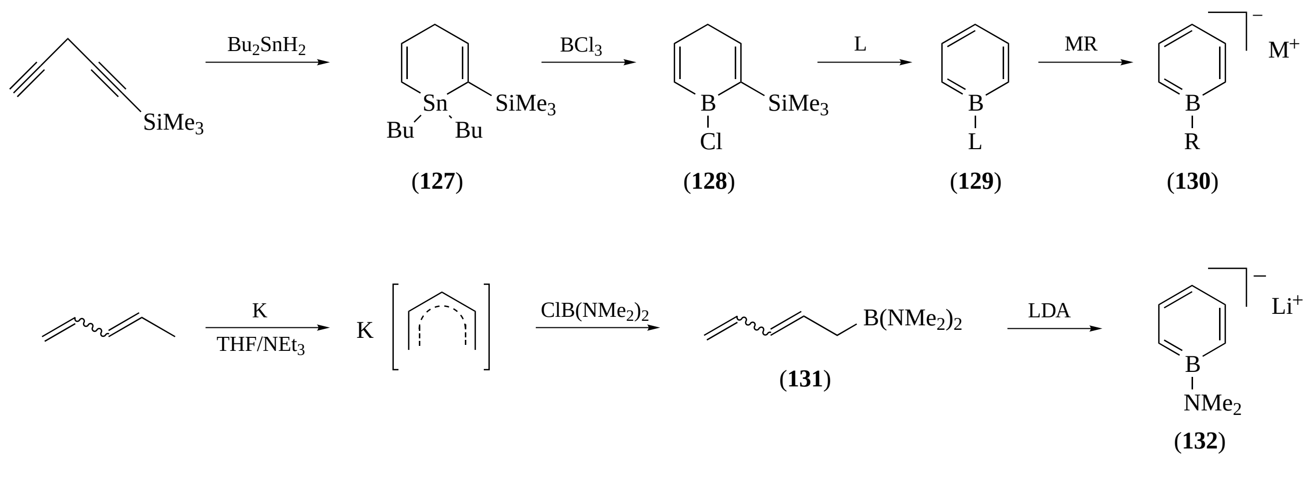
6.2 Borabenzene and Boratabenzene Complexes

Boratabenzenes represent a second important class of unsaturated boracycles.[214] While the dicoordinate borabenzene itself has not yet been reported, many Lewis base adducts, boratabenzene salts, and metal complexes are known. Boratabenzenes are six π-electron aromatic anions that resemble cyclopentadienides. For example, *N*,*N*-diisopropyl-1-amino-boracyclohexadiene shows an acidity in DMSO which is similar to that of cyclopentadiene.[215] The chemistry of boratabenzene ligands dates back to work by Herberich and Ashe in the early 1970s, which has been reviewed.[102,103] However, many new achievements have been reported over the last decade and will be discussed in the following sections.

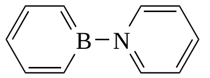
Fu recently developed a convenient general access to borabenzene adducts and boratabenzene ligands that is based on a combination of earlier work by Ashe and Paetzold (Scheme 19).[216,217] Hydrostannation of the commercially available 1-trimethylsilyl-1,4-pentadiyne followed by treatment of stannacycle (**127**) with BCl_3 selectively gives (**128**). This silylated boracycle reacts with any of a variety of Lewis bases L to produce neutral borabenzene-ligand adducts (**129**). Amines, phosphines, isonitriles, and even stable carbenes such as 1,2,3,5-tetramethylimidazol-2-ylidene readily form adducts with borabenzene derivatives.[218] The trimethylphosphine complex (**129**; L = PMe_3) serves as a convenient storage form. Subsequent nucleophilic displacement of the Lewis base PMe_3 provides access to a variety of boratabenzene species (**130**) including the parent compound 1-*H*-boratabenzene (**130**; R = H), which is isoelectronic to benzene.[216]

New convenient routes to aminoboratabenzenes from 1,3-pentadienes were developed by Herberich. Ring-closure of [bis(dialkylaminoboryl)]pentadienes (**131**) was accomplished with lithium amides, thereby generating the aminoboratabenzene (**132**) (Scheme 19).[27] Another route from dipotassium salts was also reported.[219] Thus a large number of borabenzene adducts and boratabenzene complexes including annulated boratanaphthalenes and borataanthracenes are readily available now.[214]

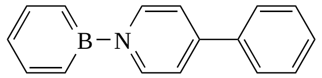
The borabenzene adducts themselves have attracted attention as heterocyclic conjugated π-systems that are isoelectronic to organic systems with extended delocalization. The first compound of this type, the borabenzene–pyridine complex (**133**), has already been reported in the 1980s. More recently, the terphenyl analog (**134**) and several other interesting adducts have been prepared.[220,221] Moreover, the intriguing diborabiphenyl complexes (**135**) and (**136**), which are isoelectronic to triphenylene and dibenzo[*g*,*p*]chrysene, have been studied by Piers.[222,223] Adducts (**135**) and (**136**) are intensely colored as a result of strong charge transfer bands and show two reversible reduction events according to cyclic voltammetry studies.



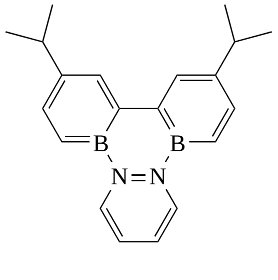
Scheme 19



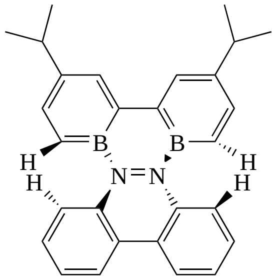
(**133**)



(**134**)

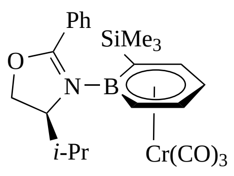


(**135**)

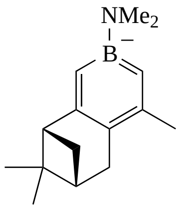


(**136**)

First examples of chiral boratabenzene complexes, which are of interest owing to potential applications as enantioselective catalysts, have recently been reported. The planar chiral chromium tricarbonyl complex (**137**) was obtained by adduct formation between borabenzene and an (S)-valinol-derived oxazoline ligand.[224] The $Cr(CO)_3$ fragment stereoselectively complexes with this borabenzene adduct. A different approach has been chosen by Herberich, who developed the chiral boratabenzene ligand (**138**), which is derived from α-pinene.[225,226]

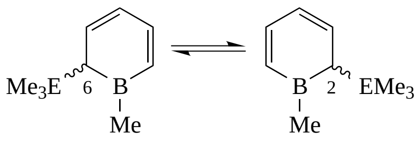


(**137**)



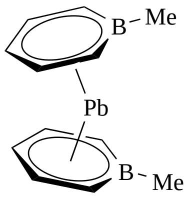
(**138**)

Several main group derivatives of boratabenzene have been synthesized through reaction of boratabenzene salts with the appropriate metal halides.[214] For example, treatment of $[C_5H_5BMe]Li$ with group 14 electrophiles Me_3EX (E = Si, Ge, Sn, Pb) led to η^1-bonded compounds (**139**) that are fluxional in solution. In contrast, reaction with divalent group 14 halides ECl_2 led to bent-sandwich structures such as the η^6-bonded complex (**140**).[227]



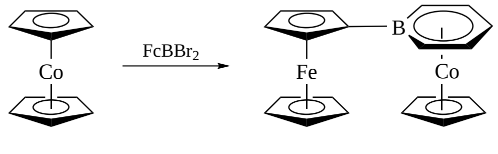
E = Si, Ge, Sn, Pb

(**139**)



(**140**)

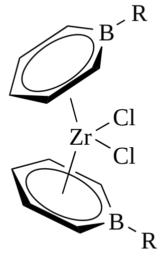
A large number of boratabenzene transition-metal complexes have been described. For instance, the multinuclear complex (**141**) has been obtained through the original Herberich route from cobaltocene with $FcBBr_2$ (equation 37).[228] Notably, a rhodium complex has recently been reported to be useful in C–H activation catalysis.[229]

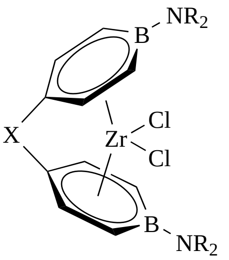


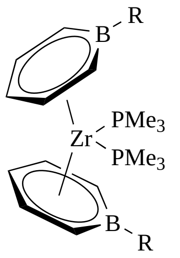
(37)

(**141**)

Strong interest in potential applications in olefin polymerization has led to a vigorous research effort aimed at the development of group 4 boratabenzene complexes.[214,230] The synthesis of the first group 4 complex, the bis(diisopropylaminoboratabenzene)zirconium dichloride (**142**; R = N*i*Pr_2), was reported by Bazan.[231] Complex (**142**) (R = NMe_2) was activated with methylaluminoxane (MAO) to produce ethylene polymerization catalysts with activities similar to those of Group 4 metallocenes. Interestingly, under similar conditions (**142**) (R = Ph) yielded predominantly 2-alkyl-1-alkenes,[232] while (**142**) (R = OEt) gave exclusively 1-alkenes.[233] The different behavior was related to a difference in the coordination chemistry of the ligands. Indeed, in the presence of amino groups η^5-coordination was observed by X-ray crystallography, while a η^6-bonding mode was found with boron substituents that do not act as π-donors to boron. The electronic nature of the boratabenzene ligand and the interaction of boron and zirconium thus critically influence the catalytic properties of these complexes.



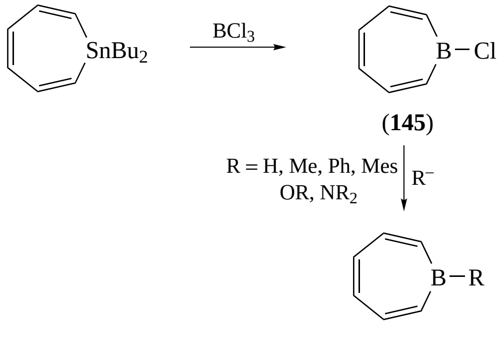




X = $-SiMe_2-$, $-CH_2CH_2-$

(**142**) (**143**) (**144**)

A variety of *ansa*-bridged complexes such as (**143**) resembling those of *ansa*-zirconocenes have also been reported.[234] Moreover, reduction of the zirconium complexes with *n*-BuLi in the presence of PMe_3 provides an entry point to Zr(II) complexes (**144**); their reactivity toward alkynes has been studied in detail.[235]



Scheme 20

6.3 Borepins

Although ring-annulated and highly substituted borepins have been known for some time, simple 1-substituted borepins have only been thoroughly studied over the past decade. The discovery of a facile synthetic route to 1-substituted borepins through tin−boron exchange has much opened up the chemistry of these 7-membered boracycles.[236] The chloro-substituted borepin (**145**) serves as a highly useful precursor to many other borepin derivatives via substitution reactions with nucleophiles (Scheme 20). In addition, several transition metal complexes of 1-borepins have been reported.[237]

Of particular interest is the degree of aromatic delocalization within these ring systems. It has been shown that significant delocalization occurs in the presence of halide and alkyl substituents on boron. Consequently, the 1-chloroborepin derivative (**145**) is perfectly planar as shown by X-ray crystallography. However, theoretical calculations demonstrate borepin to be much less aromatic than the isoelectronic tropylium ion.[238] Moreover, amino groups effectively compete with the 6p electron delocalization within the ring by forming a partial BN double bond. The barrier to rotation about the B–N bond of 1-(N-benzyl-N-methylamino)borepin was determined by NMR spectroscopy to be 18 kcal mol^{-1}.[239] DFT calculations suggest that steric hindrance in substituted borepins and attenuated aromatic character result in significant nonplanarity of the seven-membered ring.[240]

7 SELECTED APPLICATIONS OF ORGANOBORANES

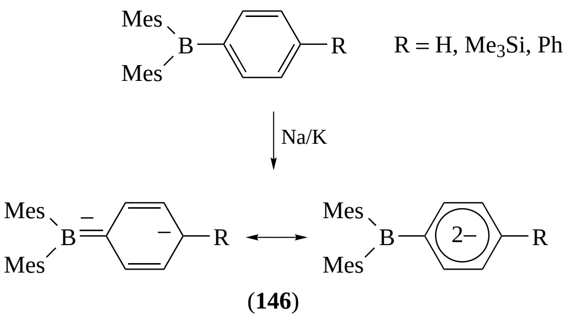
7.1 Organoboranes as Optical, Electronic and Device Materials

With its vacant p_z orbital, three-coordinate boron is inherently electron-deficient and acts as a strong π-acceptor.[241] In contrast to other strong π-acceptors such as the nitro group, however, three-coordinate boron is not generally inductively electron withdrawing. Importantly, it is the interaction between the vacant p_z orbital on boron and organic π systems that gives rise to conjugation and a certain degree of delocalization,[120] resulting in interesting linear and nonlinear optical properties of organoboranes (*see* ***Luminescence***).[111,241,242] The electro-optical properties and the rich (and in many cases reversible) reduction chemistry of organoboranes are exploited in applications as emission and electron conduction layers in devices such as organic light-emitting diodes (OLEDs).

The reduction of Ph_3B is known to result in a radical anion Ph_3B• that is in equilibrium with the dimeric species $[Ph_3B{-}BPh_3]^{2-}$. However, if bulky substituents as in Mes_3B are present and thus prevent attack of nucleophiles or dimerization, a blue-colored stable radical anion can readily be identified. While arylboranes are also known to form purple-colored dianions, the second reduction of simple triarylboranes is typically irreversible. In a recent study, Okada and Oda reported the formation of purple-colored solutions of dimesitylphenylborane dianions $[Mes_2BAr]^{2-}$ (**146**; Ar = Ph, 4-$Me_3SiC_6H_4$, biphenyl) upon extended reaction of Mes_2BAr with Na–K alloy in THF (Scheme 21). Formation of dianions was confirmed by multinuclear NMR spectroscopy.[243] While the bulky mesityl groups provide chemical stability to the dianions and thus prevent further chemical reactions, the presence of the unsubstituted phenyl group is believed to allow for effective π-interactions with the p-orbital on boron.

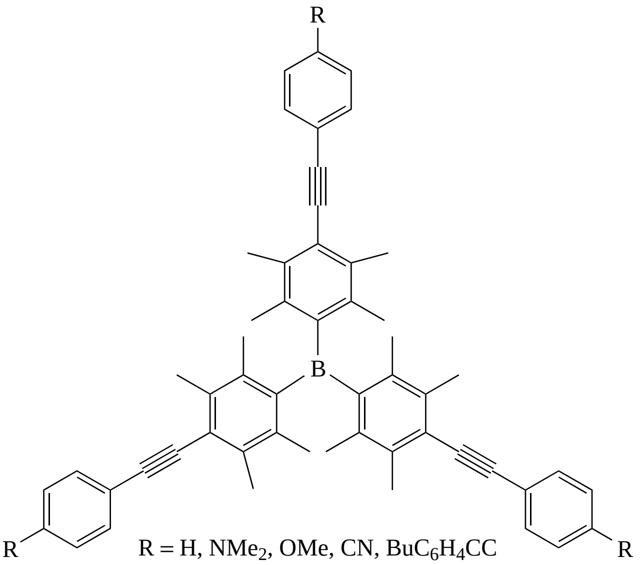
Norton recently showed that the perfluorinated analog $B(C_6F_5)_3$ is rapidly reduced with an equimolar amount of $Cp^*{}_2Co$ in THF solution at −50 °C to give a dark blue solution attributed to the radical anion $B(C_6F_5)_3^{\bullet -}$ (λ_{max} = 603 nm).[244] The radical anion has been detected by EPR spectroscopy, but decomposes at room temperature with a half-life of only about 10 min. The borate salt $[Cp^*{}_2Co]^+$ $[B(C_6F_5)_4]^-$ was identified as one of the decomposition products.

A family of amorphous molecular materials with divergently extended π-conjugation (**147**) was reported by Yamaguchi and Tamao.[25,245] Compounds (**147**) form stable amorphous glasses with high glass-transition temperatures, and are characterized by reversible cathodic reduction and relatively large HOMO−LUMO energy gaps. High-performance blue- and blue-violet-emitting organic electroluminescent



Scheme 21

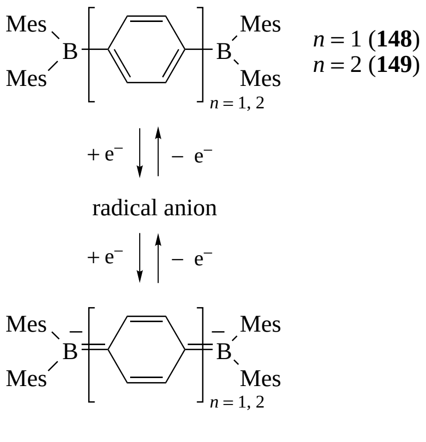
devices were developed using the boranes as hole blockers and various arylamines as emitters.[246]



(**147**)

Kaim reported on the UV/vis/near-IR spectroelectrochemistry of radical anions and dianions formed from bisborylated benzene (**148**) and biphenyl (**149**) (Scheme 22).[130] The negatively charged species exhibit intense long-wavelength absorptions in the visible or near-infrared region resembling the spectral features of the analogous isoelectronic triarylamine radical cations. The quinoidal resonance structures play an important role in the reduced species as confirmed by *ab initio* calculations.

Okada and Oda studied the electrochemical properties of the *meta*-substituted derivative 1,3-bis(dimesitylboryl)benzene (**150**) and the trifunctional species 1,3,5-tris(dimesitylboryl)benzene (1,3,5-$C_6H_3(BMes_2)_3$; (**151**)).[124] Interestingly,



Scheme 22

cyclic voltammetry in DMF (*N*,*N*-dimethylformamide) revealed a significantly more anodic reduction potential for (**150**) ($E_1 = -1.95$ V vs. SCE) and (**151**) ($E_1 = -1.98$ V vs. standard calomel electrode (SCE)) relative to that reported by Kaim for the reduction of the *para*-substituted isomer (**148**) with $E_1 = -1.55$ V and $E_2 = -2.25$ V versus SCE. Rajca further studied the electrochemical and preparative reduction of (**150**) (equation 38).[247] Cyclic voltammetry in THF indicated two reversible reduction waves at peak potentials $E_p = -2.02$ V and $E_p = -2.64$ V. By comparison with monofunctional arylboranes, the more anodic peak was attributed to formation of dianionic species. Preparative reduction with sodium metal in THF/2-MeTHF yielded the triplet diradical species (**152**) according to ESR spectroscopy results.

Reduction of the diborylated naphthalene derivative (**52**) was studied by Gabbaï, who found a reversible reduction wave at −1.81 V (vs. SCE) by cyclic voltammetry. Moreover, treatment of (**52**) with potassium in THF in the presence of 18-crown-6 led to formation of a dark purple EPR-active solution, the spectrum of which suggested coupling of the electron spin of the free radical with two boron centers (equation 39). The presence of an intramolecular one-electron σ-bond in (**153**) leads to a significant shortening of the boron–boron distance as suggested by DFT calculations.[248]

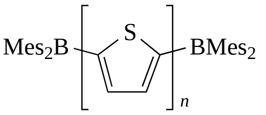
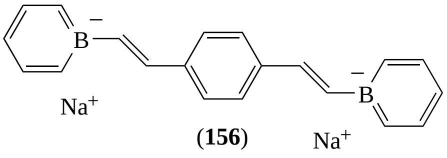
If oligothiophenes are used as the bridge between two $BMes_2$ units, amorphous luminescent materials (**154**) ($n = 2$) and (**155**) ($n = 3$) with relatively high glass-transition temperatures are obtained. Both compounds undergo two sequential reversible cathodic reductions, generating the radical anion and dianion species. The oligothiophene derivatives function not only as excellent electron-transporting materials but also as efficient blue emitters with the most intense fluorescence band at 440 and 488 nm for (**154**) and (**155**), respectively.[26,242] The bithiophene derivative (**154**) has been successfully incorporated as a blue emitter into an organic light-emitting device.[249]



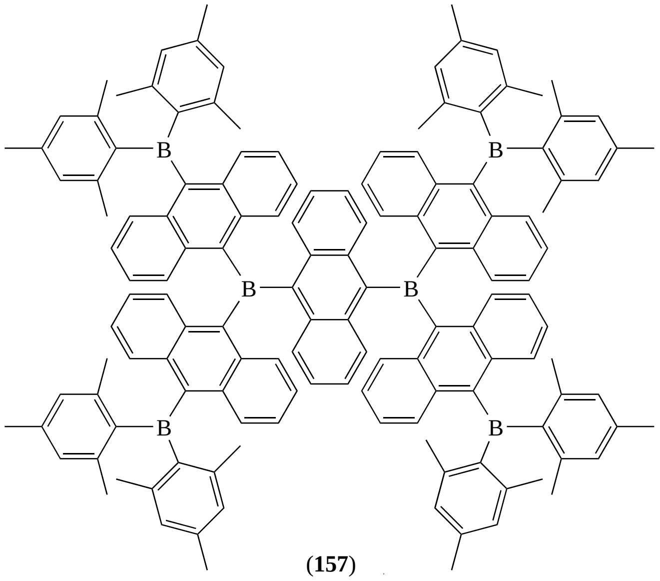
$n = 2$ (**154**)
$n = 3$ (**155**)

Bazan reported the synthesis, structure, and photophysical behavior of a number of boratastilbene derivatives, which are highly emissive in the presence of donor solvents or when crown ethers are added.[250] Extended conjugation in the bifunctional species (**156**) results in an absorption maximum at 396 nm, which is red-shifted by 55 nm relative to that of the monofunctional boratastilbene. The change in the absorption and emission spectra upon addition of dibenzo-18-crown-6 suggests a distinct effect of the counterions and of aggregation phenomena on the photophysical properties of these species.



(**156**)

A series of multifunctional anthrylboranes with up to six boron centers and divergently extended π-conjugation have been reported. Trianthrylborane itself is bright orange, whereas the extended system (**157**) is dark red colored.[25] This bathochromic shift was attributed to the more extended delocalization in the starbust oligomer (**157**). Two reversible reduction waves were found for the two different boron environments in (**157**). The anthrylboranes have also been studied as fluorescent fluoride sensors (see Section 7.2.1).



(**157**)

In an elegant synthetic approach, Chujo used the hydroboration of bifunctional alkynes with boranes RBH_2 (R = 2,4,6-trimethylphenyl, Mes) for the synthesis of

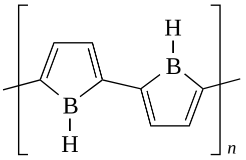
conjugated organoboron polymers (**158**), that are related to poly-p-phenylene vinylene (PPV) (Scheme 23).[251] Bulky mesityl or tripyl groups on boron prevent attack of nucleophiles on boron and thus provide good stability of these polymers. Interest in the incorporation of boron into the main chain of conjugated organic polymers is based on the expectation that extended delocalization may be observed in a polymer consisting of electron-deficient boron centers alternating with an organic π-system. Despite having relatively low molecular weight, the polymers are highly luminescent with especially large Stokes shifts for heteroaromatic polymers. An unusually large third-order nonlinear optical susceptibility was also observed. Moreover, recent electrical conductivity measurements on polymers with tripyl groups attached to boron and phenylene (or fluorenylene) bridges showed an increase in conductivity upon doping with triethylamine or iodine from less than 10^{-10} to ca. $10^{-8} - 10^{-6}$ S cm^{-1}.[252] Many other vinyl, alkynyl, and arylborane polymers, all of which show strong fluorescence, have been synthesized. For example, the polycondensation of lithiated diacetylenes with aryldimethoxyboranes was used to produce poly(ethynylene-phenylene-ethynylene-borane)s (**159**).[253] The fluorescent poly(p-phenyleneborane) polymers (**160**) were obtained

via polycondensation of aryldimethoxyboranes with a difunctional Grignard reagent that was prepared in situ.[254] Polymers (**160**) with molecular weights M_n of ca. 2000 to 3000 were obtained in high yields. The polymers show absorption maxima in the range of 359 to 367 nm and emit blue–green light upon excitation at 350 nm.

A computational study (DFT, modified B3P86 hybrid functional) on the electronic structure of polyborole (**161**) in comparison to polycyclopentadiene and related polymers containing N, O, Si, S, Se, Te, and P has been performed by Lagowski.[255] Polymer (**161**) was found to differ significantly from the other polymers in that it adopts a quinoid structure and shows a large electron affinity. Intriguingly, (**161**) was predicted to have a very small or no energy band gap, and thus exhibit metallic properties. Similar electronic properties were also predicted for poly(p-2,6-diboraphenylene).[256]



$n = 1,2,3$

(**161**)

Donor-bridge-acceptor systems (also called *push–pull* systems), in which a dimesitylboryl group acts as the acceptor that is separated from a donor group such as an amine, a phosphine, a ferrocene moiety, or other electron-rich groups through a π-conjugated bridge were studied with regard to their linear and nonlinear optical properties.[111] Some recent examples are shown in Figure 3. The fluorescence quantum yield in the *push–pull* systems (**162**) generally increases with increasing donating power of the group D. While typically only small shifts in the absorption spectra of (**162**) are observed as a function of solvent polarity (solvatochromism), a large dependence of the emission wavelength on the solvent polarity was found and attributed to a highly polar excited state. Highly efficient two-photon excited fluorescence (TPEF) was reported recently for the stilbene and styrylthiophene derivatives (**163**) and (**164**).[257]

The nonlinear optical properties of *push–pull* systems were shown to strongly depend on the nature of the bridge and the type of donor group. The first molecular hyperpolarizabilities (β) typically increase with increasing donor strength of D and increasing length of the bridge.[111] The hyperpolarizabilities were found to be significantly larger for the dithienyl-bridged species (**166**) than for related biphenyl systems (**165**).[258] This effect was attributed to stronger conjugation through the bithiophene bridge as a result of the greater planarity of the less sterically hindered conjugated system.

The thienylenephenylene-bridged species (**167**) was found to act as a bipolar radical formant that (1) allows formation of both stable cation and anion radicals, (2) shows intense

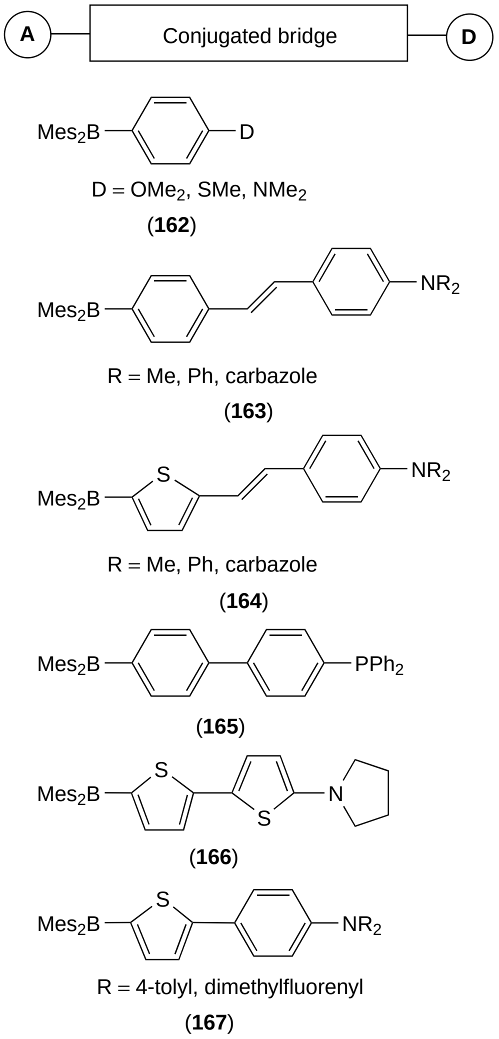


Figure 3 Selected recent examples of organoboron *push–pull* systems

fluorescent characteristics, and (3) has the capability to form stable amorphous glasses with high glass-transition temperature (T_g) and uniform thin films by vacuum deposition.[259] Compounds (**167**) were shown to function as excellent emitting materials for OLEDs. A related triarylamine with three dimesitylboryl groups was studied as a component of a photovoltaic cell.[260]

Tetracoordinate Boron. A number of tetracoordinate organoboron species that are photo- and electroluminescent, and thus of interest for device applications have been developed.[261,262] Characteristic of complexes (**168–170**) is the presence of chelating nitrogen ligands such as 8-hydroxyquinoline in (**168**). The quinolate complexes (**168**) were reported to show superior stability over more commonly used aluminum complexes.[261] Moreover, their photophysical properties were shown to be tunable through ligand variation.[263]

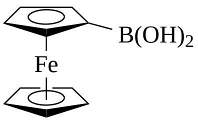
7.2 Organoboranes in Molecular Recognition

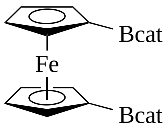
Boronic acids $RB(OH)_2$, boronic esters $RB(OR)_2$, and triorganoboranes R_3B have been studied extensively for the selective recognition of anions.[264–266] Moreover, arylboronic acids have proven highly useful for sensing of saccharides based on the facile formation of esters with diols,[267,268] thus providing an excellent alternative to more commonly employed synthetic molecular receptors based on hydrogen-bonding interactions.[267,268] Absorption and fluorescence spectroscopy, circular dichroism, and cyclic voltammetry have all been successfully used as detection methods for organoboron sensors.

7.2.1 Anion Binding

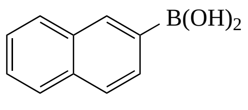
Boronic Acids and Boronate Esters. Ferrocenylboronic acid (**171**) has been studied as an electrochemical sensor for the recognition of anions. The compound shows excellent selectivity for fluoride over other anions with binding constants that are ca. 1000 times higher than for chloride and bromide.[269] Coordination of fluoride to the boron center results in an increase in electron density on ferrocene thereby facilitating oxidation of the iron center. Oxidation of ferrocene in turn leads to stabilization of the fluoride complex due to a decrease in electron density on the Lewis-acidic boron center. Coupling of this redox process with a dye allows for visual sensing of fluoride ions.[270] A similar effect has been reported for the related ferrocenyldiboronic ester (**172**), which in the presence of air is readily oxidized to a greenish colored ferrocenium species upon binding of fluoride. Thus, a direct optical method for fluoride detection based on the ferrocene/ferrocenium redox couple has been developed.[271] Simple aromatic boronic acids such as (**173**) on the other hand may serve as fluorescent PET (photoinduced electron transfer) sensors; the degree of fluorescence quenching in aqueous solution at pH 5.5 was shown to correspond to the amount of fluoride present.[272]



(**171**)

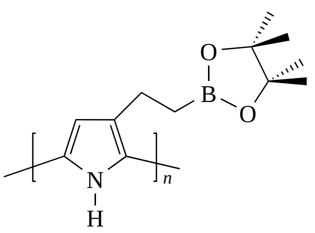


(**172**)

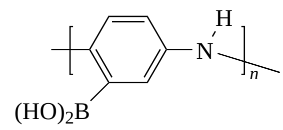


(**173**)

Using a different approach, the research groups of Fabre and Freund have synthesized boronate-functionalized conjugated polymers, which serve as electrochemical sensors. For example, a conjugated redox-active film of polypyrrole (**174**) was electrodeposited onto a platinum electrode from acetonitrile solution.[273] Addition of fluoride anions led to a new redox system that showed an anodic shift relative to polypyrrole itself, which was attributed to fluoride binding to the boronate group. A related poly(aniline boronic acid) (**175**) was also reported and studied for saccharide detection.[274]



(**174**)



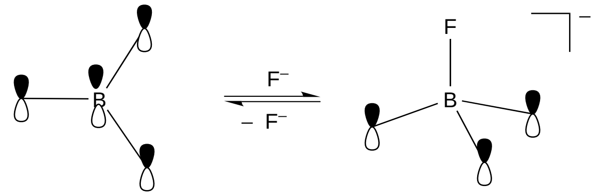
(**175**)

Triorganoboranes. As outlined above, overlap between the empty p-orbital on boron and an extended organic π-system can be exploited for the design and synthesis of photoluminescent organoboron materials. Interestingly, the coordination of a nucleophile to the boron center in such a system would be expected to lead to either quenching of the luminescence or a change in the fluorescence wavelength if the organic π-system is fluorescent itself.[242] This strategy is illustrated schematically in Figure 4 and has been extensively used by Yamaguchi and Tamao for the design of new fluorescent fluoride sensors based on triarylboranes such as anthrylboranes and 9-borafluorenes (**176**).[25,275]

An interesting example of an organoboron fluorescent sensor with metal binding sites has recently been reported by Wang.[276] The blue luminescent compounds (**177**) consist of three bipyridyl binding sites that are connected to one central three-coordinate arylborane via oligophenylene spacers. Binding of Zn(II) ions to these air-stable polypyridyl assemblies results in a slight red-shift of the emission maximum.

The suitability of conjugated main chain organoboron polymers for fluoride recognition was also investigated. Treatment of the organoboron polymer (**158**) (Ar = phenylene; Scheme 23) with a fluoride source was shown to lead to distinct changes in the emission spectra rendering this polymer a good candidate for fluoride sensing applications.[277]

An intriguing question is whether the use of bidentate Lewis acids may be advantageous for the selective recognition of anions. Early studies by Shriver, Katz, Koester, and Wrackmeyer show that a bidentate organoboron Lewis acid may coordinate a nucleophile in a bridging fashion as illustrated for Katz's hydride-sponge in Scheme 24. The relatively short distance of ca. 3 Å between the boron centers of 1,8-diborylated naphthalenes allows for effective coordination of nucleophiles in a reverse chelate fashion. Many other



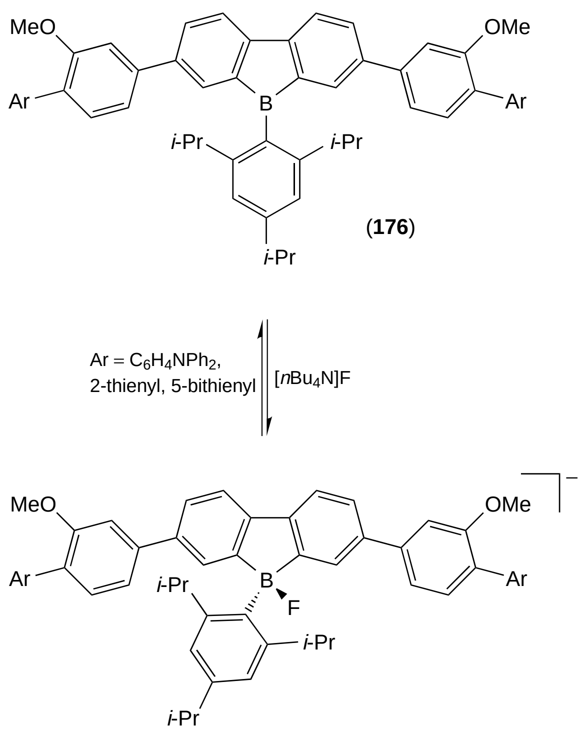


Figure 4 Fluoride sensing with luminescent triarylboranes

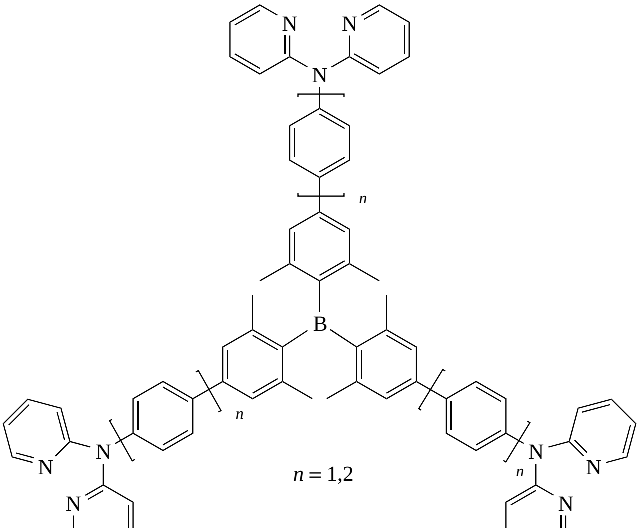
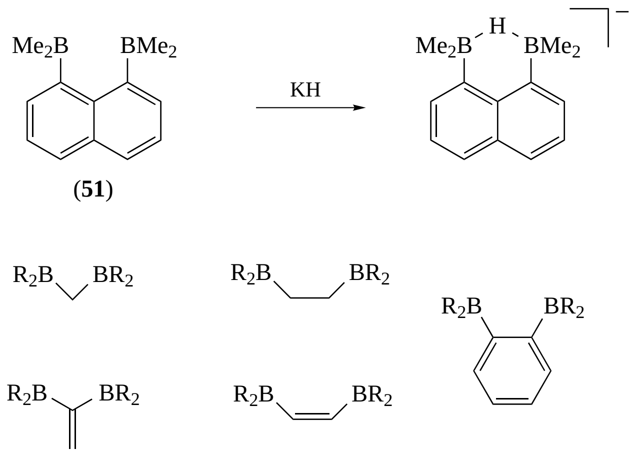


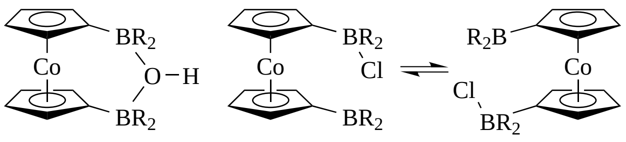
(177)



Scheme 24 Schematic representation of selected bidentate hosts for anion binding

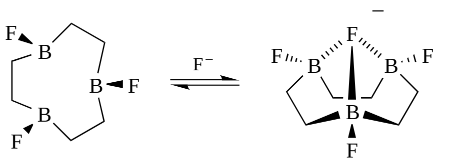
systems with aliphatic, olefinic, and aromatic backbones have been developed and their chemistry has been reviewed.[31,84,266]

The diborylated cobaltocenium species $[(CpBR_2)_2Co]^+$ (R = i-Pr) is an interesting example that illustrates the different binding modes encountered for bifunctional Lewis acids.[278,279] With hydroxy counterions, an oxygen-bridged complex (**178**), which represents an inverse chelate structure, was confirmed in the solid state and in solution (R = i-Pr, F). Salt-like structures on the other hand were observed with PF_6^- as the counterion and a zwitterionic 1:1 complex (**179**) formed upon reaction of the diborylated cobaltocene with hexachloroethane. Low-temperature NMR studies show that the chloride rapidly exchanges position between the two Lewis-acidic boron centers.



(**178**) (**179**)

Organoboron rings containing three or more boron centers may be viewed as inverse crown ethers. DFT calculations suggest that triboramacrocycle (**180**), in which the boron centers are connected via ethylene bridges, effectively coordinates halide, hydride and methide ions (equation 40).[280,281] Good selectivity for fluoride over other halides was predicted. Moreover, the binding energy was shown to further increase upon perfluorination of the backbone for all anions studied.



(40)

(**180**)

Finally, several perfluorinated bidentate organoboron Lewis acids have been developed very recently in a research effort fueled by potential applications in Ziegler–Natta olefin polymerization; they will be discussed in this context in Section 7.3.3.[282]

7.2.2 *Binding of Amines and Ketones to Bifunctional Lewis Acids*

The complexation of pyranone to 1,8-bis(dichloroboryl)-naphthalene has been investigated by Reilly and Oh.[283] NMR and IR spectroscopy suggest that pyranone simultaneously coordinates to both Lewis-acidic centers in solution to form complex (**181**). In the presence of excess pyranone, a 2:1 complex with one pyranone molecule attached to each boron center is formed (Scheme 25).

Nozaki and Takaya studied the binding of amines to bifunctional boranes. Interestingly, benzylamine binds strongly to the bifunctional Lewis acid (**182**) under exclusive formation of a 2:1 complex (**183**) as demonstrated by titration experiments. The failure to observe a 1:1 complex was explained by allosteric effects rendering the binding constant for the second amine K_2 much larger than K_1 for the initial binding process.[284] Similarly, the chiral bifunctional Lewis acid (**184**), prepared from phenylboronic acid and L-tartaric acid, selectively binds 1,6-diaminohexanes over 1,2-diaminoethane by using two boron centers and two carbonyl oxygen atoms, which play an essential role as Lewis basic site.[285]

7.2.3 *Saccharide Binding*

Organoboranes have proven highly useful for selective saccharide binding, which is based on the formation of boronic esters from arylboronic acids in the presence of diols. For example, a number of arylboronic acids containing a ferrocene unit for electrochemical readout have been recently reported.[286] The amino group in (**185**) plays an essential role as it is believed to participate in the sensing process through formation of an intramolecular B–N bond as shown in Scheme 26. Consequently, the phenylboronic acid (**185**) binds saccharides at neutral pH under formation of boronic ester (**186**), while the parent ferrocenylboronic acid requires strongly basic conditions.

Related optical and fluorescent sensor systems have been widely used. For instance, the fluorescence of the pyrene unit in species (**187**) is quenched upon saccharide binding to the boron center.[287] Boronic acid groups were also attached to dendrimers and polymers.[287,288] The benefit of systems containing at least two boronic acid centers, as shown for the luminescent saccharide sensor (**187**), is that two-point binding can more effectively control saccharide binding. Similar

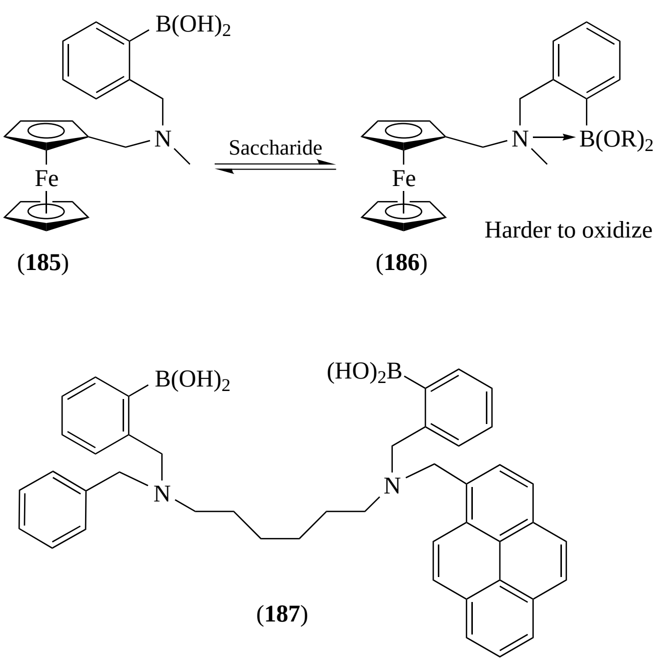
Scheme 25



(**185**) (**186**) (**187**)

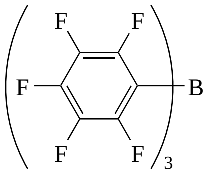
Scheme 26

modular electrochemical detection systems with multiple boronic acid groups were developed.[289]

7.3 Organoboranes as Lewis Acid Catalysts in Organic Synthesis

7.3.1 Achiral Organoboron Lewis Acids

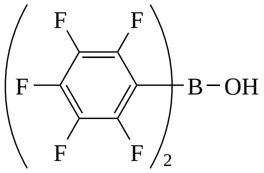
The ability of Lewis-acidic boranes to complex with and thus to activate functional groups of organic substrates has been exploited for numerous applications in organic synthesis. Among achiral reagents and catalysts, simple boron halides, BX_3, are most commonly used. However, they suffer from inherently high sensitivity to air and moisture. Therefore, a new class of fluorinated arylboranes has recently been developed and found to be useful for a large variety of organic and organometallic transformations.[16–18,290] Tris(pentafluorophenylborane) ($B(C_6F_5)_3$, (**188**)) behaves as a very strong Lewis acid as a result of the electron-withdrawing fluorine atoms attached to the aromatic rings. The Lewis acid strength has been shown through binding studies with crotonaldehyde and other nucleophiles to be similar to that of BF_3, and thus much higher than that of $B(C_6H_5)_3$.[290] Moreover, $B(C_6F_5)_3$ is remarkably stable both thermally and toward air and moisture. Indeed, the structures and Brønsted acid properties of stable water adducts of $B(C_6F_5)_3$ have been reported.[291–293] $B(C_6F_5)_3$ acts as an efficient catalyst, for example, in various aldol-type reactions, conjugate additions, Diels–Alder reactions, and in hydrosilylations and hydrostannations of alkynes and olefins.



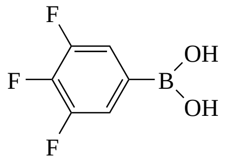
(**188**)

Diarylborinic acids $(C_6F_5)_2BOH$ (**189**) and $(3,5\text{-}(CF_3)_2C_6H_3)_2BOH$ (**190**) were also studied as Lewis acid catalysts. The borinic acid (**189**) adopts a trimeric structure in the solid state, but is monomeric in solution.[294] These borinic acids are for example effective catalysts for Mukaiyama aldol condensations and Oppenauer oxidations, and the catalytic activities are typically much higher than those of the corresponding arylboronic acids.[16] Nonetheless, 3,4,5-trifluorophenylboronic acid (**191**) and 3,5-bis(trifluoromethyl)phenylboronic acid (**192**) were found to act as highly active amidation catalysts.[295]

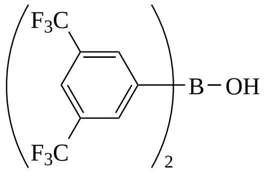
First attempts at developing supported versions of perfluorinated arylboranes have recently been reported.[28,296] Dendrimers containing a carbosilane core with up to 12 tris(perfluorophenylboryl) groups in the periphery have been



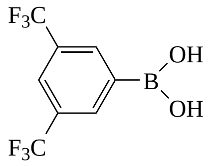
(**189**)



(**191**)



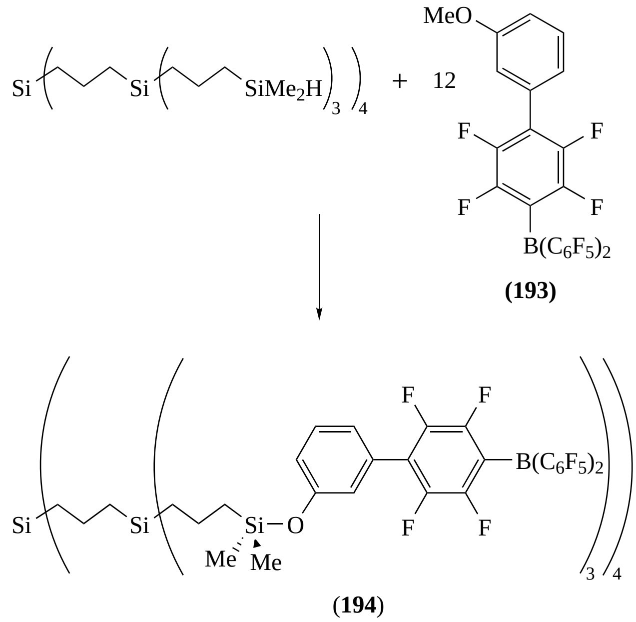
(**190**)



(**192**)

assembled by Piers (Scheme 27). The borane groups were attached in an elegant self-catalyzed reaction, that involves Lewis acid catalyzed silylation of the arylether derivative (**193**).[296] The organoborane decorated dendrimer (**194**) shows only slightly inferior activities in comparison to $B(C_6F_5)_3$ in the hydrosilylation of acetophenone.

The first polymer containing fluorinated arylborane substituents has recently been reported.[28] The highly functionalized soluble polymer (**195**) was obtained in good yield by treatment of poly(4-dibromoborylstyrene) with equimolar amounts of pentafluorophenylcopper at low temperature. Polymer (**195**) shows a slightly lower Lewis acidity than the perfluorinated borane $B(C_6F_5)_3$ as determined by complexation with crotonaldehyde (equation 41). However, in this

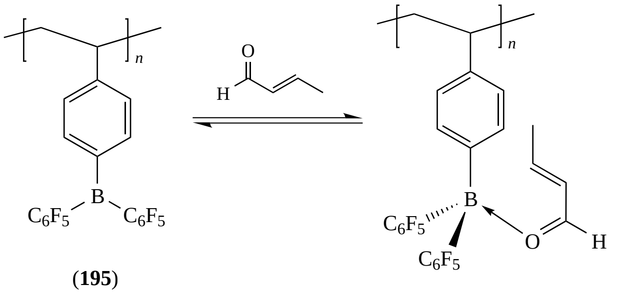


(**193**)

(**194**)

Scheme 27

context it is important to mention that Lewis acid strength does not necessarily correlate with catalyst activity. An intriguing recent study by Piers clearly shows that the weaker Lewis acid $PhB(C_6F_5)_2$ is a much more active catalysts in allylstannation reactions than $B(C_6F_5)_3$.[297]

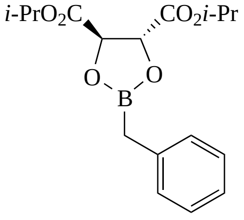


(**195**)

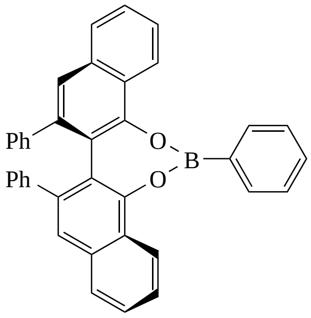
(41)

7.3.2 *Chiral Organoboron Lewis Acids*

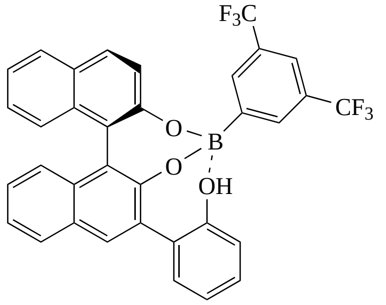
Most chiral organoboron Lewis acids reported to date are based on an organoborane that is attached to a chiral organic moiety such as a diol, aminoalcohol, or other readily available chiral substrates.[14,17,19] Organoboron derivatives recently used as catalysts in enantioselective Diels–Alder reactions include the family of chiral acyloxyboranes (CAB) with (**196**) and (**197**) as representative examples and various cyclic boronic esters such as (**198**) and (**199**). An interesting system that combines the favorable Lewis acid properties of fluorinated arylboranes with a chiral Brønsted acid has been developed by Ishihara and Yamamoto.[298,299] The Brønsted acid-assisted chiral Lewis acids (BLA) (**200**) was found to be highly effective in enantioselective cycloadditions of α,β-enals with various dienes. The presence of the Brønsted acid functionality leads to significant acceleration of the reaction.



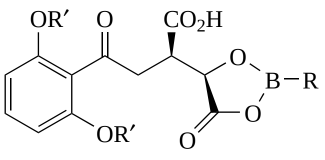
(**198**)



(**199**)

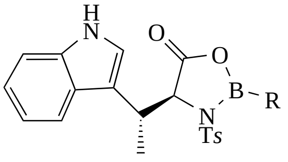


(**200**)



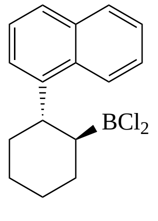
R = alkyl

(**196**)

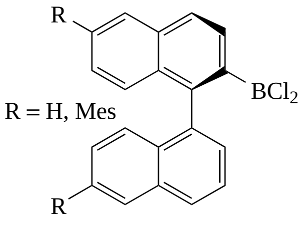


R = alkyl

(**197**)



(**201**)



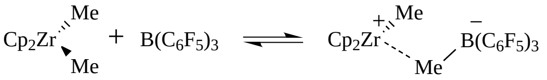
(**202**)

In contrast to the examples shown above, the organic group itself is chiral in the alkylborane (**201**) and the binaphthyldichloroboranes (**202**). The naphthyl-functionalized alkyldichloroborane (**201**) serves as an excellent catalyst in enantioselective Diels–Alder reactions.[300] The high selectivity was ascribed to a two-point binding process that involves an interaction of the substrate with the naphthyl group. While chiral alkyldihaloboranes are among the most powerful chiral Lewis acids, in general they decompose relatively easily to alkanes or alkenes as a result of protonolysis or β-hydride elimination.[17,19] It is thus difficult to recover them quantitatively as alkylboronic acids. The chiral aryldichloroboranes (**202**) are relatively more stable and can be reused as the corresponding boronic acid.[301–304] A bifunctional derivative has recently also been synthesized from distannylated binaphthyl through highly selective tin–boron exchange.[301] The binaphthylboranes (**202**) have been studied as catalysts for enantioselective Diels–Alder reactions involving cyclopentadiene as the substrate.

Although several bifunctional chiral Lewis acids have been described in the literature and binding studies have been performed as outlined in Section 7.2, relatively little is known about their use as Lewis acid catalysts. Most notably, 1,8-bis(dichloroboryl)naphthalene was treated with various chiral organic amines, alcohols, and acids. The resulting products were found to be efficient catalysts for asymmetric Diels–Alder reactions.[305,306] The simultaneous coordination of the substrate by both Lewis acid centers is believed to play a significant role (see also Scheme 25).

7.3.3 *Fluorinated Arylboranes as Cocatalysts for Olefin Polymerization*

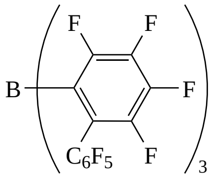
Another exciting property of highly Lewis-acidic organoboranes is their ability to abstract ligands from transition-metal complexes, thereby generating highly reactive coordinatively unsaturated species. A tremendous research effort has been sparked by the independent discovery by Marks and Ewen in the early 1990s that tris(pentafluorophenyl)borane ($B(C_6F_5)_3$, (**188**)) may serve as a well-defined and highly effective activator in Ziegler–Natta olefin polymerization (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***).[152,307] The Lewis-acidic borane is believed to (partially) abstract a methyl group from complexes such as Cp_2ZrMe_2 thus yielding a highly active cationic zirconium species that catalyzes polymerization of olefins (equation 42). Many other examples of the generation of highly active catalysts through abstraction of substituents from transition-metal complexes have been discovered.[152] Experimental and theoretical studies clearly show that the ion pair formation and dissociation critically influences the activity of the transition-metal complexes.[152] One of the challenges in this chemistry has been to further enhance the Lewis acidity of the borane activator and in turn to stabilize the borate anion formed. Toward this end a wealth of highly sophisticated fluorinated organoboranes have been recently reported.[152,282,290,308]



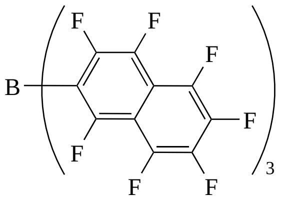
(42)

In an attempt at increasing the Lewis acidity of the borane through use of more highly fluorinated aryl groups, Marks prepared a series of perfluorinated biphenyl compounds.[152] While tris(2,2′,2″-perfluorobiphenylyl)borane (**203**) is highly Lewis-acidic and generally generates cationic species more readily than $B(C_6F_5)_3$, steric effects hinder efficient activation of group 4 metallocene dimethyl compounds.[309] In order to improve the catalytic activity, a related mixed-substituted borane, bis(pentafluorophenyl)(2-perfluorobiphenylyl)borane (**204**) was developed.[310] Moreover, a highly Lewis-acidic perfluorinated naphthylborane derivative, tris(β-perfluoronaphthyl)borane (**205**), was prepared from β-bromoheptafluoronaphthalene.[311] An alternative method to increase the Lewis acidity of the organoborane is to incorporate the electron-deficient boron center into an antiaromatic ring and thus to stabilize the Lewis base adduct relative to the free Lewis acid.[32] The Lewis acidity of (**206**) was found to surpass that of the noncyclic species $B(C_6F_5)_3$, an effect that was attributed to the antiaromaticity of the central 4-π-electron ring. Indeed, a competition experiment showed that (**206**) binds acetonitrile more effectively than $B(C_6F_5)_3$. Thus the incorporation of boron into the antiaromatic ring more than compensates for the loss of two fluorine atoms.

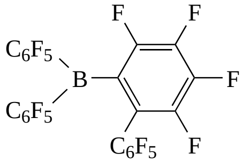
Marks first suggested that the use of bifunctional activators in olefin polymerization might be advantageous. They were



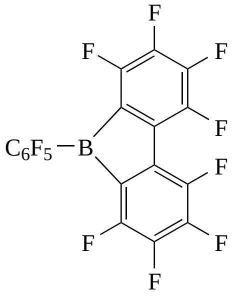
(**203**)



(**205**)

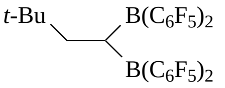


(**204**)

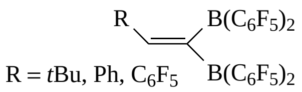


(**206**)

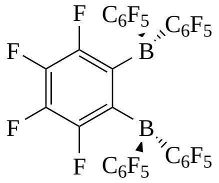
expected to show enhanced Lewis acidity since counterions formed from diboranes are potentially less coordinating than $[RB(Ar^F)_3]^-$.[282,312] The bifunctional Lewis acid (**207**) was obtained by double hydroboration of t-butylacetylene followed by treatment of the intermediate bis(dichloroborane) with pentafluorophenyl lithium. In an effort to obtain a more stable analog of (**207**), the bifunctional borane (**208**) was prepared via tin–boron exchange and subsequent hydroboration reaction. Retrohydroboration reactions are not a concern for (**208**), because the two Lewis-acidic centers are connected by an sp^2-carbon atom. However, the stability under catalysis conditions was also found to be moderate in the case of (**208**). More recent efforts have therefore focused on bifunctional boranes that are bridged by fluorinated aromatic groups. Toward this end, Piers recently reported the synthesis of the fully fluorinated bidentate Lewis acid (**209**) (see equations 14 and 15).[38,313] The use of a perfluorinated backbone, while synthetically challenging, has been found to be an essential feature for good proteolytic stability and high Lewis acidity. Thus, the bifunctional Lewis acid shows superior properties in comparison to the more readily accessible protonated analog 1,2-$C_6H_4(B(C_6F_5)_2)_2$. The B···B separation of 3.1328(2) Å is large enough to incorporate first-row element anions comfortably. Indeed, bridging complexes (**210**) are readily formed with a variety of anions (X = F, OH, OMe, OC_6F_5, N_3, NMe_2) from either alkali metal salts or trityl derivatives Ph_3CX.[313] Methide abstraction from Cp_2ZrMe_2 on the other hand leads to a borate, in which the methyl group is not bridging. Even in the presence of excess of Cp_2ZrMe_2, only one methyl group is transferred to the bifunctional Lewis acid (**209**). However, complexes (**210**) (X=OR) themselves serve as highly efficient noncoordinating anions in olefin polymerization catalyst systems.[313]



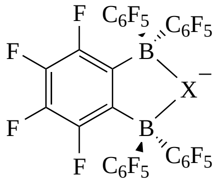
(**207**)



(**208**)

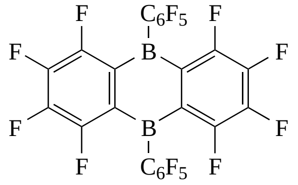


(**209**)

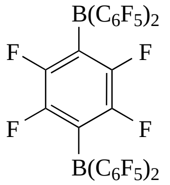


(**210**)

The perfluorinated diboraanthracene (**211**) shows an unusually high Lewis acidity as a result of the antiaromatic nature of the central six-membered ring as described above for the monofunctional borane (**206**).[37,123] The exocyclic pentafluorophenyl groups are nearly perpendicular to the diboracycle thus preventing any significant π-electron density from being transferred to the boron centers. The bifunctional species (**211**) is capable of coordinating a methyl group to each Lewis acid center and shows very good catalytic activity in combination with a number of transition-metal complexes. Finally, a fluorinated 1,4-diborylbenzene derivative (**212**), was studied as a nonchelating bifunctional activator in olefin polymerization. Use of (**212**) has been shown to result in unusual polymer microstructures and has proven particularly beneficial in copolymerizations.[152]



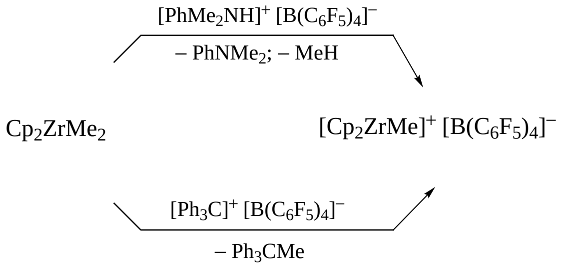
(**211**)



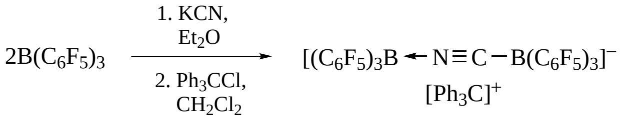
(**212**)

It is important to note that a large number of perfluorinated tetraorganoborates that are for the most part directly related to the tricoordinate species shown above have been prepared and proven highly useful as activators in olefin polymerization. Usually either trityl, ammonium, or oxonium borates are reacted with a suitable transition-metal complex as shown in Scheme 28.[152] Borate salts may serve as highly active cocatalysts since counterions BAr_4^{F-} such as $B(C_6F_5)_4^-$ typically show a very low tendency for ion pairing with the cation Cp_2ZrR^+.

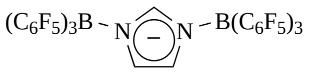
Several weakly coordinating anions, in which the anion is bound to more than one borane moiety, and thus the negative charge is more effectively dissipated have been reported. Treatment of $B(C_6F_5)_3$ with KCN yields the weakly nucleophilic anion (**213**) in a simple one pot procedure (Scheme 29).[314,315] Related imidazolyl and amido-bridged



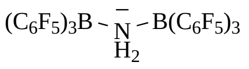
Scheme 28



(**213**)



(**214**)



(**215**)

Scheme 29

bis(borane)s (**214** and **215**) have also been reported.[316,317] Moreover, borane complexes of transition-metal cyanides such as $[Ni(CN)_4]^{2-}$ provide access to anions with even more extensive delocalization.[317] Anion complexes of the bidentate Lewis acids 1,2-$C_6F_4(B(C_6F_5)_2)_2$ (**210**) function on the same principle.[313] All these counterions have been found to be highly effective in olefin polymerization. Finally, borane or borate functionalities may also be directly attached to transition-metal complexes as shown in Section 5.2, thus giving access to 'self-activating' catalyst systems.[146,154–156,159]

1 DISCOVERY AND BACKGROUND

Carbaboranes, commonly known as 'carboranes', can formally be considered as arising from the substitution of one or more $\{BH\}^-$ vertices in an electron-deficient polyhedral borane framework by isolobal {CR} (where R = H or a cage carbon substituent) units without altering the gross geometry of the cage molecules.[1] The first carboranes reported in the literature were obtained in low yields (1–2%) from the reaction of pentaborane (B_5H_9) and acetylene (C_2H_2) in an electric glow discharge.[2,3] This reaction is shown in equation (1).

$$B_5H_9 + C_2H_2 \longrightarrow 1{,}5\text{-}C_2B_3H_5 + 1{,}6\text{-}C_2B_4H_6 + 2{,}4\text{-}C_2B_5H_7 \quad (1)$$

Closed polyhedral cage structures were suggested for these carboranes on the basis of spectroscopic characterization. In a series of papers appearing in the 1963 *Inorganic Chemistry*, the preparation of icosahedral carborane, $(CR)_2B_{10}H_{10}$, was reported from the reaction of acetylenes (R_2C_2) with $B_{10}H_{14}$ in the presence of base.[4] In 1974, the first four carbon-containing open-icosahedral carborane, $(C\text{–}Me)_4B_8H_8$, was synthesized in Grimes's laboratory by oxidative fusion of two $[(C\text{–}Me)_2B_4H_4]^{2-}$ ligands.[5] In recent years, a number of systematic methods were developed for the preparation of a wide variety of carboranes containing one, two, three, four, five, and six carbon atoms as integral parts of the cage framework.[1,6]

1.1 Structures, Properties, and Multicenter Bonding

The electron-deficiency in carboranes arises because of the fact that the number of valence atomic orbitals used in bonding within the molecule is greater than the number of valence electrons available. This can be clearly illustrated by making a comparison between the boron hydrides (boranes) and the carbon hydrides (alkanes), as shown in Figure 1.

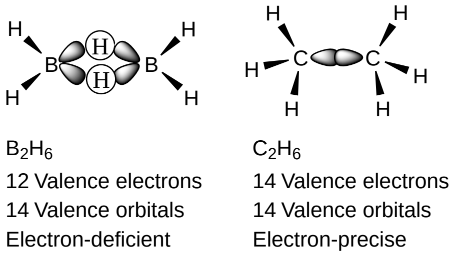

Figure 1 Structures of diborane and ethane

Thus, in carboranes, there are fewer electrons than would be required for a classical Lewis structure in which the bonding can be described in terms of two-electron two-center bonds. Therefore, some type of multicenter bonding, such as shown in Figure 1, for diborane is required.

Almost all of the known carborane cage structures are either closed polyhedra (all faces triangular) or fragments thereof, as shown in Figure 2.[6] According to the general rules of electron counting in clusters, the cage structure would be expected to become progressively more open as the carbon content increased. Thus, carboranes are classified into three geometric categories: (1) closo, (2) nido, and (3) arachno. In the closed (closo) structure (Figure 2), the skeletal atoms occupy all corners of a polyhedron, while in the open (nido) structure (Figure 2) one corner of the polyhedron is vacant. When a heteroatom is introduced into the system, the open face becomes conducive for the location of attachment to the heteroatom. In some cases, two vertices can be removed from the corresponding closo structure to yield an arachno geometry (Figure 2). In general, the structures of carboranes can be predicted from electron-counting rules commonly known as 'Wade's rules'.[7] The application of 'Wade's rules' to these compounds provides a relatively simple relationship between the number of skeletal bonding electron pairs and the geometry of a carborane molecule. For a carborane-containing x skeletal atoms with formula $(CH)_a(BH)_{x-a}H_b{}^{c-}$, where a, $x - a$, and b are the number of CH, BH, and bridged H's, respectively, and c^- is the overall charge on the anionic species, the number of electron pairs (z) involved in cage bonding is $x + 1/2$ $(a + b + c)$. Each CH unit provides three electrons, each BH units furnishes two electrons, and each bridge hydrogen contributes one electron. The electrons are contained in $x + 1$ bonding molecular orbitals (MOs). These bonding MOs are formed by the interaction of three orbitals from each of the framework atoms (C's and B's). The orbitals are the radially oriented p or sp hybrid and the tangentially oriented two p orbitals. Generalizing the rules, a closo structure is preferred if $z = x + 1$, nido if $z = x + 2$, arachno if $z = x + 3$, hypo if $z = x + 4$, fisco if $z = x + 5$, and a reticulo structure is preferred if $z = x + 6$ (see Table 1).

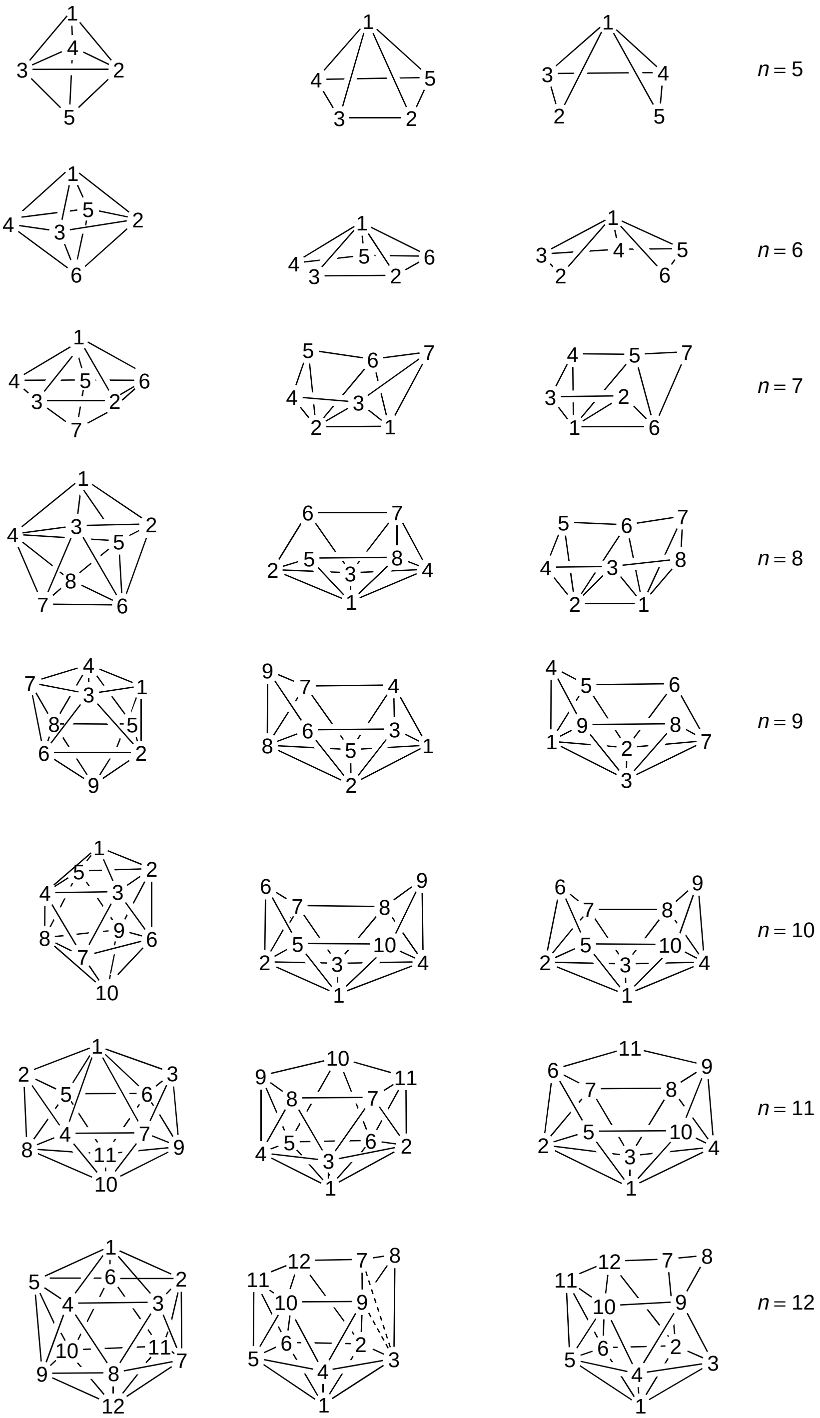

Figure 2 Polyhedral atomic frameworks of idealized (a) *closo*, (b) *nido*, and (c) *arachno* carboranes showing conventional numbering schemes. The lines drawn between cage atoms merely illustrate cluster connectivity, and should not necessarily be taken as bonds[6]

The structures of these compounds seem to dictate their methods of preparation as well as their properties. The closo carboranes are more thermally stable and less air sensitive than the corresponding nido and arachno carboranes. This is due to the fact that the nido and arachno carboranes lack a closed polyhedral structure. The closo carboranes, such as $C_2B_4H_6$, $C_2B_8H_{10}$, $C_2B_{10}H_{12}$, and their $C_{(cage)}$-substituted derivatives, are also fairly stable to 250 °C and above, and they often undergo thermally induced rearrangements that results in greater separation of the relatively negative carbon atoms

Table 1 Summary of electron-counting rules and structure relationship

	Structure types					
	Reticulo	Fisco	Hypo	Arachno	Nido	Closo
Occupied vertices	x	x	x	x	x	x
Skeletal electron pairs	$z = x + 6$	$z = x + 5$	$z = x + 4$	$z = x + 3$	$z = x + 2$	$z = x + 1$

via several diamond-square-diamond (DSD) processes.[8] The nido and arachno compounds, however, seem to generate the corresponding closo carboranes at higher temperatures indicating their thermal instability. Clearly, the structures of these carboranes seem to dictate their properties.

1.2 Practical Applications

The rapid development of carborane chemistry is mainly due to their practical applications. For instance, the potential utility of carborane polymers as gaskets, O-rings, and electrical connector inserts has been reported.[1a] Their functionality for solvent extraction of radionuclides as well as the potential medicinal value of the isoelectronic and isostructural boron analogues of biologically important molecules has been the subject of many review articles.[1,9,10] For example, a number of boron compounds have been found to possess anti-inflammatory and antiarthritic activity in animal model studies. Boron compounds have also been implicated in studies designed to probe the importance of the so-called anionic subsite of acetylcholine esterase and Ach receptors. But, by far the most interesting practical applications of carboranes are in areas of boron neutron capture therapy (BNCT) and supramolecular assembly.

Carboranes in Boron Neutron Capture Therapy of Cancer (BNCT):[9,10] The stable isotope of boron, ^{10}B (19.8% natural abundance), is very effective as a neutron capture agent with the effective nuclear cross section of 3837 barns, while the ^{11}B nucleus is incapable of undergoing a BNC reaction. Therefore, the ^{10}B-enriched carborane and borane-substituted biomolecules and drugs are selectively delivered to the cancer cells in the human body and then the tumor-localized ^{10}B nucleii are bombarded with either thermal or epithermal neutrons that results in a fission reaction producing the high energy alpha (α) particles as shown in equation (2).

$$^{10}_{5}B + ^{1}_{0}n \longrightarrow ^{7}_{3}Li + ^{4}_{2}He + 2.7\,MeV \qquad (2)$$

Since the α particles travel only 10 µm or less distance, the ^{10}B nucleii-localized cancer cells are destroyed selectively. However, the estimated amount of ^{10}B nucleii needed for tumor destruction is approximately 10^{18} atoms or 10–30 µg ^{10}B/g tumor. Therefore, the polyhedral borane and carborane-containing biomolecules are found to be ideal for use in BNCT as they have a high probability of preferentially localizing in tumor cells rather than normal tissues and are rapidly cleared from normal tissues and blood, while being retained in tumor tissues. This results in high tumor to normal tissue ratios and high tumor to blood ratios. The research to date has shown that BNCT has significantly prolonged the lifespan of patients with deadly brain tumors. A number of carborane compounds such as boronated organic species and boronated monoclonal antibodies have been employed for this purpose.

Molecular Assemblies:[11,12] Because of their rigid, thermally and chemically stable three-dimensional structure, the three icosahedral carborane isomers, commonly known as *o*-, *m*-, and *p*-carborane (or 1,2-, 1,7-, and 1,12-$C_2B_{10}H_{12}$, respectively), are being used as subunits for the assembly of larger arrays. The examples of such molecular assemblies include linear rigid rod-like molecules obtained by direct coupling of the carbon vertices of *p*-carborane, hybrid linear rods by joining opposite boron vertices of *p*-carborane through acetylene or diacetylene linkages, nonlinear oligomers of both *o*- and *m*-carboranes, cycles of *o*- or *m*-carborane connected *via* their carbon or boron vertices through mercury atoms to form novel mercuracarboranes, and carboracycles, which are cyclic compounds composed of *o*- and *m*-carboranes joined through carbon vertices by a series of bifunctional organic linking groups of varying complexity. Thus, the development of the systematic synthetic routes toward nanometer-scale, structurally well-defined and rigid molecules has become a rapidly growing area of chemistry.

Glossary

Cottrel's trap: an electrostatic precipitator for removing dust from a gas stream
Cross section: states the probability that an interaction will occur between a projectile particle (e.g. a neutron) and a target particle, which could be a nucleus in a piece of metal
Dendritic form: branching figure, whose form resembles that of a tree or shrub
Zone refining: a method of purifying metals. An ingot of metal passes through an induction heater, and in this way impurities are accumulated in the melted portion of the ingot

Abbreviations

Asn = asparagine; $CitH_2$ = citric acid; tu = thiourea (*see Thiourea*); Ettu = ethylenethiourea; Glu = glutamic acid; Met = methionine; tren = tris(2-aminoethyl)amine; Me_6 tren = tris(2-dimethylaminoethyl)amine, en = ethane-1,2-diamine; pn = propane-1,2-diamine.

1 INTRODUCTION

Cadmium was discovered in Germany in 1817. The first industrial applications were developed in the late 19^{th} century, even if the use of CdS based pigments dates from about 1850. The most remarkable properties of cadmium are great resistance to corrosion, excellent electric conductivity, and low-melting point. For these reasons, cadmium is employed in many important industrial applications, even though its release in the environment can cause ecological and health effects. Its chemistry is similar to that of zinc and shows versatile coordination abilities, giving Cd^{2+} structures ranging from simple complexes to 1D, 2D, and 3D polymeric architectures. Interesting physical properties are exhibited by these polymers. Moreover, Cd^{2+} is able to substitute Zn^{2+} in the active site of Zn-enzymes (*see Enzyme*) and to interfere with the metabolism of Ca^{2+}. This is why several investigations in the last decade have been devoted to the coordination chemistry of cadmium and to development of new kind of compounds of applied interest.

2 DISCOVERY

Cadmium was discovered almost simultaneously in 1817 by F. Stromeyer, professor of metallurgy at the Gottingen University, K.S.L. Hermann, chemical manufacturer, and J.C.H. Roloff, pharmacy inspector, in samples of zinc oxide obtained by roasting zinc carbonate from Salzgitter (Germany).[1] The name cadmium is derived from the Latin *cadmia* (*fornacum* or *fornacea*), used in the ancient times to indicate the most important zinc ore, the zinc carbonate. The Greek $\kappa\alpha\delta\mu\varepsilon\iota\alpha$ (or $\kappa\alpha\delta\mu\varepsilon\iota\alpha\ \gamma\eta$) means cadmean earth and in antiquity this mineral was first mined near Thebes, a town founded by king Cadmo (Lat. *Cadmus*, Gr. K$\alpha\delta\mu o\varsigma$).

3 GENERAL REMARKS

Cadmium (Cd) is a silvery grey, shining but tarnishable metal, similar to Zn and Sn (*see* ***Zinc: Inorganic & Coordination Chemistry*** and ***Tin: Inorganic Chemistry***).[1] The structure of the form stable at room temperature (γ form) is hexagonal (space group: P63/mmc; cell parameters: a = 297.94 pm, b = 297.94 pm, c = 561.86 pm, $\alpha = 90.00°$, $\beta = 90.00°$, $\gamma = 120.00°$). It deviates from perfect hexagonal close packing (*see Close Packing*) by elongation along the six-fold axis: each atom is regularly surrounded by six near neighbors in the close-packed plane and by three more distant neighbors in each adjacent plane. A stable α form is observed at high temperature. Cd is isostructural with Zn, Be, and

Mg. In vapour phase, unstable Cd_2 molecules have been detected[1] (bond energy about 7.4 $KJ\,mol^{-1}$). Cd exhibits a certain stability when exposed to dry air, but in the presence of moisture it is slowly covered with an oxide layer. It is softer and more malleable than Zn and can be easily laminated, extruded, drawn, and processed. A characteristic sound (a sort of scream) is generated on bending a bar of the metal. Cd shows a great resistance to corrosion, a low-melting point, and excellent electrical conduction. Unlike zinc, Cd has

no amphoteric properties and, although cadmiate anions are known, Cd does not dissolve in bases. With Zn and Hg (*see* ***Zinc: Inorganic & Coordination Chemistry*** and ***Mercury: Inorganic & Coordination Chemistry***), Cd forms Group 12 and has two s electrons outside filled d shells. Its usual oxidation state is +2, but also Cd^I species are known. Zn and Cd prove to be considerably more electropositive than their neighbors in the transition groups and no carbonyl, nitrosyl, alkene, and so on complexes of the type given by transition metal are known. However, their ability to form coordination compounds with ammonia, amines, cyanide (*see Cyanides*), and halide ions resembles that found for the d-group elements. Even though Cd chemistry closely resembles that of Zn, in some cases differences are still observed.[2] Physical properties of metal cadmium and Cd^{2+} ion are reported in Tables 1 and 2, respectively.

4 OCCURRENCE

The presence of Cd in the Earth's crust is estimated to range between 0.15 and 0.11 $\mu g\,g^{-1}$ (67th element in order of abundance), with a Zn/Cd molar ratio about 450:1 (strongly dependent on the nature of the rocks).[3] Cd^{2+} ionic radius (0.97 Å) is similar to that of Ca^{2+} (0.99 Å) and Na^+ (0.98 Å), therefore Cd^{2+} is expected to be found substituting for Ca^{2+} and Na^+ in their minerals. Moreover, Cd^{2+} shows high affinity for calcite[4] and iron oxyhydroxides surfaces. It reveals a chalcophile nature and forms few minerals: the most important are two sulfides, greenockite and hawleyite (hexagonal and cubic form of CdS, respectively), a carbonate (otavite) and an oxide (monteponite). Greenockite, in particular, is formed as a yellow coating on weathering sphalerite (ZnS). Cd^{2+} gives isomorphous replacement in several Zn minerals, which can contain up to 0.5% of Cd. For this reason, sphalerite is the main industrial source of Cd. Under natural conditions, Cd can be found in the atmosphere (0.1 to 5 $ng\,m^{-3}$) as a result of volcanic emission and release from vegetation.[3]

5 PRODUCTION

Almost all the metal Cd is obtained as a by-product of the metallurgy of Zn but it may be produced also using flue dusts gathered from lead and copper smelters.[1,5,6] Cd can be recovered from Zn minerals as CdO fume (pyrometallurgical process), owing to the higher volatility of CdO over ZnO, or as precipitate from the Zn solutions used in electrolytic production of Zn (hydrometallurgical process). In the first case, during the pyrometallurgical extraction of Zn, a considerable volatilization of Cd compounds (most of all CdO) occurs. In this way a 90–99% recovery of Cd can be obtained. Cd not removed can be recovered in the residual high-boiling fraction from Zn purifying process by fractional distillation. The concentration of Cd in dust is too low to proceed to a direct reduction: therefore the dust, separated by an electrostatic Cottrel's trap, is leached with H_2SO_4. The solution, after elimination of Pb as $PbSO_4$, is treated with Zn dust. After precipitation and filtration, Cd is exposed to reductive distillation and fusion in the presence of NaOH to eliminate Zn and other impurities. A further distillation can be used to obtain higher purity. In the hydrometallurgic process, the roasted zinc mineral is dissolved in H_2SO_4. After elimination of As and Cu, Cd is precipitated with Zn dust and leached again with H_2SO_4. The solution is then electrolyzed (*see* ***Electrochemistry: Applications in Inorganic Chemistry***) using insoluble anodes of Pb (with 1% Ag), coated with MnO_2 to avoid acidic corrosion, and cathodes of Al. Cd is deposited on cathodes, but often in dendritic form. A more compact deposition is obtained using rotating or oscillating cathodes. The applied potential is about -2.75 V with a current density of about 100–200 A m^{-2}. Thus produced, Cd undergoes double fusion with NaOH to eliminate residual Zn. Ultrapure Cd can be produced using zone refining.[7] This last process requires oxygen exclusion. Single crystals of desired orientation can be obtained using the Bridgman technique.

6 USES

Cd and its compounds find applications in several industrial materials: electrode materials in Ni–Cd batteries (about 70% of total produced Cd), pigments in ceramics, glasses, paper, plastics, artists colors (13%), stabilizers for polyvinyl chloride and related polymers (7%), coatings on steel, aluminium, and other nonferrous metals (8%), and specialized alloys[1,5] (*see* ***Alloys***) and others (2%).

Ni–Cd batteries are extensively utilized in cordless power tools (cellular telephones, portable computers, toys, and so on), in electric vehicles, and for emergency and starting power. They have excellent performance both at low and high temperature and high cycle life. CdS is an important yellow pigment, with other compounds (CdSe in particular) it gives rise to different colors. Cd pigments show a remarkable ability to withstand high temperature and pressure without fading; they are, therefore, suitable for industrial processes involving severe conditions. Cd stabilizers for polyvinyl chloride (PVC) are usually organic carboxylate Cd salts (such as stearate or laurate), which are included in the polymeric structure before processing and retard degradation processes due to exposure of PVC to ultraviolet light and heat. They are used in mixture with barium and lead organic salts and constitute about 0.5–2.5% of the final polymeric material. Cd plating is used to provide the best combination of corrosion resistance and low friction coefficient on metal component involved in mechanical stress. A thin film of Cd may be applied by electroplating or, less commonly, by dipping in fused Cd, spraying or vacuum deposition. This protection is better than that obtained using Zn and the Cd film reveals a higher resistance to alkali, seawater and salinity. It is highly ductile and easily soldered. Cd surface, unlike Zn, retains a high lustre for a long period, even in a moist environment. In general, Cd electroplating is carried out using sodium cadmiocyanide solutions and anodes of Cd (99.95%). Due to its great cross section towards neutrons (2500 barns), Cd (especially ^{113}Cd) possesses high neutron-absorbing ability and is used for control rods and shielding in nuclear reactors. Copper with 1% of Cd shows a maximum tensile stress, 50% higher than that of electrolytic copper, without appreciable lowering of electrical conductivity. This alloy is used in telephone and trolleybus cables. Also Pb with 1% of Cd proves to be more resistant against repeated mechanical stresses. Small amounts of Cd in Al–Cu alloy delay the natural aging after solution hardening. Cd is a component of special alloys melting at low temperatures: the Wood's alloy (50% Bi, 25% Pb, 12.5 Cd, 12.5 Sn) melts at 70 °C and is used in fuses for telephone installation and fire-prevention systems. Special antifriction bearings can be produced using Cd–Ag or Cd–Ag–Cu alloys. Cd is used as a deoxidizer in melting Ag or Ag alloys and to prepare soft solders. Brazing alloys based on Ag–Cu–Cd–Zn are employed in the mechanical and electrical industry. Some Ag–Cd and Au–Cd alloys display shape memory properties.[8] CdS, CdSe, and CdTe are semiconductors (*see* ***Semiconductor Interfaces***) and used in solar cells and a variety of electronic devices. CdS shows photoconductive and electroluminescent properties and can be employed in X-ray fluorescent screens and in scintillation counters. $CdCO_3$ and $CdCl_2$ have fungicides properties, $CdCl_2$ is also used in photography, in dyeing and printing of textiles, in galvanoplasty, in mirror manufacture, and in the preparation of Cd yellows and reds. $CdBr_2$ finds application in photography, process engraving, and lithography. CdO is used in ceramic glazes, in silver-zinc batteries, and in plastics to improve high-temperature properties. $Cd(CH_3COO)_2$ creates iridescent effects in potteries and porcelains. $CdSO_4$ also has applications in industry: electrodeposition of Cd, manufacture of Cd salts, fungicides, production of vacuum tubes, electrolyte in standard cells, as a chemical accelerator in cement formation.

Table 3 Main cadmium isotopes

	Natural abundance (%)	Emitter type	Half-life
97	–	β^+	3 s
98	–	β^+	8 s
99	–	β^+,γ	16 s
100	–	β^+,γ	1.1 min
101	–	β^+,γ	1.2 min
102	–	β^+,γ	6 min
103	–	β^+,γ	7.5 min
104	–	γ	58 min
105	–	β^+,γ	55.5 min
106	1.22	–	stable
107	–	β^+,γ	6.53 h
108	0.88	–	stable
109	–	γ	462 d
110	12.39	–	stable
111	12.75	–	stable
112	24.07	–	stable
113	12.26	–	stable
114	28.86	–	stable
115	–	β^-,γ	59 h

120	–	β^-	50.8 s
121	–	β^-,γ	13.5 s
122	–	β^-	5.3 s
123	–	β^-	2.09 s
124	–	β^-,γ	1.24 s

7 ISOTOPES

Several isotopes (*see Isotopes & Isotope Labeling*) of Cd are known,[8] and 8 are stable (Table 3). For ^{111}Cd and ^{113}Cd, the nuclear spin is 1/2 and they are used for NMR studies of Cd compounds and in biological fields (*see* ***Cadmium: Organometallic Chemistry***). ^{113}Cd is used in the nuclear industry because of its high neutron cross section. Unstable isotopes are prepared from nuclear reactions.[9] Cd stable isotope composition in geological and meteorite samples has been investigated using multiple collector inductively coupled plasma mass spectrometry.[10]

8 TOXICOLOGICAL AND ECOLOGICAL INFORMATION

Extraction and manufacture of Zn, Pb, and Cu ores can give pollution of the environment with Cd derivatives. Cd is present also in industrial sludge and waste water. A source of Cd release is the burning of fossil fuels and the incineration of rubbish. Fertilizers can contain variable amount of Cd. Toxicological characteristics and environmental fate[3,11] of Cd resemble those of Pb and Hg (*see* ***Metal Ion Toxicity***). In aqueous environment Cd^{2+} shows a relative mobility: it depends on pH, presence of organic molecules, and water hardness. Cd concentration in soil can reach high levels,[12] but high acidity increases the release of Cd^{2+} and, consequently, its uptake by plants and bioaccumulation.[3,11] In aquatic environment, invertebrates (most of all molluscs and crustaceans) accumulate Cd rapidly, followed by fish and aquatic plants;[13] as a matter of fact, sea organisms are more resistant to Cd poisoning than those living in freshwater environment. Bioaccumulation in terrestrial plants results in higher Cd level in animals involved in alimentary cycle of the plants; in some cases the presence of Cd in soil inhibits the growth of some plants.[3,11] Workers in Cd, Zn, and Pb processing plants may be exposed to direct poisoning by Cd, but human uptake of Cd occurs mainly through food.[3] Uncontaminated foodstuffs and cigarette smoke contain low amount of Cd (*see* ***Nutritional Aspects of Metals & Trace Elements***) and drinking water normally does not show significant metal content. Ingestion of Cd from contaminated foodstuffs gives rise to several diseases: in the case of that named itai-itai, Cd in the rice was found the etiological agent. Cd is particularly absorbed by the respiratory tract: cigarette smokers may absorb 10–40% of inhaled Cd. Cd fume is an intense irritant and so pulmonary edema develops rapidly. In the case of acute poisoning, the gastrointestinal tract absorbs only a small amount of Cd even though salivation, choking, nausea, vomiting, convulsion, and collapse may occur. Cd tends to accumulate in the liver and kidneys (about 50% of total body Cd). Metalothioneins (*see* ***Metallothioneins***) found in these two organs show high affinity for Cd^{2+}.[14] These metal-binding proteins act as sequestering agents, lowering Cd^{2+} concentration in critical tissue sites. The presence of Cd^{2+} seems to induce the synthesis of the protein in the liver and kidneys. The half-life of Cd in the body is 10–30 years. Cd compounds show high oral toxicity, even though the emetic and irritant action is so violent that only a little Cd is absorbed so that fatal poisoning is rather uncommon.[15] Cd compounds cause damage to kidney and to the central nervous system and are carcinogenic for connective tissue, lungs and liver and, perhaps, teratogenic.[15,16] Direct relationship between Cd poisoning and thyroid dysfunction has been established.

9 SPECTROSCOPY

9.1 NMR Spectroscopy

^{111}Cd and ^{113}Cd NMR spectroscopy has been used to study several complexes, both in solid state and in solution, and to investigate the binding site of the metal ion in different metalloproteins.[17] These isotopes have a spin 1/2 and, therefore, the broadening of the NMR signals due to the quadrupolar contribution to NMR relaxation is avoided. The natural abundance is 12.75 and 12.26% for ^{111}Cd and ^{113}Cd, respectively, but due to the lower receptivity of ^{111}Cd respect to ^{113}Cd, NMR investigations have mainly been

performed with the latter isotope. ^{113}Cd chemical shift varies nearly linearly with concentration for cadmium perchlorate, sulphate, and nitrate, while the halide salts show a large nonlinear relationship owing to the formation of mono- and polyhalogeno complexes. Studies on a variety of organic and inorganic ligands bearing different donor atoms (*see Donor Atom*) revealed linear dependence on concentration and that: (i) ligands binding through the oxygen atom (sulphate, nitrate, nitrite, carboxylic acids, etc.) cause increased shielding of the Cd nucleus; (ii) those binding through nitrogen (ammonia, pyridine, azide, ethylenediamine, etc.) induce a marked deshielding; and (iii) ligands binding through the sulphur atom (thiourea (*see Thiourea*), thiocyanate, etc.) cause a remarkable deshielding.[17] Several Cd complexes with N-ligands (*see* ***Ammonia & N-donor Ligands***) show a line broadening, probably due to their slow dissociation rate in solution. In many cases, binding constants of Cd complexes can be calculated by the chemical shift or broadening. Extensive investigations have been performed on Cd^{2+}-halide systems, in aqueous and nonaqueous media, and the equilibria have been characterized.[17] A somewhat surprising effect of halide ions on ^{113}Cd NMR spectra in the presence of ATP as a function of pH can be observed: the $Cd(ClO_4)_2$–ATP system shows a downfield shift on increasing pH; the $CdCl_2$–ATP system, however, shows an upfield shift. In the former case, the downfield shift may be due to the displacement of bound H_2O, whilst in the latter the upfield shift is due to the displacement of coordinated Cl^-. Cd-substituted porphyrins, in particular tetraphenylporphyrin (TPP), have been studied using ^{111}Cd NMR and the ^{111}Cd–^{15}N coupling constants determined.[17] Cd–TPP adducts have been investigated by ^{111}Cd and ^{113}Cd NMR.[17] The ^{113}Cd chemical shift observed for aqueous Cd-EDTA is independent of pH between 4 and 11, but at pH $>$ 13.8 gives evidence for the formation of mixed hydroxo complexes. A large group of Cd compounds containing N-donor ligands have been investigated as a function of counterion, chelate ring size, and basicity: in the case of trisdiamine species, the deshielding effect decreases in the order $4 \rightarrow 5 \rightarrow 6 \rightarrow 7$-membered chelate ring. The deshielding effect of anionic N-donors is much greater than for neutral N-donors. ^{113}Cd–^{113}Cd and ^{113}Cd–^{111}Cd coupling constants have been determined for a number of compounds containing multiple Cd centers.[17] The trinuclear anion $(Na[Cd(SOPh)_3]_2)^-$ has been studied through ^{111}Cd NMR spectra in Me_2CO and MeCN. In both the cases retention of bonding between Cd and S,O has been observed. Complexes with simple and N-protected amino acids have been investigated at different pH values. The results are consistent with the presence of Cd complexes in which the ligand is bidentate, acting through N and O atoms. ^{113}Cd NMR chemical shifts strongly depend on substituent effects in alkylcadmium compounds (*see* ***Cadmium: Organometallic Chemistry***). Results have also been obtained by application of magic angle spinning techniques to the ^{113}Cd NMR study of solid compounds, as powders, or as single crystals.[2,17] Cd complexes with glycine, alanine, and cysteine have been investigate using solid-state ^{113}Cd NMR spectroscopy and the principal components of the ^{113}Cd shielding tensor determined. Cross polarization/magic angle spinning NMR experiments have been used to calculate the principal elements of the ^{113}Cd shielding tensor for a collection of N-donor ligands. Composition and structure of a unusually highly charged $[ClCd_8\{SCH(CH_2CH_2)_2NHMe\}_{16}]^{15+}$ cation have been determined by X-ray, XPS, and ^{113}Cd NMR measurements on microcrystalline powder.[18] Solid-state ^{113}Cd NMR spectroscopy has been used to characterize a number of Cd thiocyanate complexes of varying stoichiometry.[19] Several reviews have been published on metalloprotein studies.[17,20] ^{113}Cd NMR spectroscopy has been successfully applied to environmental studies.[21]

9.2 Photoelectron and Vibrational Spectroscopy

Photoelectron spectra of Cd compounds have been reported (*see* ***Photoelectron Spectroscopy of Transition Metal Systems***), but discrepancies have been noted.[2] X-ray photoelectron spectroscopy has been used in surface studies.[22] Simmetry, bond length, and equilibrium constants (*see Equilibrium Constant*) of Cd complexes have been determined through IR and Raman spectroscopy. Resonance Raman spectroscopy and Photoluminescence allow investigation of the optical properties of ultrathin CdS films.[23] Electron diffraction studies have been reported.[24]

10 ELECTROCHEMISTRY

$E°$ and $E_{1/2}$ values of Cd^{2+}/Cd couple and Cd complexes in aqueous solution have been measured through potentiometric and voltammetric methods (Table 4).[25] Few data are available

Table 4 Electrochemical data for Cd^{2+} in aqueous solvents

Standard potentials		
Electrode		$E°$(V) vs. NHE
$Cd^{2+} + 2e^- = Cd$		−0.4025
$Cd^{2+} + 2e^- + Hg = Cd(Hg)$		−0.3515
$Cd(OH)_2 + 2e^- = Cd + 2OH^-$		−0.824
$[Cd(CN)_4]^{2-} + 2e^- = Cd + 4CN^-$		−1.028
$[Cd(NH_3)_4]^{2+} + 2e^- = Cd + 4\,NH_3(aq)$		−0.613
Half-wave Potentials (Hg electrode)		
Species	Conditions	$E_{1/2}$ (V) vs. SCE
Cd^{2+}	$NaClO_4$, 0.1 M	−0.59
Cd^{2+}	KNO_3, 0.1 M	−0.58
$[CdCl_x]^{2-x}$	KCl, 0.1 M	−0.60
$[CdI_4]^{2-}$	KI, 0.1 M	−0.65
$[Cd(NH_3)_4]^{2+}$	NH_4Cl, 1 M; NH_3, 1 M	−0.81
$[Cd(CN)_4]^{2-}$	KNO_3, 0.1 M; KCN, 1 M	−1.16
$[Cd(SCN)_x]^{2-x}$	KSCN, 2 M	−0.664

Table 5 Electrochemical data for Cd^{2+} in nonaqueous solvents

Species	Solvent	Conditions	$E_{1/2}$(V)
$Cd(ClO_4)_2 \cdot 6H_2O$	MeCN	0.1 M, $NaClO_4$	−0.27 vs. SCE
$Cd(ClO_4)_2$	PhCN	0.1 M, TEAP	−0.17 vs. SCE
$Cd(ClO_4)_2$	DMF	0.1 M, TEAP	−0.17 vs. $Ag/AgCl_s$
$Cd(ClO_4)_2 \cdot 2H_2O$	$MeCO_2H$	1 M, $LiClO_4$	−0.295 vs. SCE
$Cd(NO_3)_2$	ethylenediamine	0.1 M, $NaNO_3$	−0.50 vs. NCE
$Cd(ClO_4)_2$	ethylenediamine	0.1 M, $NaNO_3$	−0.70 vs. NCE
$CdCl_2$	ethylenediamine	0.1 M, $NaNO_3$	−0.64 vs. NCE
$CdCl_2$	MeOH	0.2 M, LiCl	−0.595 vs. $Ag/AgCl_s$
$CdCl_2$	$HCONH_2$	0.2 M, LiCl	−0.672 vs. $Ag/AgCl_s$

in nonaqueous media. The potential-pH diagram for Cd^{2+}/Cd system has been determined and discussed in connection with corrosion, immunity, and passivation.[26] Cd can be corroded at acidic and very alkaline pH values, but the corrosion rate is fast only in the presence of oxidizing and complexing agents due to the high hydrogen overpotential. In aqueous solution, Cd^{2+} gives a well-defined voltammetric wave on Hg electrode, corresponding to a reversible, two-electron reduction.[25] In the presence of complexing agents (*see* ***Electrochemistry: Applications in Inorganic Chemistry***), the $E_{1/2}$ value shifts towards more negative values (Table 4): type and stability of the complex(es) can be often determined using DeFord-Hume or Shaap-McMasters methods. In organic solvents, Cd^{2+} undergoes a single step bielectronic reduction; on Hg electrode it is in most the cases reversible or quasi-reversible (Table 5). Cd^{2+} dodecyl sulphate micelles have been characterized using voltammetric methods.[27] CdS thin films can be electrochemically obtained and pulsed sonoelectrochemical synthesis of CdSe nanoparticles has been realized.[28] Cd^{2+} sensitive electrodes are known.

11 CHEMICAL PROPERTIES

Cd dissolves in acids, but more slowly than Zn; warm H_2SO_4 rapidly corrodes the metal. Cd reacts with NH_3 and SO_2 in presence of moisture and with concentrated NH_4NO_3 solutions. Cd is slowly oxidized by moist air, rapidly by steam and by air at very high temperature, giving a brown oxide CdO. Unlike Zn, Cd is insoluble in alkali. NaOH precipitates Cd^{2+} as white hydroxide $Cd(OH)_2$. This is insoluble in excess of NaOH (unlike $Zn(OH)_2$), but dissolves in ammonia solution, giving $[Cd(NH_3)_4]^{2+}$. H_2S precipitates Cd^{2+} as a canary-yellow sulfide, which is insoluble in $(NH_4)_2S$ or $(NH_4)_2CN$, but dissolves in oxidizing acids. White $Cd(CN)_2$ is soluble in CN^- excess, giving $[Cd(CN)_4]^{2-}$. Cd^{2+} precipitates as $CdCO_3$ with $(NH_4)_2CO_3$ and as $CdCrO_4$ with concentrated K_2CrO_4. NH_4SCN and Cd^{2+} form colorless soluble $[Cd(SCN)_n]^{(2-n)}$ ($n = 1-4$), but in presence of pyridine a white precipitate of $[Cd(py)_2(SCN)_2]$ is observed.

12 ANALYTICAL METHODS

Cd^{2+} can be detected by the insolubility of its yellow sulfide (*see* ***Analytical Chemistry of the Transition Elements***). Several reaction and spot tests allow the identification of Cd^{2+}. Quantitative determinations are based on gravimetric (CdS or β-naphthylquinoline complex) or titrimetric (EDTA) methods. Several physical techniques can be used in quantitative and qualitative analysis: polarography (or related techniques, even in the presence of Zn, Cu, Bi and Pb), electrodeposition, colorimetric methods, flamephotometric methods, neutron activation, atomic absorption, and ICP spectrometry and ion selective electrodes.

13 STEREOCHEMISTRY

The stereochemistry of Cd^{2+} is summarized in Table 6. The main coordination numbers (*see* ***Coordination Numbers & Geometries***) are 4, 5, and 6.[29] Due to the larger size, Cd^{2+} assumes coordination number 6 more easily than Zn^{2+}: in the case of $[M(DHA)_2(DMSO)_2]$ (DHA = 3-acetyl-6-methyl-2H-pyran-2, 4(3H)-dione, M = Cd^{2+} or Zn^{2+}), both the crystal structures (*see Crystal Structures*) show a distorted octahedral geometry, but in solid-state significant differences in the coordination sphere of the two complexes are observed.[30] In $CdMe_2$ and dihalides in gas phase, Cd^{2+} is coordinated to only two ligands with $D_{\infty h}$ symmetry. In solid and solution phase, the coordination number is higher than 2. Coordination number 3 characterizes CdX_3^- (D_{3h} symmetry) in organic media, but in aqueous solution $CdBr_3^-$ is pyramidal due to the binding of one or more water molecule. Coordination numbers higher than 3 are observed in solid $MCdX_3$. In aqueous solution, CdX_4^{2-} anions (X = Cl^-, I^-, CN^-) are four-coordinated while tetrahedral (*see Tetrahedral*) $CdCl_4^{2-}$ is observed only as diquinolinium salt, less bulky

Table 6 Coordination chemistry of Cadmium

Coordination number	Compound {coordination core}
2	$CdMe_2$, CdX_2(gas phase, X = F, Cl, Br, I)
3	CdX_3^- (nonaqueous solvents, X = F, Cl, Br, I)
4	$CdS_2\{CdS_4\}$, $CdCl_2(biuret)_2\{CdCl_2O_2\}$, $CdCl_2tu_2\{CdCl_2S_2\}$, $CdCl_2py_2\{CdCl_2N_2\}$, $CdCl_2(Ph_3P)_2\{CdCl_2P_2\}$, $Cd(HCO_2)_2tu_2\{CdO_2S_2\}$
5	$[Co(NH_3)_6][CdCl_5]$ $\{CdCl_5\}$, $Cd(S_2CNEt_2)_2\{CdS_5\}$, $CdSO_4tu_3\{CdS_4O\}$, Cd(thioglycollate)$_2\{CdS_4O\}$, CdI_2(py N-oxide) CdI_3O_2
6	CdO $\{CdO_6\}$, $[Cd(H_2O)_6]$ $\{CdO_6\}$, Cd(acac)$_2\{CdO_6\}$, [Cd(imidazole)$_6$]$(NO_3)_2\{CdO_6\}$, [Cd(en)$_3$]$S_2O_3\{CdN_6\}$, $NH_4CdCl_3\{CdCl_6\}$, $RbCdBr_3\{CdBr_6\}$, $CdCl_2$(urea)$_2\{CdCl_4O_2\}$, $CdCl_2$(imidazole) $\{CdCl_5N\}$, $CdBr_2py_2\{CdBr_4N_2\}$, $Cd(NCS)_2\{CdN_2S_4\}$, Cd(glycinate)$_2\cdot H_2O$ $\{CdO_4N_2\}$, Cd(L-methioninate)$_2\{CdO_4N_2\}$, Cd(histidinate)$_2\{CdO_2N_4\}$
7	$Cd(MeCO_2)_2\cdot 2H_2O$ $\{CdO_7\}$, Cd(salicylate)$_2\cdot 2H_2O$ $\{CdO_7\}$, $Cd(NO_3)_2py_2\{CdO_4N_2\}$, $Cd(NO_2)_2$en $\{CdO_4N_3\}$
8	$CdF_2\{CdF_8\}$, $Cd(NO_3)_2\cdot 4H_2O$ $\{CdO_8\}$, Cd(maleate)$\cdot 2H_2O$ $\{CdO_8\}$, Cd(1,8-naphthpyridine)$_4(ClO_4)_2\{CdN_8\}$

cations give Cd^{2+} coordinated by six chlorides. Cd^{2+} is found tetracoordinated in $RbCdI_3\cdot H_2O$ or in tetralkylammonium salts in which dinuclear (*see Dinuclear*) $[X_2CdX_2CdX_2]^{2-}$ anions are present. $Cd(CN)_2$ and CdS_2 have CdC_2N_2 and CdS_4 cores, respectively. Most CdX_2L_2 complexes show a coordination number higher than 4, but a distorted tetrahedral geometry is found in CdX_2L_2 ($X = I^-$, Cl^-) when L is a P- or S-donor.[29] Cd^{2+} is five coordinated in the monomeric $[Cd(NCS)_2L]$ (L = bis(2-dimethylaminoethyl)methylamine), in $CdCl_5^{3-}$ (D_{3h} symmetry) and in [Cd(*o*-ethylxantato)$_3$]$^-$ (CdS_5 core). A very large number of Cd compounds are six coordinated, for example, $[Cd(H_2O)_6]^{2+}$, [Cd(acac)$_2$], and [Cd(acac)$_3$]$^-$ have a CdO_6 core. Six-coordinated CdN_6 ions are formed with mono- and bidentate ligands such as imidazole, en, and thiocarbohydrazide. In the solid state, CdX_2 ($X = Cl^-$, Br^-, I^-) compounds are six coordinated. Halide adducts of the type CdX_4L_2 are common; halogen bridging leads to an approximately octahedral Cd^{2+} for Cl^- and Br^-, but I^- gives either four and five-coordinated Cd^{2+}. A few seven-coordinated compounds are known, but none is mononuclear or involves monodentate ligands (*see Monodentate Ligand*). In the solid state, each Cd^{2+} ion in $[Cd(H_2O)(CH_3OC_6H_4COO)_2]_n$ is seven coordinated in a distorted pentagonal bipyramidal (*see Pentagonal Bipyramid*) geometry. In [Cd(tea)$_2$](sac)$_2$ (tea = triethanolamine, sac = saccharinate anion), the cation [Cd(tea)$_2$]$^{2+}$ adopts a monocapped trigonal prism (*see Trigonal Prism*) geometry and the seven coordination is achieved acting the former tea ligand as tetradentate (*see Tetradentate Ligand*) and the latter as tridentate (*see Tridentate Ligand*). A monocapped trigonal prism (*see Trigonal Prism*) geometry is found also in $[Cd_4(TCPM)_2(DMF)_4]\cdot 4DMF\cdot 4H_2O$ (TCPM = tetrakis(4-carboxyphenyl)methane) that contains a tetranuclear Cd-carboxylate cluster (*see Cluster*).[31] Eight coordination is rare. CdF_2 contains a CdF_8 core in a fluorite structure. In $Cd(NO)_3\cdot 4H_2O$, the four water molecules are square planar (*see Square Planar*) and bidentate NO_3^- anions lie above and below this plane. The structure of Cd(tea)$_2(NO_3)_2$ (tea = triethanolamine) reveals eight-coordinated Cd^{2+} in a distorted hexagonal bipyramidal geometry.

14 COMPOUNDS

14.1 Cd^{I} Compounds

Few compounds of Cd^{I} have been prepared and identified. In melts of LiCl/KCl or $NaAlCl_4$, Cd and $CdCl_2$ react to give Cd_2^{2+}. Solid $Cd_2(AlCl_4)_2$ has been isolated from molten $NaAlCl_4$ by reduction of $Cd(AlCl_4)_2$ with Cd. Spectroscopic and X-ray studies (*see* ***Diffraction Methods in Inorganic Chemistry***) indicate the presence of Cd_2^{2+} ($d_{Cd\text{–}Cd} = 2.576$ Å) and $AlCl_4^-$ units: three Cl atoms of each $AlCl_4^-$ unit weakly bridge each Cd atom, which reveals a distorted tetrahedral (*see Tetrahedral*) coordination.[32] A complex containing a Cd–Cd bond can be synthesized by reaction between $CdCl_2$ and $LiBHEt_3$ in the presence of Tl[HB(3,5-Me$_2$pz)$_3$] (pz = pyrazolyl ring). No X-ray structure is available but NMR studies indicate a strong bond between Cd atoms. Cd_2^{2+} ion was obtained in aqueous solution (O_2 free) by reaction of $Cd(ClO_4)_2$ or $Cd(O_3SCF_3)_2$ with Cd powder and the redox properties evaluated: E° for Cd(II,I) = −0.45 V and E° for Cd(I,0) = −0.35 V.[33] Cd^+ and Cd_2^{2+} ions have been observed in fully Cd^{2+}-exchanged zeolite A (*see* ***Zeolites***) after exposure to Cd vapour. Cd^+ can be generated in water *via* pulse radiolysis (*see Pulse Radiolysis*).[34] Cd^{2+} is rapidly reduced by $[e_{aq}]^-$ or $[CO_2^\bullet]^-$ to give Cd^+, which rapidly dimerizes to Cd_2^{2+}. This species is unstable and decomposes in Cd and Cd^{2+}. Cd^+ is oxidized to Cd^{2+} by alkyl and $OH^\bullet$ radicals. $[CdL]^+$ (L = [14]ane-1,4,8,11-N_4) was prepared by pulse radiolysis (*see Pulse Radiolysis*).[2] Cd^+ and Cd_2^{2+} species have been identified using ^{113}Cd NMR relaxation measurements by adding Cd to CdI_2.[2]

14.2 Cd^{II} Compounds

14.2.1 Hydrides

Cd does not dissolve hydrogen in any significant quantities (*see* ***Hydride Complexes of the Transition Metals***).[35] CdH_2 is quite unstable at room temperature, but its decomposition

is slow below 253 K (*see* ***Hydrides: Solid State Transition Metal Complexes***). It can be obtained in organic solvents as shown in equation (1) and (2):

$$LiAlH_4 + 2CdR_2 \longrightarrow 2CdH_2 + LiAlR_4 \quad (1)$$

$$2LiAlH_4 + CdI_2 \longrightarrow CdH_2 + 2AlH_3 + 2LiI \quad (2)$$

Gaseous CdH, CdD, CdH^+, and CdD^+ are known, but not gaseous CdH_2.[35] The Cd hydride complex Cs_3CdH_5 has been isolated and characterized.[36] It can be synthesized by reaction of CsH_2 with metal Cd at high temperature and pressure. A tetragonal Cs_3CoCl_5-type structure containing tetrahedral (*see Tetrahedral*) $CdH_4{}^{2-}$ units has been proposed with a Cd–D bond distance of 1.82 Å. In several complexes, Cd–H bond has been observed.[37]

14.2.2 Halides

All four halides (*see* ***Halides: Solid-state Chemistry***) are known (Table 7).[1] CdF_2 has a fluorite structure and is more ionic than the other halides, which have a substantially covalent nature (*see Covalent Bonds*) and a layer structure.[38] In fact, CdF_2 shows higher melting and boiling points and lower solubility. $CdCl_2$, $CdBr_2$, and the α form of CdI_2 consist of cubic close-packed halides with Cd^{2+} in octahedral sites between alternate pairs of layers. In the β form of CdI_2, however, the stacking of iodine layers follows the pattern ABACAB.[38] Unlike the other halides, CdF_2 is not soluble in ethanol, ether, and anhydrous ammonia. CdF_2 and CdI_2 do not form hydrate (*see Hydrates*) while $CdCl_2$ and $CdBr_2$ can crystallize with 4, 2.5, or 1 and 4 or 1 water molecules, respectively. On heating, these hydrate species (*see Hydrates*) generally change into basic halides. CdF_2 may be prepared by reaction between aqueous HF and $CdCO_3$. Several methods are known to obtain $CdCl_2$:[1] (i) reaction between $Cd(OH)_2$ and thionyl chloride; (ii) reaction between $Cd(CH_3COO)_2$ and acetyl chloride in glacial acetic acid; (iii) reaction between metal Cd and gaseous HCl at 450 °C; (iv) reaction between $Cd(NO_3)_2{\cdot}4H_2O$ and concentrated HCl. $CdBr_2$ and CdI_2 may be prepared by direct reaction of the elements.[1] $CdBr_2$ may also be obtained by reaction between $Cd(CH_3COO)_2$ and acetyl bromide in glacial acetic acid. Oriented CdI_2 crystals have been prepared by reaction of gaseous HI with an Langmuir-Blodgett film of cadmium arachidate. Doped cadmium halide crystals have been grown and characterized.[39] $CdCl_2$, $CdBr_2$, and CdI_2 form auto-complexes in aqueous solution.

14.2.3 Pseudohalides

White $Cd(CN)_2$ is sparingly soluble in water, except in the presence of CN^- ions, owing to the formation of soluble anionic complexes.[1] On heating it darkens and decomposes at about 200 °C. $Cd(CN)_2$, like $Zn(CN)_2$, has a cubic anti-cuprite structure. Colorless cadmium thiocyanate is sparingly soluble in water, ethanol, and liquid ammonia. In the solid, Cd^{2+} is surrounded by an N_2S_4 octahedron. Cadmium thiocyanate polymers exhibit highly anisotropic physical properties.[40] Yellow $Cd(N_3)_2$ is prepared by mixing solutions of $Cd(NO_3)_2$ and NaN_3. The crystals are orthorhombic and decompose with detonation when heated. Cadmium pseudohalides (*see Pseudohalide*) may be prepared by metathesis (equation 3).

$$CdSO_4 + Ba(SCN)_2 \longrightarrow BaSO_4 + Cd(SCN)_2 \quad (3)$$

14.2.4 Oxides

CdO is obtained by burning the metal in air or by pyrolysis of nitrates, carbonates, formate, or oxalate;[1] the last two, in

particular, give rise to a particularly finely divided form (*see* ***Oxides: Solid-state Chemistry***). Oxide smoke are formed by combustion of cadmium alkyls. Large single crystals may be prepared hydrothermally. Heat treatment of the oxide produces dramatic changes in electrical properties. CdO color depends on the preparation method and varies from green-yellow to brown or nearly black. It does not melt but sublimes without decomposition at very high temperature (the sublimation pressure is 1 atm at 1559 °C). The crystals are cubic of NaCl type ($a = 4.695$). CdO acts a catalyst in gas reactions and as an intrinsic n-type semiconductor (*see* ***Semiconductor Interfaces***) (Band Gap (*see Band Gap*) energy 222 $kJ\,mol^{-1}$). Large third-order nonlinear optical properties are shown by cadmium oxide thin films. CdO is insoluble in water and alkali solutions but dissolves in acids and aqueous NH_3. Several mixed cadmium oxides are isostructural with their zinc analogs. The peroxide CdO_2 shows a cubic structure of pyrite type ($a = 5.27$), with Cd^{2+} coordinated by six oxygens. Physical properties of CdO and CdO_2 are reported in Table 8.

14.2.5 Hydroxides

$Cd(OH)_2$ is precipitated from aqueous Cd^{2+} by addition of bases.[1] It is colorless and soluble in acids and aqueous NH_4Cl, but only slightly in NaOH solutions. $Cd(OH)_2$ is a base stronger than $Zn(OH)_2$; its solubility product is $10^{-4.4}$ and log K for the equilibrium $Cd^{2+} + OH^- = CdOH^+$ is 6.38. $Cd(OH)_2$ begins to undergo thermal decomposition at about 150 °C (at 200 °C it is complete). Several basic salts are known and may be prepared from alkaline Cd^{2+} solutions or by heating CdO with solutions of Cd^{2+} salts at 200 °C. Hydroxide halides have been carefully investigated both in solution and in solid state.[41] Physical properties of $Cd(OH)_2$ are reported in Table 8.

14.2.6 Sulfide, Selenide and Telluride

CdS may exhibit different structures and its color varies from yellow to orange-brown.[1,42] The stable α-form (greenockite) has a wurtzite type structure. The β-form, however, shows a cubic zinc blende structure. At 20 kbar, CdS adopts a rocksalt form. By doping with other metals or organic molecules it may become luminescent (*see* ***Luminescence***). Crystalline CdS is obtained by reactions of Cd vapour in presence of H_2S at 800 °C. Due to the good lattice match between cubic CdS and Au, low Miller-index planes of Au have been used to template the growth of CdS monolayers. CdS nanoparticles have been formed both in Langmuir-Blodgett films and on graphite surface. CdS nanorods have been synthesized by reaction between CS_2 and $CdCl_2$ in ethylenediamine aqueous solution.[43] The disulfide CdS_2 prepared at high pressure has a pyrite structure. Amorphous polysulfides are also known.[42] Mixed sulfides are obtained by partially replacing of Cd^{2+} with M^{3+} or M^{4+} ions. $CdCr_2S_4$ and $CdIn_2S_4$ exhibit a normal spinel structure, while $CdGa_2S_4$ adopts the so-called thiogallate structure. CdSe is a brown or green solid obtained by direct reaction between Cd and Se vapour;[1] two different forms are known: hexagonal with wurtzite type structure or cubic with zinc blende type structure. CdSe nanoparticles have been formed using different methods; also a synthesis based on pulsed sonoelectrochemical technique is known.[28] CdTe is black and may be prepared by reduction of cadmium tellurate with hydrogen or by treating $Cd(CH_3COO)_2$ with Na_2Te in CH_3COOH. CdTe thin films have been obtained by direct reaction of a CdS film with tellurium vapor. The structure of CdTe is cubic of zinc blende type, but at high temperature a hexagonal, wurtzite type form is stable. Both CdSe and CdTe are intrinsic semiconductors. A variety of mixed selenides and tellurides are known.[38] Physical properties of CdS, CdSe, and CdTe are reported in Table 9.

$S°$ ($J\,K^{-1}\,mol^{-1}$) (c)	64.9	–	100.4

14.2.7 Oxyacid Salts

$CdSO_4$ is soluble in water, but not in ethanol. It may be prepared as $CdSO_4 \cdot 8/3H_2O$ by dissolving CdO, CdS, or $CdCO_3$ in H_2SO_4. Metal Cd directly reacts with H_2SO_4 to give the sulfate; n water molecules ($n = 1$, 8/3, 4, 7) may be present and the monohydrate species is obtained by heating. Mixed sulfates $M_2Cd_2(SO_4)_3$ (M = K, NH_4, Rb, Tl) show a cubic structure, but $M_2Cd(SO_4)_2 \cdot 6H_2O$ (M = K, NH_4) is monocline.[4] $Cd(NO_3)_2$ is soluble in water, ethanol, and

acetone, but insoluble in concentrated HNO_3. $Cd(NO_2)_2$ decomposes at 150–230 °C and is obtained by reaction between $Ba(NO_2)_2$ and $CdSO_4$ in aqueous solution. Mixed species $MCd(NO_2)_3$ (M = K, NH_4, Cs, Rb, Tl) have a perovskite type structure.[2] $Cd(PO_4)_2$ is prepared by reaction between $Cd(NO_3)_2$ and KH_2PO_4 in the presence of NaOH. $CdCO_3$ separates in crystalline form on heating a solution containing $CdCl_2$ and $(NH_4)_2CO_3$ in the presence of ammonia. It decomposes at about 332–355 °C, is insoluble in water but dissolves in acids, cyanide (*see Cyanides*) and ammonium solutions. $Cd(ClO_4)_2{\cdot}6H_2O$ may be obtained by reaction between CdO and $HClO_4$. It is soluble in water and ethanol. $Cd(HCO_2)_2{\cdot}2H_2O$ forms monoclinic crystals and decomposes on heating without melting. $Cd(CH_3COO)_2$ is obtained in anhydrous form by heating $Cd(NO_3)_2$ with acetic anhydride. It may crystallize with 1, 2, or 3 water molecules; the hydrate forms become anhydrous at about 130 °C. Cd_2SiO_4 is obtained by fusion or hydrothermal synthesis of CdO and SiO_2. It is a white solid insoluble in water and becomes phosphorescent after activation with manganese. $CdSiO_3$ forms rhombohedral white crystals insoluble in water.

14.2.8 Nitride, Amide, Phosphide, Arsenide, and Antimonide

Cd_3N_2 is a black solid, oxidizable in air and characterized by a cubic, anti-Tl_2O_3 type structure (*see* ***Nitrides: Transition Metal Solid-state Chemistry***). It is prepared by heating $Cd(NH_2)_2$ at 180 °C.[1] $Cd(NH_2)_2$ is an amorphous, slightly yellow, air-sensitive solid obtained by reaction of $Cd(SCN)_2$ and KNH_2 in liquid ammonia.[1] Three distinct cadmium phosphides are known (*see* ***Phosphides: Solid-state Chemistry***).[1] Cd_3P_2 forms grey, lustrous needles or leaflets with a distorted anti-Tl_2O_3 type structure. It is soluble in HCl with an evolution of PH_3 and gives an explosive reaction with HNO_3. Cd_3P_2 is obtained by heating Cd and P in a 3:2 molar ratio at 400–600 °C. Crystalline nanoclusters (*see Cluster*) have been synthesized using a sol-gel like route. CdP_2 forms orange or red tetragonal needles. It is prepared by fusion of Cd and P in a 1:2 molar ratio. CdP_4 forms black, highly reflective, monoclinic crystals. It decomposes into the elements on heating in vacuum and dissolves in boiling aqua regia. It is prepared by heating a Cd/Pd alloy with white phosphorous. Two arsenides of cadmium are known,[38] Cd_3As_2 and $CdAs_2$. Cd_3As_2 is obtained by heating the metal in a stream of hydrogen and arsenic vapour. It is a grey solid, isostructural with Cd_3P_2. It is a semiconductors which exhibits n-type intrinsic conductivity. $CdAs_2$ is prepared in the same way as CdP_2; it is a grey-black solid, harder than Cd_3As_2. Cadmium arsenide chlorides are known. In particular, Cd_8As_7Cl exhibits a peculiar type of crystal structure (*see Crystal Structures*).[44] Two antimonides, Cd_3Sb_2 and CdSb, have also been synthesized.[38] A deformed diamond-like structure characterizes CdSb.[38]

14.2.9 Cadmium-metal Compounds

Volatile $Cd(SiEt_3)_2$ and $Cd(GeEt_3)_2$ contain Cd-Si and Cd-Ge bonds, respectively.[45] Cd is linked to Sn in $[(Me_3SiCH_2)Sn]_2Cd$ and in $[(Ph_3Sn)_2CdL_2]$ (L = bipyridyl, dimethoxyethane or tetramethylenediamine). In several Cd-transition metal derivatives of the type $LCd[ML_n]$ or $Cd[ML_n]_2$, Cd^{2+} forms one or two covalent bonds (*see Covalent Bonds*) to a transition metal ion that bears ligands (*see Ligand*).[45] L may be carbon oxide, halide, pseudohalide (*see Pseudohalide*), or an organic group; M is generally chromium, manganese, iron, cobalt or nickel. Examples are $Cd[Mn(CO)_5]_2$, $Cd[Co(CO)_4]_2$, $Cd[Fe(CO)_2(\pi\text{-}C_5H_5)]_2$ and $Cd[Cr(CO)(\pi\text{-}C_5H_5)]_2$. A Cd_4Fe_4 ring characterizes the structure of $[CdFe(CO)_4]_4{\cdot}(Me_2CO)_2$. Dative Pt(II)→Cd(II) bonds have been observed in $[\{Pt(phpy)_2\}\{Cd(cyclen)\}](ClO_4)_2$, $[\{Pt(CH_3)_2(bipy)_2\}\{Cd(cyclen)\}](ClO_4)_2$, and $[\{Pt(thpy)_2\}\{Cd(cyclen)\}](ClO_4)_2$ where Hphpy = 2-phenylpyridine, cyclen = 1,4,7,10-tetraazacyclododecane, bipy = 2,2′-bipyridine, Hthpy = 2-(2-thienyl)pyridine. An unusual decanuclear cluster (*see Cluster*) containing Pt-Cd interactions has been synthesized by reaction between $Cd(ClO_4)_2{\cdot}6H_2O$ and $(NBu_4)_2[Pt(C{\equiv}CPh)_4]$.[46] Intermetallic compounds (*see Intermetallics*) are known: examples are $K_{0.4}Cd_2$, $Na_{26}Cd_{141}$, $Na_8K_{23}Cd_{12}In_{48}$.

14.2.10 Cadmium Glasses

Cd may be present in glasses as Cd, CdO, CdS, and CdF_2.[47] Metallic Cd is formed by reduction in the absence of an excess of sulfur in sulfocadmium glasses. This fact gives a gray or black opacity, similar to that caused by Pd (color firing). A certain electrical conductivity is shown by lithium–cadmium–phosphate glasses.

15 Cd^{II} COORDINATION CHEMISTRY

15.1 Halides and Pseudohalides

In solution, CdX_2(X = Cl, Br, I) gives complex equilibria involving species of the type $CdX_n^{(2-n)}$.[2] The nature of the solvent medium strongly affects the species distribution. In fact, in aqueous solution, $[Cd(H_2O)_6]^{2+}$, $[Cd(H_2O)I]^+$, $[CdI_3]^-$ and $[CdI_4]^{2-}$ are formed but in DMSO, the main species are $[Cd(DMSO)_6]^{2+}$, $[Cd(DMSO)_nI]^+$, $[CdI_3]^-$, and $[CdI_4]^{2-}$. In both the solvents, $[CdI_3]^-$ and $[CdI_4]^{2-}$ maintain the trigonal and tetrahedral (*see Tetrahedral*) geometry and no evidence for additional solvent coordination is observed. In DMSO, the distance Cd–I in $[CdI_4]^{2-}$, $[CdI_3]^-$, and $[Cd(DMSO)_nI]^+$ is 2.790, 2.773, and 2.75 Å, respectively. Similar equilibria are found in the case of $CdCl_2$ and $CdBr_2$, but also the species $[CdCl_5]^{3-}$ has

been observed. In aqueous solution, the role of the hydration sphere in the equilibria involving CdX_2($X = Cl$ or Br) has been investigated through experimental and theoretical methods: the results are consistent and suggest that CdX^+ and CdX_2 are strongly hydrated to form a pseudooctahedral (*see Octahedral*) structure around Cd^{2+}, CdX_3^- is weakly hydrated, and CdX_4^{2-} is almost fully unhydrated. In water, DMF, acetone, and ROH solvents, the anion donor strength follows the order $I^- > Br^- > Cl^-$.[2] Stability constants of halide complexes in several solvents have been determined.[48] A trigonally distorted $CdBr_6$ octahedral (*see Octahedral*) structure characterizes $Cs[CdBr_3]$ in solid phase. Complexes of the type $[CdX_2(C_5H_4NCOOR)_n]$ ($n = 1, 2$) may be obtained by reaction between esters of 2-pyridinecarboxylic acid and CdX_2 ($X = Cl$, Br, I). In the case of $[CdI_2(C_5H_4NCOOR)_2]$, Cd^{2+} shows a distorted octahedral (*see Octahedral*) structure with $CdI_2N_2O_2$ coordination *core*. In aqueous Cd^{2+}–CN^- system, the species $[Cd(CN)_n]^{(2-n)}$ ($n = 1-4$) have been observed with no evidence for the presence of species with $n > 4$. Stepwise complexation pattern in liquid ammonia have been established by IR and Raman spectroscopy. $Cd(CN)_2{\cdot}2/3H_2O{\cdot}t$-BuOH with 3D honeycomb-like $[Cd(CN)_2]_n$ structure is obtained by recrystallization of cadmium cyanide (*see Cyanides*) in aqueous *ter*-buthyl alcohol. On exposure to chloroform vapour, the $[Cd(CN)_2]_n$ framework undergoes a large-scale reorganization and gives a diamond-like structure with $CHCl_3$ in the interstices. In water, the complexes $[Cd(SCN)_n(H_2O)_x]^{(2-n)}$ ($n = 1-4$) have been detected but no polynuclear species. The solvent plays a certain role in the binding ability of SCN^-: in $[Cd(SCN)_2]$ and $[Cd(SCN)_3]^-$, the anion coordinates the metal ion through nitrogen in water and through sulfur in DMSO.[2] $[Cd_2(pn)_2(SCN)_2]$ is polymeric with bridging SCN^-. In $[Cd(en)_2(SCN)_2]$ and $[Cd(en)_2(SCN)Cl]$, SCN^- ion is monodentate via nitrogen, but the complexes have *trans* and *cis* octahedral (*see Octahedral*) structure, respectively. High-resolution ^{113}Cd MAS NMR spectroscopy has been successfully used to investigate the structure of a variety of cadmium thiocyanate coordination compounds in the solid state. The results indicate a correlation between Cd–N distances and values of the Cd–N indirect spin-spin coupling constants.[19] Unusual structures have been observed in hybrid crystalline materials based on the anionic $[Cd(SCN)_3^-]_\infty$ polymeric complex and a cationic host-guest complex such as a Cd^{2+}–crown ether (*see Crown Ethers*) system.[49] Stability constants of selected Cd^{2+}–halide and –pseudohalide (*see Pseudohalide*) complexes are given in Table 10.

Table 10 Stability constants for Cd^{2+}-halide (or pseudohalide) systems in water

Ligand	$\log K_1$	$\log K_2$	$\log K_3$	$\log K_4$
F^-	1.15	0.41	0.98	–
Cl^-	1.77	0.80	0.64	−0.2
Br^-	1.77	0.56	1.00	0.76
I^-	1.96	1.33	1.15	1.44
CN^-	5.62	5.18	4.90	3.50
SCN^-	1.16	0.33	0.14	0.02

15.2 Oxygen Donor Ligands

Stability constants for Cd^{2+}–oxygen ligand (*see Ligand*) systems are reported in Table 11. Cd^{2+} in aqueous and solid $Cd(ClO_4)_2{\cdot}6H_2O$ is coordinated by six water molecules ($d = 2.31$ Å).[2] The Cd^{2+} ion is easily hydrolyzed in water to give the equilibria shown in equations (4) and (5): the former prevails when $[Cd^{2+}] < 0.1$ M, the latter at higher concentration.

$$Cd^{2+} + H_2O \longrightarrow CdOH^+ + H^+ \quad (4)$$

$$2Cd^{2+} + H_2O \longrightarrow Cd_2OH^{3+} + H^+ \quad (5)$$

NMR and IR studies indicate that in water and methanol the covalency of the metal-oxygen bond varies in the order $Hg < Cd < Zn$. Several mixed Cd^{2+}–hydroxide complexes are known. Multinuclear species containing Cd–(μ-OH)–M (M = Cd, Co or Cr) units have been structurally characterized. In the case of $[(bmnpaCd)_2(\mu\text{-}OH)_2](ClO_4)_2{\cdot}CH_3CN$ (bmnpa = N,N-bis-2-(methylthio)ethyl-N-((6-neopenthyl-amino-2-pyridyl)methyl)amine), the reaction with CO_2 gives a mixed carbonate complex: $[(bmnpaCd)_2(\mu\text{-}CO_3)_2](ClO_4)_2{\cdot}CH_3CN$. $Cd(MeSO_3)_2{\cdot}2H_2O$ may be prepared by reaction of $CdCl_2$ and $MeSO_3H$ in water. In $Cd_2SO_4(OH)_2$, Cd^{2+} lies in a highly distorted CdO_6 environment, while a CdO_7 *core* is found in $Cd(BrO_3)_2{\cdot}2H_2O$. Complexes of the type $[Cd(H_2O)_{(6-n)}(SO_4)_n]^{(2-2n)}$ are observed in concentrated aqueous solution of cadmium sulfate. In the crystalline structure (*see Crystal Structures*) of $CdSO_4$, a very distorted CdO_4 tetrahedron is found while solid $Cd_2(NH_4)_2(SO_4)_3$ is characterized by two nonequivalent Cd^{2+} octahedral (*see Octahedral*) sites. Templated linear and layered Cd^{2+}–sulfate complexes have been obtained by reaction between cadmium salts and H_2SO_4 in the presence of organic amines. In $M[Cd(S_2O_3)_2]$ ($M = NH_4$ or Rb), the ligands (*see Ligand*) behave as bidentate (*see Bidentate Ligand*) through O and S. Cd^{2+} interacts with nitrite in aqueous solution to give

Table 11 Stability constants for Cd^{2+}-O-donor ligand in water

Ligand	$\log K_1$	$\log K_2$	$\log K_3$	$\log K_4$

$[Cd(NO_2)_n]^{(2-n)}$ ($n = 1$–4). For $n = 1$ or 2, nitrite acts as an O-bidentate ligand but for $n = 3$ or 4, monodentate nitrite is also found. In aqueous solutions of $Cd(NO_3)_2$ spectroscopic measurements suggest the presence of $[Cd(H_2O)_5(NO_3)]^+$ ion.[2] Solid trihydrate species contains an eight-coordinate Cd^{2+}. Cd^{2+}–nitrate coordination polymers of different dimensionality have been synthesized: $[Cd(NO_3)_2$(1,2-bis(4-pyridyl)ethine)$_{1.5}]_n$ has an infinite one-dimensional structure in which Cd^{2+} lies in a heptacoordinate environment, $[Cd(NO_3)_2$(1,4-bis(4-pyridoxy)benzene)$_{1.5}]_n$, however, is characterized by a two-dimensional network in which Cd^{2+} has a pentagonal bipyramidal (*see Pentagonal Bipyramid*) geometry. In $Cd(PO_3)_2$ and $CdBa(PO_3)_4$, Cd^{2+} is octahedral (*see Octahedral*). In $Cd_3(P_3O_9)_2{\cdot}14H_2O$ the anion consists of discrete cyclic trimetaphosphate units; in each, Cd^{2+} is octahedrally surrounded by four phosphate oxygen and two water molecules. Layered cadmium-phosphonates have been obtained and their structure solved: in $Cd(O_3PR){\cdot}H_2O$ and $Cd(O_3PC_2H_4NH_2)$ the layer arrangement is similar, the only difference being the replacement of the coordinated water molecule with the nitrogen atom of $O_3PC_2H_4NH_2{}^{2-}$. Formate anion acts as a bridging ligand (*see Bridging Ligand*) in $Cd(HCO_2)_2$ and $Cd(HCO_2)_2{\cdot}2H_2O$; in the former, Cd^{2+} is seven-coordinate, but in the latter it is octahedral (*see Octahedral*). Systems of the type $Cd(HCO_2)_2{\cdot}M(HCO_2)_x$ are well known.[2] In $Cd(MeCO_2)_2{\cdot}2H_2O$, the acetate ions act as bridging ligands (*see Bridging Ligand*).[50] The structure of $[Cd(MeCO_2)_2(tu)]$ indicates Cd^{2+} six-coordinate by one bidentate and two bridging bidentate acetate groups and by two bridging sulfur atoms of two thiourea (*see Thiourea*) groups.[50] A Cd^{2+}–oxalate polymeric species $Cd(C_2O_4){\cdot}3H_2O$ is obtained by slow decomposition of ascorbic acid in presence of Cd^{2+}. The metal ion is found in a $\{CdO_7\}$ distorted pentagonal bipyramidal (*see Pentagonal Bipyramid*) geometry due to five oxalate and two water oxygens. In cadmium cyanoacetate, Cd^{2+} lies in a NO_5 octahedron.[4] $[CdL_2(H_2O)_n]_m$ (HL = phenylthioacetic acid) has a polymeric structure with Cd^{2+} in an O_5S octahedron. A polymeric structure with bridging oxalate groups has also been observed in $[Cd(C_2O_4)L_2]$ (L = substituted pyridines or 4-toluidine). Cd^{2+} is found in seven-coordinate pentagonal bipyramidal (*see Pentagonal Bipyramid*) O_7 and O_4N_3 environments in $[Cd(SalH)_2(H_2O)_2]_2$ and $[Cd(SalH)_2(py)_3]$, respectively.[50] Other examples of seven-coordinate Cd^{2+} are known.[2,51] Cadmium maleate dihydrate contains both six and eight-coordinate Cd^{2+}. Cd^{2+}–succinate complexes of different dimensionalities may be obtained employing organic amines.[52] The Cd^{2+}–citrate system in aqueous solution includes the species $[Cd(CitH_2)]^+$, $[Cd(CitH)]$, $[Cd(Cit)]^-$, and $[Cd(Cit)_2]^{4-}$.[50] $[Cd(CitH)(H_2O)]_n$ crystallizes in the orthorhombic space group and Cd^{2+} is octahedrally coordinated to citrate molecules and one water molecule. Citrate acts as a tridentate ligand (*see Tridentate Ligand*) through the central and one terminal carboxylate group and the alcoholic oxygen. The complex $[CdLCl_2]$ (L = pyridoxine) consists of infinite chains of chloro-bridged Cd^{2+} in a $CdCl_3O_3$ environment. Each pyridoxine acts as a bidentate ligand through two oxygen donors and a third oxygen of the ligand bridges another Cd^{2+}. $[CdI_2L]$ (L = pyridine N-oxide) has a trigonal bipyramidal (*see Trigonal Bipyramidal*) structure characterized by infinite chains of [CdI] units alternately bridged through two I atoms and two O atoms. In CdL_3Cl_2($L = OP(NH_2)_3$), Cd^{2+} is hexacoordinate and L acts as a N,O chelate. $[Cd(O_2SR)_2L]$ (L = bipy or phen) and $[Cd(O_2SR)_2L_2]$ (L = bipy or en) are pseudooctahedral; sulfinate acts as bidentate in the former and monodentate in the latter. $[Cd(NCS)_2(urea)_2]$ shows Cd^{2+} in a distorted octahedral configuration forming chains bridged by thiocyanate ions.[2] Bidentate acetate and six-coordinate Cd^{2+} ions have been observed in $[Cd(MeCO_2)_2(urea)_2]$. Synthesis and structure of $[Cd(3,3'\text{-AZDB})_2](H_2Nme_2)(NH_4)$, a complex characterized by interpenetrating diamond networks, have been reported.[53] Cd^{2+} lies in a height-coordinate environment with a tetragonal antiprismatic geometry. In $[Cd(acac)_2(bipy)]$, all the ligands are bidentate, while in $[Cd(acac)(bipy)(H_2O)]$ water is also coordinated to Cd^{2+} and acac acts as a monodentate. Both the compounds show a distorted octahedral (*see Octahedral*) structure, more marked for the bipy adduct.[2] Discrete $[Cd(acac)_3]^-$ units have been identified in $KCd(acac)_3{\cdot}H_2O$, in which Cd^{2+} is trigonal prismatic (*see Trigonal Prism*). A number of dimethylphosphine oxide complexes of cadmium with halides have been obtained.[50] The complex $[CdL_2(THF)_2]$ (HL = 2,6-t-$Bu_2C_6H_3OH$) shows an unusual square-planar Cd^{2+} structure, in which the metal ion is coordinated to four oxygen atoms. This compound was isolated from THF (equation 6).

$$Cd[N(SiMe_3)_2]_2 + 2HL + 2THF \longrightarrow [CdL_2(THF)_2] + 2HN(SiMe_3)_2 \quad (6)$$

Cd^{2+} reacts with 3,5-di-t-buthyl-1,2-o-benzoquinine to form a biradical compound which can add a neutral N-donor ligand (py or bipy) to give 1:1 and 1:2 adducts.

15.3 Sulfur Donor Ligands

Selected stability constants for Cd^{2+}–sulfur ligand systems are reported in Table 12. Heterometallic ion $[Mo_3CdS_4(H_2O)_{12}]^{4+}$ may be obtained by reaction of $[Mo_3S_4(H_2O)_9]^{4+}$ with Cd^{2+} in the presence of a reductant

Table 12 Stability constants for Cd^{2+}-S-donor ligand in water

Ethyl thioacetate	1.27	0.85	0.39	0.21

or with metal Cd in *p*-toluenesulfonic acid aqueous solution. Polymeric compounds of the type $[Cd(RS)_2]_n$ are obtained from electrochemical oxidation of Cd anodes in CH_3CN containing RSH or RSSR.[2] In the polymeric cadmium thiolate of the type $Cd(SC_6H_4R)_2$, nature, and position of the substituent R determine the dimensionality of the structure. In the case of aliphatic thiolates, one, two, and three-dimensional structures have been observed. In *catena*-bis[μ-(N-methylpiperidinium-4-thiolate)] cadmium perchlorate dihydrate, each Cd^{2+} is found in a CdS_4 environment, the structure is characterized by infinite chains of Cd^{2+} ions bridged by sulfur atoms.[2] Polynuclear complexes (*see Polynuclear Complexes*) are observed in a solution of Cd^{2+} and 3-(dimethylamino)-1-propanethiol (HL). In the pH range 3–11, the predominant species are $[Cd(HL)_4]^{2+}$, $[Cd_3(HL)_6]^{6+}$, $[Cd_3(HL)_8]^{6+}$, $[Cd_4(HL)_9]^{8+}$, and $[Cd_4(HL)_{10}]^{8+}$. Both mononuclear and polynuclear species can be formed by ligand deprotonation. Clusters (*see Cluster*) of the type $[ECd_8(E'Ph)_{16}]^{2-}$ (E, E′ = S, Se, Te) have been identified using ^{113}Cd NMR. $[ClCd_8\{SCH(CH_2CH_2)_2N(H)Me\}_{16}](CLO_4)_{15}\cdot 16H_2O$ exhibit an unusually high cationic charge and a peculiar structure.[18] The thioacetate complex $[Ph_4P][Cd(SC\{O\}CH_3)_3]$ has been synthesized and the structure determined. Cd^{2+} is strongly bound to the sulfur atoms of three thioacetate anions and weakly to the corresponding oxygen atoms of the carbonyl groups. Thiocarboxylate complexes with 4,4′-bipyridine have a polymeric structure.[54] The complexes $[Cd(HL)_2X_2]$ (X = Cl, Br, I), $[Cd(HL)_3](ClO_4)_2\cdot 2H_2O$ and $[CdL_2]$ (HL = 4,6-dimethyl-2(1H)-pyrimidinethione) have been synthesized.[2] A polymeric structure with a bridged halogen characterizes $[Cd(HL)_2X_2]$. In $(Et_4N)[CdL_3]$ (HL = benzothiazole-2(3*H*)-thione) the ligand L is bidentate through N and S. 1,4,6-trimethylpyrimidine-2-thione (L) and 1-methylpyrimidine-2-thione (L′) form halogenated complexes with Cd^{2+}.[51] In $[CdL_2X_2]$ (X = Cl, Br) and $[CdL'_2X_2]$ (X = Br, I), the ligands act as bidentate through N,S atoms. $[CdL_2Cl_2]$ (L = 2-thiouracil) shows a pseudotetrahedral structure. In most of the cases, a stronger binding ability of aromatic versus aliphatic sulfur donor has been observed.[51] Cd^{2+} in $[Cd(thiooxinate)_2]$ is found in a distorted tetrahedral CdN_2S_2 environment. Pseudooctahedral Cd^{2+} is observed in $[Cd(ethylxantate)_2(phen)]$, in which the ethylxantate is bidentate. In cadmium thiodiacetate hydrate the ligand is an O_2S donor and the metal ion lies in a distorted octahedral geometry. In $Cd(NH_3)_3S_2O_3$ and $3Rb_2S_2O_3\cdot CdS_2O_3\cdot H_2O$, the thiosulfate acts as a monodentate S-donor, but in $Rb_2Cd(S_2O_3)_2$ it is bidentate. In $[Cd(CS_3)_2]^{2-}$, the ligand binds as bidentate to give a four-membered chelate ring.[2] In $[Cd(tu)_n](ClO_4)_2$ ($n = 4$ or 6), Cd^{2+} is bound through the S atom of the ligand. $[Cd(tu)_2Cl_2]$ is monomeric with the metal ion in a tetrahedral $CdCl_2S_2$ environment. In $[Cd(tu)_2(HCO_3)_2]$ and $[Cd(Ettu)_2(NCS)_2]$, Cd^{2+} is six coordinated with infinite chains bridged by sulfur ligands for the former and by the NCS^- ions for the latter. In the monomeric $[CdL_2Cl_2]$, L (= pyridyl-2-thiourea) binds through the pyridine nitrogen and thione sulfur atoms. $[Cd(tu)_2(MeCO_2)_2]$ exhibits a CdS_2O_4 arrangement. *N,N*-diehtyl- and *N,N*-dimethylthiourea form 1:1 and 2:1 complexes. The 1:1 complex reveals a polymeric, halogen-bridged structure with tetrahedral Cd^{2+}. Two types of 2:1 complexes have been isolated: one is monomeric with tetrahedral metal center; the other is polymeric, halogen-bridged with octahedral (*see Octahedral*) geometry. Cd^{2+} reacts with *N,N*-dimethyl- and *N,N*-dicyclohexyldithiooxamide (L) to give $CdLX_2$ when X = Cl, Br, I or CdL_2X_2 and CdL_3X_2 when X = ClO_4; the former are nonelectrolytes, while the latter are electrolytes; in all the cases the ligand L is bidentate through S and N atoms and in $CdLX_2$ the metal ion is octahedral with bridged halides.[2] Cadmium bis(*N,N*-diethyl-monothiocarbamato) complex $[Cd(OSCNEt_2)_2]_n$ is polymeric and crystallizes in monoclinic group; Cd^{2+} lies in a distorted trigonal-prismatic geometry and interacts with two S,O-bidentate and two O-monodentate ligands (*see Monodentate Ligand*). A structure intermediate between octahedral (*see Octahedral*) and trigonal prismatic (*see Trigonal Prism*) has been found for $(Bu_4N)[CdL_3]$ (HL = Et_2NCS_2H), where each dithiocarbamate (*see Dithiocarbamate*) chelates Cd^{2+} through two nonequivalent S atoms. Using an appropriate tetralkylammonium salt, complexes of the type $(NR_4)[Cd(S_2CNEt_2)_2X]$ (R = Et, X = Cl, Br, SCN; R = *n*-Bu, X = I) have been prepared in acetone by interaction between cadmium bis(dithiocarbamate) and halides or pseudoahalides. In $(Et_4N)[Cd(S_2CNEt_2)_2(SCN)]$, Cd^{2+} shows a distorted trigonal-pyramidal geometry. Bis(thiosemicarbazide)cadmium sulfate is polymeric with a sulfate-bridged structure in which the bidentate N,S-chelating thiosemicarbazide binds an octahedral Cd^{2+}. $[Cd(thiazolidine\text{-}2\text{-}thione)_2]$ exhibits a polymeric structure in which the ligand is bidentate through N,S atoms. In $[CdL_2L'_2]$ (HL = $(EtO)_2PS_2H$, L′ = hexamethylenetetramine), Cd^{2+} has a distorted octahedral geometry, but in $(Me_4N)[CdL_3]$ (HL = $(i\text{-}PrO)_2PS_2H$) a coordination intermediate between octahedral and trigonal prismatic (*see Trigonal Prism*) is found. Some Cd^{2+} complexes with crown thioethers (*see Crown Ethers*) are known; in $[(CdI_2)_2([24]aneS_8)]$ two CdI_2 units interact with the macrocycle (*see Macrocycle*). Each Cd^{2+} lies in a distorted trigonal bipyramidal environment and is bound to three consecutive S atoms of the macrocycle (*see Macrocycle*) and two I^- ions. In metallothioneins, sequences of the type Cys–Y–Cys are the primary binding sites for Cd^{2+}; the structure and properties of this kind of protein have been extensively investigated.[55,56]

15.4 Nitrogen Donor Ligands

Selected stability constants for Cd-nitrogen ligand systems are reported in Table 13. $[Cd(NH_3)_2X_2]$ (X = Cl, Br) is polymeric with Cd^{2+} octahedrally surrounded by two NH_3 and four bridged halogens. In $[Cd(NH_3)_6]X_2$, however, $[Cd(NH_3)_6]^{2+}$ octahedrons ($d_{Cd\text{–}N} = 2.37$ Å) characterize the structure.[2] The

Table 13 Stability constants for Cd^{2+}-N-donor ligand in water

cation $[Cd(NH_3)_6]^{2+}$ is found to be the prevailing species in aqueous solution of $CdCl_2$ when the molar ratio NH_3/Cd^{2+} is higher than 10. IR and Raman studies on $[Cd(NH_3)_4]^{2+}$ and $[Cd(NH_3)_6]^{2+}$ indicate that the binding strength increases with decreasing the coordination number. The crystal structure (*see Crystal Structures*) of $[Cd(NH_3)_2][Ni(CN)_4]$ shows two-dimensional polymeric sheets of $[Ni(CN)_4]^{2-}$ anions bridged by coordinating $[Cd(NH_3)_2]^{2+}$ ions. This unusual structural arrangement allows clathration of small aromatic molecules such as furan, pyrrole, pyridine, or thiophene, which interact via hydrogen bonds (*see Hydrogen Bonding*) with host lattice ammonias. Similar clathration ability is shown by $[Cd(py)_2][Ni(CN)_4]$. $[Cd(H_2N(CH_2)_8NH_2)][Ni(CN)_4]\cdot PhMe$ has a monoclinic structure in which toluene is found orientationally disordered within a rigid host cage. Cd^{2+} is found to be coordinated through the oxygen atom of $HONH_2$ in $[Cd(HONH_2)_2X_2]$ (X = Cl or Br) but through the N atom of $MeONH_2$ in $[Cd(MeONH_2)_2X_2]$ (X = Cl, Br, I). In aqueous solution, $[Cd(N_3)_n]^{(2-n)}$ ($n = 1$–5) and the mixed species $[Cd(NO_3)(N_3)_n]^{(1-n)}$ ($n = 1$–4) have been observed and the stability constants calculated.[2] Hydrazine in aqueous solution (80%) reacts with CdF_2 to give $(N_2H_5)_2(CdOF_2)$ but in anhydrous hydrazine $CdF_2\cdot 2N_2H_4$ and $CdF_2\cdot 3N_2H_4$ are formed in which the presence of double and triple hydrazine bridges has been suggested. $Cd(C_2O_4)(N_2H_4)\cdot 0.5H_2O$ and $Cd(C_2O_4)(N_2H_4)_2$ may be obtained by reaction between CdC_2O_4 and N_2H_4. In both the compounds hydrazine acts as a bridging ligand (*see Bridging Ligand*), but oxalate is ionic in the former case and bidentate in the latter. N-acylhydrazine derivatives act as N,O-chelate ligands (*see Chelating Ligands*) in complexes of the type $[CdX_2L]$ (X = NCS, NO_2, NCO, $1/2SO_4$; L = formyl-, benzoyl-, or nitrobenzoylhydrazine). $[Cd(PhNH_2)X_2]$ (X = Cl or Br) shows an octahedral Cd^{2+} environment, while in $[Cd_3(PhNH_2)_4Cl_6]$ two types of octahedral sites have been observed: $\{CdCl_6\}$ and $\{CdCl_4N_2\}$.[2] In $[CdCl_2(Ph_3P=NH)]_2$, $[CdI_2(Ph_3P=NH)_2]_2\cdot 2(CHCl_3)$ and $[Cd_2Br_4(Ph_3P=NH)_3]$ IR spectra indicate that $Ph_3P=NH$ acts as a N-donor. In the dimeric complexes the units are linked by *trans*-halogen bridges, while $[Cd_2Br_4(Ph_3P=NH)_3]$ is polymeric with halogen atoms bridging $[CdBr_2(Ph_3P=NH)_2]$ and $[CdBr_2(Ph_3P=NH)]$ structural units. In the aqueous Cd-en system, the prevailing species are $[Cd(en)_2]^{2+}$ and $[Cd(en)_3]^{2+}$ with tetrahedral and octahedral geometry, respectively. Complexes such as $[Cd(en)][Pd(CN)_4]$ and $[Cd(NH_3)_2][Pd(CN)_4]$ are able to form clathrate (*see Clathrate*) compounds and may accept two guest molecules of phenol, thiophene or benzene.[2] $[Cd(en)(NO_2)_2]$ is polymeric with a seven-coordinate Cd^{2+} in pentagonal prismatic geometry. Ethylenediamine and cadmium halides yield polymeric complexes with bidentate bridging en; with $Cd(CN)_2$, however, en gives 1:1 and 1:2 monomeric complexes, binding the metal ion as a bidentate chelating ligand. The polymeric $[Cd(en)(NO_3)_2(4,4'\text{-bipy})]_n$ has a zigzag chain structure bridged by bipyridine molecules. Cd^{2+} exhibits a distorted N_4O_2 octahedral geometry, being coordinated to one μ_2-en, two 4,4′-bipy, and two NO_3^- ions. The observed three-dimensional network is due to two kinds of N–H···O hydrogen bonds (*see Hydrogen Bonding*). A square pyramidal (*see Square Pyramidal*) five-coordinate Cd^{2+} has been found in [bis(2-dimethylaminoethyl)-methylamine] cadmium thiocyanate: the amines and one of the thiocyanate ligand occupy the basal positions while the second thiocyanate is apical. 1:1 complexes are formed by interaction of Cd^{2+} with $MeNH(CH_2)_3NH_2$, dien, $H_2N(CH_2)_2NH(CH_2)_3NH_2$ and $H_2N(CH_2)_3NH(CH_2)_3\ NH_2$. Unusual compounds are formed with tripod-like tetramines: the crystal structure (*see Crystal Structures*) of $Cd_2(Me_6tren)I_4$ reveals the presence of a five-coordinate cation $[CdI(Me_6tren)]^+$ with a slightly distorted trigonal bipyramidal (*see Trigonal Bipyramidal*) structure and of a dinuclear (*see Dinuclear*) anion $[Cd_2I_6]^{2-}$, formed from edge sharing between pairs of CdI_4 tetrahedra.[2] In $[Cd(Me_6tren)X_2]$ (X = Cl, Br), Me_6tren acts as a terdentate ligand and Cd^{2+} is five-coordinate. In [Cd(tren)Br]Br, however, tren is tetradentate (*see Tetradentate Ligand*). A five-coordinate Cd^{2+} and tetradentate (*see Tetradentate Ligand*) amines are found in $[Cd(H_2O)L](ClO_4)_2$ (L = Me_6tren or tren). In the corresponding anhydrous complex, a perchlorate ion substitutes the water molecule in the coordination sphere: $[Cd(ClO_4)L](ClO_4)$. Analogously, in the complex $[Cd(NO_3)L](NO_3)$, a nitrate ion binds Cd^{2+}. The coordinative properties of amino acids towards Cd^{2+} have been extensively investigated.[2] Type and stability of the complexes strongly depend on the structure of the amino acid. In absence of interacting side chain, the amino acid acts as a chelate ligand (*see Chelating Ligands*) through the amine nitrogen and the carboxylate oxygen. In $[Cd(L\text{–}Asn)_2]$, Cd^{2+} is octahedrally coordinated in an O_4N_2 environment and the amide of the side chain results unbound. No evidence for any interaction between the metal ion and the thioether group is found in Cd^{2+}–Met system. Two different structures have been found to correspond to the formula $Cd(Glu)\cdot H_2O$. In the former case, Cd^{2+} has a distorted octahedral (*see Octahedral*) geometry and is coordinated by N(amino) and O(α-carboxylate) of one glutamate, by both the oxygen atoms side chain carboxylate of a second glutamate, by

an α-carboxylate oxygen of a third glutamate, and by a water molecule. The latter case is better represented by the formula $Cd(Glu)(H_2O)\cdot Cd(Glu)(H_2O)_2\cdot H_2O$; the glutamate binds three Cd^{2+} ions and two different geometries for Cd^{2+} occur: one is a distorted pentagonal bipyramidal (*see Pentagonal Bipyramid*), the other is a distorted square-based trigonal-capped polyhedron. ^{13}C and ^{113}Cd NMR studies indicate Cd^{2+} unable to promote peptide nitrogen deprotonation (*see* ***Peptide–Metal Interactions***). Surprisingly, Cd^{2+} substitutes for nitrogen-bound hydrogen on RSO_2N-protected amino acids, especially in the presence of bipyridyl. In $[CdX_2(acetamide)_2]$ (X = Cl, Br, I or SCN), acetamide is an N,O donor and halogens act as bridging ligands (*see Bridging Ligand*).[2] In $[CdCl_2(malonamide)_2]\cdot MeOH$, Cd^{2+} is octahedral (*see Octahedral*) and coordinated to bidentate malonamides through N atoms. Complexes of the type $[CdX_2L_2]$, formed by N-(2-pyridyl)acetamide (*see Amide (Amido) Complexes*), are octahedral and the amide binds through the carbonyl oxygen and the heterocyciclic nitrogen. In $[CdL_2(SCN)_2]$ and $[CdL_2](NO_3)_2$ (L = $RCONHNH_2$; R = Et, *n*-Pr, *n*-C_5H_{11}, *n*-C_7H_{15}) L behaves as an N,O bidentate ligand, but in $[CdL_nCl_2]$ (L = *i*-$PrCH_2CONHNH_2$, $n = 1$ or 2) L binds only through an N atom. Cd^{2+} is found in a distorted octahedral coordination in $[CdL_2(SCN)_2]$ (L = $PhCONHNH_2$) in which the hydrazide ligand acts as an N,O bidentate ligand and one thiocyanate ion binds through an S atom, but the other through an N atom.[2] In Schiff base complexes obtained from 2-benzoylpyridine and benzoylhydrazine or salicylhydrazine, Cd^{2+} is coordinated by two N and one O atoms. The quinquedentate ligand 2,6-bis(2-methyl-2-benzothiazolinyl)pyridine reacts in basic conditions as deprotonated ligand to give a five-coordinated complex of unusual structure.[2] In tris(ethylenediamine)cadmium dibenzohydroxamate, the metal ion lies in an octahedral (*see Octahedral*) N_6 environment. A number of tetraacetate ligands bind Cd^{2+}. Structural aspects control the stability of such complexes: the formation constant value for the 1:1 complex of ethylene-bis(*N*,*N*′-(2,6-dicarboxy)piperidine) is lower than that for EDTA due to the steric hindrance of the piperidine ring. Dinuclear (*see Dinuclear*) species of the type $[Cd_2L]$ have been observed when H_4L is ethylenedinitrilotetraacetic acid or 1,2-trans-cyclohexylenedinitrilotetraacetic acid. $[CdCl_2(imidazole)]$ has a polymeric structure in which octahedrally coordinated Cd^{2+} ions are bridged by two chloride ions.[2] $[Cd(imidazole)_3](SO_4)\cdot H_2O$ is also polymeric: the metal ion shows an octahedral (*see Octahedral*) geometry due to three imidazole nitrogens, a water molecule, and two oxygens from sulfate. A number of species are observed in Cd^{2+}–imidazole aqueous system: $[CdL]^{2+}$, $[CdL_2]^{2+}$, $[CdL_3]^{2+}$ and $[CdL(OH)]^{+}$. Monomeric tetrahedral (*see Tetrahedral*) species $[Cd(N\text{-alkylimidazole})_2X_2]$ (X = Cl, Br, I) or dimeric species have been synthesized. CdL_2F_2 (L = 3,5-dimethylpyrazole) is obtained by reaction between $Cd(BF_4)_2$ and L: the octahedrally coordinated Cd^{2+} ions are bridged by F^- ions to form a linear chain. 5-methylpyrazole (L′), however, gives a tetrameric species $[Cd_4F_4L'_{12}](BF_4)_4$ containing a Cd_4F_4 cluster (*see Cluster*). $[Cd(py)X_2]$ (X = Cl, Br) reveals a polymeric halogen-bridged structure in which Cd^{2+} is coordinated by one pyridine, two bicoordinated, and three tricoordinated halogens.[51] Cadmium halides react with cyanopyridine to give 1:2 complexes; $CdCl_2$, alone, forms a 1:1 complex with 2-cyanopyridine. The cyano-group does not bind the metal ion. Cd^{2+} is octahedral (*see Octahedral*) with halogen bridges in a 1:2 complex but tetrahedral in a 1:1 species. A polymeric structure containing Cd–SCN–Cd units is observed when 2- and 3-cyanopyridines react with $Cd(SCN)_2$ to give a 1:2 compound.[2] Even in this case, Cd^{2+} is octahedral. In $[Cd(HCO_2)_2L_2(H_2O)_2]$ (L = nicotinamide) and $[Cd(MeCO_2)_2L'_2(H_2O)_2]$ (L = N,N-diethylnicotinamide), the metal ion lies in an octahedral environment and is bound to the amide through the N atom. In the monomeric compounds $[CdL_2I_2][CdLX_2]$ (X = Cl, Br; L = bis(2-pyridyl)ketone), L acts as a bidentate N_2 donor. $[CdL(NO_3)_2(H_2O)]_2(NO_3)_2$ (L = adenine) is dimeric, Cd^{2+} lies in a N_2O_6 environment and is bridged by two water and two adenine molecules. In $Na_2Cd_3(ATP)_2\cdot 6H_2O$, ATP binds through the nitrogen of the base and phosphate oxygens. Aqueous $Cd(ATP)^{2-}$ is proposed to be in dimeric form. Interactions between Cd^{2+} and guanosine occur. Depending on pH, 1:1 complexes of the type $[CdL]^{+}$ and $[Cd(HL)]^{2+}$ have been detected. The structure of $[CdL(H_2O)_5]\cdot 3H_2O$ (L = guanosine 5′-phosphate) shows Cd^{2+} octahedrally coordinated by five water molecules and the N-7 of the purine ring. 4,6-dimethylpyrimidine-2(1H)-thione (HL) forms the complexes $[Cd(HL)_2X_2]$ (X = Cl, Br, I), $[Cd(HL)_3](ClO_4)_2\cdot 2H_2O$, $[Cd(HL)_2(CF_3CO_2)_2]$, and CdL_2. The ligand binds via S and N; in the chloride and bromide, the ligand seems to coordinate only through the N atom and bridging halides. In $[CdL_2(H_2O)_4]$ (L = 8-azohypoxanthinate), Cd^{2+} is octahedrally bound to four water molecules and two N-7of the purine anions. Flavoquinones acts as a chelate via N and O atoms to give complexes of the type $[CdL_3]^{2+}$. In $[Cd(bipy)_2(NO_3)_2]\cdot 1/2H_2O$, Cd^{2+} is found in two distinct N_4O_2 octahedral environments, being the oxygen donors and two nitrate ions in one case and one nitrate ion and one water molecule in the other. In $[Cd(bipy)_2(SCN)_2]$, Cd^{2+} has a N_6 octahedral geometry. Studies have been performed on the interaction of Cd^{2+} with bipy in water and DMF.[57]

Bipyridyl-based molecules are used as bridging ligands (*see Bridging Ligand*) to obtain a variety of network topologies and structural motifs starting from $Cd(NO_3)_2$.[58] $\{[Cd(4,4'\text{-bipy})_2](NO_3)_2\}_\infty$ gives a clathrate (*see Clathrate*) complex by interaction with *o*-dibromobenzene and shows catalytic properties towards cyanosilylation of aldehydes. $[Cd(2,4'\text{-bipy})_2(NO_3)_2(H_2O)_2]$ shows a distorted pentagonal bipyramidal (*see Pentagonal Bipyramid*) geometry, being Cd^{2+} coordinated by one monodentate and one bidentate NO_3^-, two water molecules and two 2,4′-bipy (both through 4-pyridyl N atom).[58] In $[Cd_2(4,4'\text{-bipy})_2(H_2O)_3(SO_4)_2]\cdot 3H_2O$,

the Cd^{2+} ions lies in two nonequivalent octahedral environments and are connected by 4,4′-bipy molecules to form one-dimensional chains. Heptacoordinate Cd^{2+} is found in $[Cd_2(SO_4)_2$(1,3-bis(4-pyridyl)propane)$_3(H_2O)_{2.7}]\cdot 4.5H_2O$ and $[Cd_2(NO_3)_4$(1,5-bis(4-pyridyl)pentane)$_3(H_2O)]$.[58] Triazole ligands such as 3,5-dialkyl-4-amino-1,2,4-triazole give complexes with dimensionality from zero to three.[59] In the phosphoraniminato complexes $[CdX(NPEt_3)]_4$ (X = Cl, Br, I), a $[Cd_4N_4]$ heterocubane core is found. The Cd^{2+} ions are bridged by N atoms of the phosphoranimidate ligands. Interactions between Cd^{2+} and macrocyclic ligands (*see* ***Macrocyclic Ligands***) bearing N and/or O donor atoms (*see Donor Atom*) (cyclic amines, ethers, porphyrin derivatives, etc.) have been extensively investigated:[2,50,51,60] Interesting spectroscopic and photochemical properties are shown by several of these complexes. Generally, Cd^{2+} macrocycles (*see Macrocycle*) undergo metal exchange more easily than the corresponding Zn^{2+} compounds. Some cryptands (*see Cryptands & Cryptates*), however, reveal a remarkable selectivity for Cd^{2+} respect to Zn^{2+} and Ca^{2+} and thus could be used in chelation therapy (*see Chelation Therapy*).[2] The octaazacryptand $L = N(CH_2CH_2NHCH_2CH_2NHCH_2CH_2)_3N$ shows a particularly high affinity for Cd^{2+}. In the cation $[CdL]^{2+}$, the metal ion is eight-coordinated in a bicapped octahedral geometry.

15.5 Phosphorus and Arsenic Donor Ligands

Cadmium halides react with phosphines to give complexes of the type $[CdX_2(R_3P)]_2$ and $[CdX_2(R_3P)_2]$.[61] The former are halogen-bridged dimers, the latter are tetrahedral (*see Tetrahedral*). In $[CdBr_2(Et_3P)]_2$, Cd^{2+} lies in a Br_3P environment with two bridged Br^- ions. In several solvents a monomer/dimer equilibrium occurs. $[CdLI_2]$ ($L = P(CH_2SiMe_3)_3$) is monomeric in $CHCl_3$ and the metal ion seems to be three-coordinated. Complexes with a CdX_2/R_3P molar ratio of 2:3 are rare and of uncertain structure and, as a matter of fact, they are not a mixture of 1:1 and 1:2 compounds. $[Cd(R_3P)(SCN)_2]$ has a polymeric trigonal bipyramidal (*see Trigonal Bipyramidal*) structure, but $[Cd(Ph_3P)(CF_3CO_2)_2]_2$ is dimeric with two Cd^{2+} ions bridged by four carboxylate ligands. Complexes of the type $[(\text{phenoxide})_2CdL_n]$ (L = monotricyclohexylphosphine, $n = 1$, $L = Me_3P$ or n-Bu_3P, $n = 1$ and 2) are obtained by reaction between $Cd[N(SiMe_3)_2]_2$ and the phenol in the presence of the phosphine.[62] [(2,6-di-*ter*-butylphenoxide)$_2$Cd(monotricyclohexylphosphine)] has Cd^{2+} in a near trigonal planar geometry and a Cd-P bond length of 2.5247 Å. In the bis(phosphine) complex [(2,6-di-*ter*-butylphenoxide)$_2$Cd(Pme$_3$)$_2$], however, Cd^{2+} lies in a distorted tetrahedral environment and the (average) Cd-P bond length is 2.737 Å. Adamantanoid cationic complexes of the type $[(\mu\text{-ER})_6(CdPPh_3)_n(Cd)_{4-n}]^{2+}$ ($ER = S{-}Pr^i$, $S{-}c{-}C_6H_{11}$, SPh, SePh, SPr^n, $S{-}n{-}C_5H_{11}$; $n = 2$–4) have been synthesized. Cd^{2+} forms $[Cd(diars)X_2]$ (X = Cl, Br, I) and $[Cd(diars)_2](ClO_4)_2$ (*see Arsine & As-donor Ligands*). $[Cd(diars)Cl_2]$ is believed to have a polymeric octahedral structure.[61]

15.6 Multinuclear Complexes

The anions $[CoCdCl_6]^{2-}$ and $[Co_2CdCl_8]^{2-}$ show an unusual structure: in the former, both the metal ions are tetrahedral and a Co–Cd bond is present;[2] in the latter, the tetrahedral (*see Tetrahedral*) Cd^{2+} is connected by four bridging chlorides to two tetrahedral Co^{2+} ions. The polynuclear complex (*see Polynuclear Complexes*) $[I_2Cd\{(\mu\text{-NC})MnL_x\}_2]$ ($L_x = cis$ or *trans*-$(CO)_2\{P(OR)_3\}$(dppm); R = Ph or Et, dppm = $Ph_2PCH_2Ph_2$) is obtained by reaction between CdI_2 and *cis*- or *trans*-$[Mn(CN)(CO)_2\{P(OR)_3\}(dppm)]$, Cd^{2+} is tetrahedrally coordinated to two I^- ions and two N atoms of bridged CN^- ions. Complexes of the type $[CoCd(SCN)_4L_n]$ have a structure determined by the nature of the ligand L: when L = py or bipy, the compound is better formulated as $[CoL_n][Cd(SCN)_4]$ ($n = 3$ or 6), when L = phen, as $[Co(phen)_3][Cd(SCN)_4(phen)]$. $[NiCd(SCN)_4(THF)_n]$ ($n = 2$ or 4) shows octahedral Cd^{2+} and Ni^{2+} for $n = 4$, but only octahedral Ni^{2+} with bridging thiocyanate for $n = 2$. In $[CoCd(SCN)_4(en)_3]$, Co^{2+} is square planar (*see Square Planar*). $Cd[Mn(CO)_5]_2$ forms a terpyridyl adduct with a very distorted trigonal bipyramidal (*see Trigonal Bipyramidal*) structure. $CdM(SCN)_4$ (M = Ni, Fe, Zn, Cu, or Co) reacts with a variety of N-donor ligands. Three type of complexes can be obtained: $[Cd(SCN)_4][ML_6]$, polymeric $CdM(SCN)_4\cdot 2L$ or $CdM(SCN)_4\cdot 4L$, and monomeric $CdM(SCN)_4\cdot 2L$ or $CdM(SCN)_4\cdot 4L$. Tetranuclear $[Cd_2Cu_2I_4L_4(DMSO)_2]$, pentanuclear $[Cd_2Cu_3Br_6L_4(DMSO)_2]$, and hexanuclear $[Cd_4Cu_2Cl_6L_6(H_2O)]$ (HL = 2-dimethylaminoethanol) have been prepared and the unusual structures determined.[63] Clathrates (*see Clathrate*) containing octahedral Cd^{2+} and tetracyanonichelate (II) units have been synthesized and structurally characterized.[64]

1 INTRODUCTION

The chemistry of organocadmium compounds is closely analogous to that of their zinc analogs, but is noticeably less well developed.[1] Organocadmium reagents are in general mild and regioselective.[2] Their principal importance is in the preparation of ketones from RCOCl and $(RCO)_2O$. Organocadmium compounds have also been used for the regioselective alkylation of quinones,[3] although more recently organocadmium compounds have found use in MOCVD processes (*see Metal–Organic Chemical Vapor Deposition*). Organometallic cadmium compounds, as with cadmium compounds in general, are highly toxic.[4] Specifically, mammals accumulate cadmium in the liver and kidneys. A number of review articles on organocadmium compounds and their uses are available.[1,5–8]

2 R_2Cd: DIHYDROCARBYLCADMIUM COMPOUNDS

2.1 General Properties

Dialkyl- and diarylcadmium derivatives are colorless compounds that are either liquids or low-melting solids. The compounds are noticeably more stable to air than the corresponding zinc derivatives. For example, whereas Me_2Zn is pyrophoric, Me_2Cd only fumes in air. However, although the cadmium derivatives are more air stable, they are substantially less thermally stable and more light sensitive than the zinc derivatives. As such, R_2Cd compounds should be stored cold and in the absence of light. A notable exception is $[(Me_3Si)_3C]_2Cd$, which decomposes at ca. 300 °C, and is also stable to both air and water (as is the zinc analog).[9]

The lower thermal stability of R_2Cd compounds compared with R_2Zn is undoubtedly a consequence of weaker Cd–C bonds. The mean Cd–C bond dissociation energies (D) have been determined for some R_2Cd compounds, and are intermediate between those of the Zn and Hg analogs, as summarized in Table 1[10] (*see Bond Energies* and ***Bonding Energetics of Organometallic Compounds***). The individual first and second bond dissociation energies have been calculated for Me_2Cd, demonstrating that the second bond dissociation energy is substantially smaller than the first [$D_1 = 234 \pm 6\,\mathrm{kJ\,mol^{-1}}$; $D_2 = 64 \pm 10\,\mathrm{kJ\,mol^{-1}}$].

R_2Cd compounds have been studied by ^{113}Cd (12.3% abundance) NMR spectroscopy,[11–13] which indicates that the ^{113}Cd shielding increases irregularly in the order Me_2Cd < i-Bu_2Cd < n-Bu_2Cd < n-Pr_2Cd < Et_2Cd < i-Pr_2Cd. Organocadmium derivatives are also characterized by the observation of ^{113}Cd-^1H coupling as satellites in the ^1H NMR spectrum (Table 2).

2.2 Synthesis of R_2Cd Compounds

R_2Cd compounds were first obtained by the direct reaction of cadmium metal with alkyl halides. Unfortunately, this method is limited and typically does not readily yield pure products. However, the direct method is facilitated by the use of highly activated cadmium slurries.[14–16]

The most general method of preparation of organocadmium derivatives involves the reactions of RLi, RMgX, or R_3Al with cadmium salts.[17] For example, Me_2Cd is readily prepared by the reaction of Me_3Al with $Cd(OAc)_2$ (equation 1),

Table 1 Mean bond dissociation energies for some R_2M (M = Zn, Cd, Hg) compounds

	D(M–R) (kJ mol^{-1})		
	Zn	Cd	Hg
Me_2M	183 ± 7	147 ± 4	124 ± 4
Et_2M	133 ± 10	111 ± 8	100 ± 8

Table 2 ^{113}Cd NMR data for some R_2Cd compounds

	δ^{113}Cd (ppm)	$^2J_{Cd–H}$ (Hz)	$^3J_{Cd–H}$ (Hz)
Me_2Cd	0	52	–
Et_2Cd	−94	53	60
i-Pr_2Cd	−207	–	56
n-Pr_2Cd	−46	50	55
n-Bu_2Cd	−44	52	–
i-Bu_2Cd	−22	50	70

and $(Me_3SiCH_2)_2Cd$ is obtained by (i) the reaction of Me_3SiCH_2Li with $CdCl_2$ (equation 2),[18] and (ii) the reaction of Me_3SiCH_2MgCl with CdI_2 (equation 3).[19] An analogous method has also been used to synthesize the silyl derivative $(Me_3Si)_2Cd$ (equation 4).[20] $(Me_3Si)_2Cd$ is very unstable and decomposes over 2 days at $-20\,°C$.

$$2Me_3Al + 3Cd(OAc)_2 \longrightarrow 3Me_2Cd + 2Al(OAc)_3 \quad (1)$$

$$2Me_3SiCH_2Li + CdCl_2 \longrightarrow (Me_3SiCH_2)_2Cd + 2LiCl \quad (2)$$

$$2Me_3SiCH_2MgCl + CdI_2 \longrightarrow (Me_3SiCH_2)_2Cd + 2MgClI \quad (3)$$

$$CdCl_2 \xrightarrow{LiAl(SiMe_3)_4} (Me_3Si)_2Cd \quad (4)$$

It is also noteworthy that, in contrast to the synthesis of R_2Zn compounds, R_2Cd derivatives are not readily accessible by transmetalation (*see Transmetalation*) between R_2Hg and Cd metal, presumably since the electropositivity of Cd and Hg is so similar that equilibrium mixtures are obtained.

Cp_2Cd is obtained by reaction of $Cd[N(SiMe_3)_2]_2$ with CpH (equation 5).[21] The orange–red, light-sensitive pentamethylcyclopentadienyl analog $Cp^*{}_2Cd$ has also been prepared by the reaction between $Cd(acac)_2$ and $LiCp^*$ (equation 6).[22] It is worth noting that, in contrast, the analogous reaction between $CdCl_2$ and $LiCp^*$ gives only colloidal cadmium and the organic dimer $Cp^*{}_2$.[23]

$$Cd[N(SiMe_3)_2]_2 + 2CpH \longrightarrow Cp_2Cd + 2HN(SiMe_3)_2 \quad (5)$$

$$Cd(acac)_2 + 2LiCp^* \longrightarrow Cp^*{}_2Cd + 2Li(acac) \quad (6)$$

Perfluoroalkyl cadmium compounds are also known. Bis(trifluoromethyl)cadmium has been prepared at $-78\,°C$ by cocondensing Cd atoms with $\cdot CF_3$ radicals generated in a hexafluoroethane plasma (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***),[24,25] and also by the unusual reaction of activated cadmium powder with difluorodihalomethanes, for example, CF_2Cl_2, CF_2Br_2, or CF_2BrCl, in DMF (equation 7).[26]

$$2Cd + 2CF_2X_2 + Me_2NCHO \longrightarrow CF_3CdX[\text{or } 0.5(CF_3)_2Cd + 0.5\,CdX_2] + CdX_2 + CO + [Me_2N{=}CFH]^+X^- \quad (7)$$

The related trifluorosilyl derivative bis(trifluorosilyl)cadmium has been obtained by an analogous procedure to $(CF_3)_2Cd$ involving the cocondensation of Cd atoms with $\cdot SiF_3$ radicals (generated in a Si_2F_6 glow discharge).[24,25] $(SiF_3)_2Cd$ is marginally stable with a half-life of approximately 1 day at room temperature, but the adduct $(SiF_3)_2Cd(glyme)$ (*see Addition Compound*) is stable indefinitely in an inert atmosphere.

Although R_2Cd compounds cannot be prepared by transmetalation with R_2Hg, bis(perfluorophenyl)cadmium has been obtained by transmetalation with the thallium derivative $(C_6F_5)_2TlBr$ (equation 8).[27] $(C_6F_5)_2Cd$ can also be prepared by (i) the reaction of $CdCl_2$ with C_6F_5Li (equation 9) and (ii) the decarboxylation of $(C_6F_5CO_2)_2Cd$ (equation 10).[28]

$$(C_6F_5)_2TlBr \xrightarrow{Cd} (C_6F_5)_2Cd \quad (8)$$

$$CdCl_2 + 2C_6F_5Li \longrightarrow (C_6F_5)_2Cd + 2LiCl \quad (9)$$

$$(C_6F_5CO_2)_2Cd \longrightarrow (C_6F_5)_2Cd + 2CO_2 \quad (10)$$

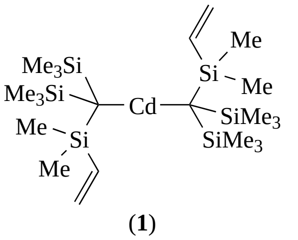
A general synthesis of perfluoroalkyl derivatives $(R_f)_2Cd$ ($R_f = CF_3$, C_2F_5, n-C_3F_7, i-C_3F_7, n-C_4F_9, C_6F_5) that occurs in quantitative yield involves the reaction of perfluoroorganoiodides R_fI with a dialkylcadmium reagent R_2Cd (R = Me, Et) in the presence of a Lewis base (*see Lewis Acids & Bases*), for example, glyme, diglyme, TMEDA, pyridine, or MeCN (equation 11).[29] However, since the perfluoroalkylcadmium derivatives are strong Lewis acids (*see Lewis Acids & Bases*), they are actually isolated as adducts, for example, $(R_f)_2Cd(py)_2$.

$$2R_fI + R_2Cd + 2L \longrightarrow (R_f)_2CdL_2 + 2RI \quad (11)$$

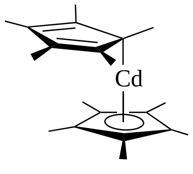
$$L_2 = \text{glyme, diglyme, } (MeCN)_2,\ (py)_2$$

2.3 Structures of R_2Cd Compounds

Structural studies on simple R_2Cd compounds are rare. However, Me_2Cd is known to be linear with $d(Cd–C) = 2.112(4)$ Å in the gas phase on the basis of Raman studies,[30] and $[(CH_2 = CHMe_2Si)(Me_3Si)_2C]_2Cd$ is linear in the solid state [Cd–C = 2.172(3) Å] on the basis of X-ray diffraction (*see* ***Diffraction Methods in Inorganic Chemistry***) as shown in (**1**).[31] The structure of $Cp^*{}_2Cd$ is not known, but an η^1,η^5-arrangement (*see Hapticity*) of Cp^* ligands (**2**) has been proposed by analogy with that observed for $Cp^*{}_2Zn$. Similarly, on the basis of comparison with the zinc system, Cp_2Cd has been proposed to be polymeric.[32]



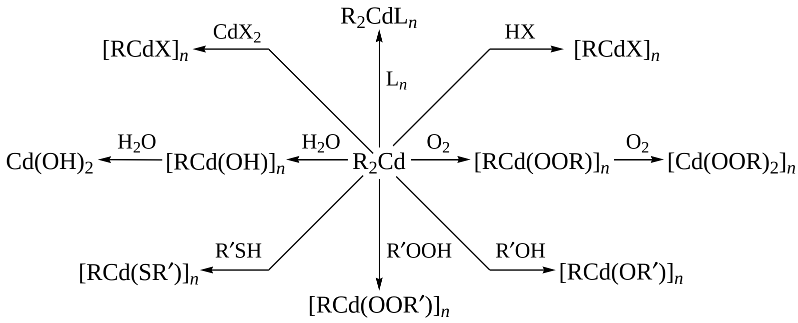
(**1**)



(**2**)

2.4 Reactivity of R_2Cd Compounds

R_2Cd compounds are generally much less reactive than their zinc analogs, although the overall reactions may be similar. A summary of the reactivity of R_2Cd compounds is provided in Scheme 1, and further details concerning these reactions will be found in Sections 2.4–5.

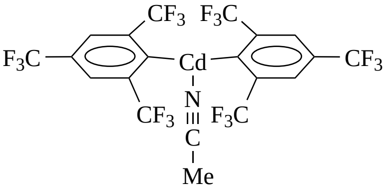


Scheme 1 Summary of the reactivity or R_2Cd derivatives

2.4.1 Adduct Formation

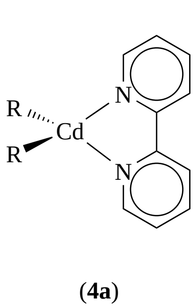
Intermolecular Adduct Formation. The metal center in R_2Cd compounds is noticeably less Lewis acidic than in the corresponding zinc compounds. Hence, R_2Cd compounds form weaker, and fewer, adducts than do the R_2Zn analogs. However, the Lewis acidity of the Cd center may be increased by incorporation of electron-withdrawing substituents.

$[2,4,6\text{-}(CF_3)_3C_6H_2]_2Cd(MeCN)$ (**3**) is an example of a structurally characterized three-coordinate diaryl cadmium compound.[33] The molecule is 'T'-shaped with Cd–C distances of 2.184(3) and 2.181(3) Å, and a C–Cd–C bond angle of 165.7(1)°.

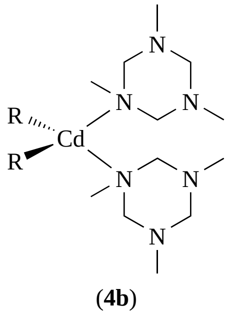


(**3**)

The four-coordinate 2,2′-bipyridyl and triazine adducts $Me_2Cd(bipy)$,[34] $(Me_3SiCH_2)_2Cd(bipy)$,[35] and $Me_2Cd[(CH_2NMe)_3]_2$[36] have been isolated, and the bipyridyl derivatives (**4a**) have been structurally characterized by X-ray diffraction. Notably, the coordination environments about the cadmium centers in both compounds deviate substantially from tetrahedral, with large C–Cd–C bond angles (Table 3).



(**4a**)

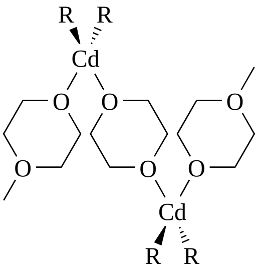


(**4b**)

Table 3 Cd coordination environment in bipyridyl adducts[37]

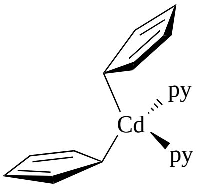
	$Me_2Cd(bipy)$	$(Me_3SiCH_2)_2Cd(bipy)$
Cd–C	2.17(3) Å	2.19(6) Å
	2.15(2) Å	2.09(5) Å
Cd–N	2.50(1) Å	2.53(3) Å
	2.54(1) Å	2.52(4) Å
C–Cd–C	148.4(8)°	156(2)°
N–Cd–N	64.0(5)°	65(1)

In contrast to the triazine adduct $Me_2Cd[(CH_2NMe)_3]_2$ (**4b**), in which each triazine ligand coordinates to one Cd center, the 1,4-dioxane adduct $[Me_2Cd(1,4\text{-dioxane})]_n$ (**5**) is polymeric, with 1,4-dioxane molecules bridging Cd centers.[38] As with the bipyridyl compounds described above, the coordination environment [d(Cd–C) = 2.09(2) Å; C–Cd–C = 173.0(8)°] also deviates substantially from tetrahedral, and the near linearity of the C–Cd–C bond angle suggests that the Cd–C interactions involve sp hybrids, so that the oxygen lone pairs donate into orbitals on Cd that are mainly p in character.



(**5**)

The pyridine adduct of the cyclopentadienyl derivative, $Cp_2Cd(NC_5H_5)_2$, also exhibits a distorted tetrahedral structure (**6**) in which both cyclopentadienyl ligands are coordinated in monohapto fashion [d(Cd–C) = 2.353(5), 2.307(5) Å, d(Cd–N) = 2.309(3), 2.360(3) Å; C–Cd–C = 129.1(2)°].[32,39] The pentamethylcyclopentadienyl complex $Cp^*{}_2Cd$ also forms a yellow adduct with glyme, $Cp^*{}_2Cd(glyme)$.[22] The



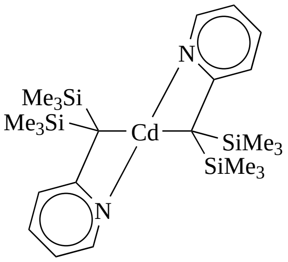
(**6**)

adduct formation is reversible and dissolving $Cp^*{}_2Cd(glyme)$ in toluene regenerates $Cp^*{}_2Cd$.

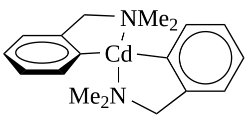
Perfluoroalkyl derivatives are strong Lewis acids owing to the electron-withdrawing effects of the fluorine substituents, and readily form stable adducts, for example, $(CF_3)_2Cd(glyme)$, that have been characterized by ^{19}F NMR spectroscopy.[29,40,41]

Interest in adducts of R_2Cd compounds derives from their potential as a source for pure R_2Cd for use in metal organic chemical vapor deposition (*see Metal–Organic Chemical Vapor Deposition*).[42]

Intramolecular Adduct Formation. By analogy with zinc compounds, the incorporation of donor atoms in the alkyl groups of R_2Cd derivatives may result in the formation of intramolecular adducts. For example, the pyridyl group in the complex $[(NC_5H_4)(SiMe_3)_2C]_2Cd$ (**7**) coordinates to the Cd center [d(Cd–C) = 2.27 Å; d(Cd–N) = 2.49 Å; C–Cd–C = 174.3°; N–Cd–N = 108.9°].[43]



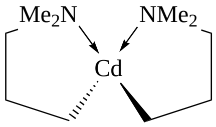
(**7**)



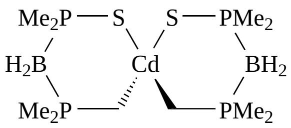
(**8**)

The coordination environment about cadmium in $[2\text{-}(Me_2NCH_2)C_6H_4]_2Cd$ (**8**) is also far removed from tetrahedral, with the best description being a trigonal bipyramid with a vacant equatorial site.[44,45] The Cd–C bond length is 2.154(8) Å, and the C–Cd–C bond angle close to linear [174.1(1)°]. The molecules pack in the crystal lattice in a manner such that there are weak Cd···Cd interactions between adjacent molecules through the vacant coordination sites on cadmium. The Cd···Cd separation of 3.176 Å is close to twice the van der Waals radius of Cd (3.20 Å) (*see van der Waals Forces*).

Some other examples of intramolecular adducts include $(Me_2NCH_2CH_2CH_2)_2Cd$ (**9a**)[46] and $(SPMe_2BH_2PMe_2CH_2)_2Cd$ (**9b**).[47]



(**9a**)



(**9b**)

3 RCdX: MONOALKYLCADMIUM COMPOUNDS

Although there exists a series of monoalkyl cadmium compounds of the type $[RCdX]_n$, such compounds are not as extensive as the zinc analogs. For example, alkylcadmium hydride compounds are unknown. Furthermore, the $[RCdX]_n$ compounds that have been isolated are often not as well characterized as their zinc analogs.

3.1 RCdX (X = Cl, Br, I)

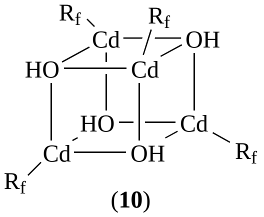
Alkylcadmium halide derivatives are typically obtained by ligand redistribution between R_2Cd and CdX_2 (equation 12).[1] Relatively little is known about their detailed structures, although it is likely that they are either oligomeric or polymeric by comparison with the zinc analogs.

$$R_2Cd + CdX_2 \rightleftharpoons 2RCdX \qquad (12)$$

3.2 RCd(OH)

The pentafluorophenyl derivative $(C_6F_5)_2Cd$ is hydrolyzed by water to give the tetrameric cadmium hydroxide complex $[(C_6F_5)Cd(\mu\text{-}OH)]_4$ (equation 13).[28] The molecular structure (**10**) of $[(C_6F_5)Cd(\mu\text{-}OH)]_4$ is based on a cube with the cadmium and oxygen atoms occupying the vertices. The hydroxy derivative is characterized by observation of a ν(OH) band at 3640 cm^{-1}.

$$4(C_6F_5)_2Cd + 4H_2O \longrightarrow [(C_6F_5)Cd(\mu\text{-}OH)]_4 + 4C_6F_5H \qquad (13)$$



(**10**)

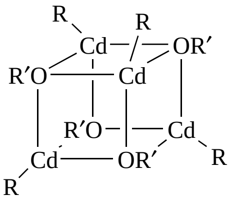
3.3 RCd(OR′)

Alkylcadmium alkoxides may be prepared by the reaction of R_2Cd with one equivalent of R′OH (equation 14).[48,49] The mechanisms of the reactions of Et_2Cd with R′OH have been

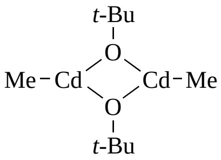
investigated, confirming that the formation of EtCd(OR′) is more rapid than that for the bis(alkoxide) $Cd(OR')_2$.[50]

$$R_2Cd + R'OH \longrightarrow RCd(OR') + RH \qquad (14)$$

The alkoxides $[MeCd(OR)]_4$ (R = Me, Et, *i*-Pr, Ph) are tetrameric and are assumed to have cubic structures (**11**) by analogy with the related zinc compounds. In contrast, the *t*-butoxy derivative $[MeCd(O\text{-}t\text{-}Bu)]_2$ (**12**) has been reported to be dimeric in benzene with the proposed structure shown, whereas the zinc analog is tetrameric. However, methylcadmium alkoxides have also been studied by ^{113}Cd NMR spectroscopy, which has suggested that the *t*-butoxy derivative may in fact also be tetrameric.[51]



(**11**)



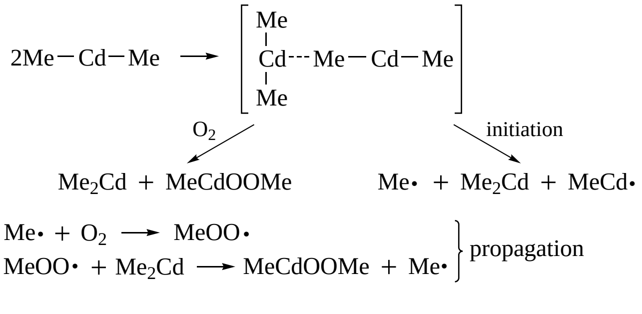
(**12**)

3.4 RCd(OOR′)

R_2Cd compounds react sequentially with O_2 to give alkylperoxo compounds, RCdOOR and $Cd(OOR)_2$ (equation 15).[52–56] Little is known about the detailed structures of the alkylperoxo compounds, but the complex $[MeCd(OOMe)]_4$ is proposed to be tetrameric in solution.

$$R_2Cd \xrightarrow{O_2} RCd(OOR) \xrightarrow{O_2} Cd(OOR)_2 \qquad (15)$$

The mechanism of the reaction between Me_2Cd and O_2 has been investigated and a radical chain process has been proposed (see Scheme 2). The initiation step is believed to involve an ill-defined bimolecular reaction between two Me_2Cd molecules. The rate of initiation is inversely related to O_2 concentration, so it has been suggested that O_2 can also react competitively with the dimer. The reaction between



Scheme 2 Possible mechanism for the reactions of R_2Cd with O_2

Et_2Cd and O_2 has also been studied and it has been claimed that an unusual adduct of composition $Et_2Cd{\cdot}2O_2$ is formed *reversibly* prior to formation of the alkylperoxo complex.[57]

Mixed alkylperoxide derivatives of the type MeCd(OO-*t*-Bu) may be obtained by the reaction of Me_2Cd with *t*-BuOOH (equation 16). Thermal decomposition of MeCd(OO-*t*-Bu) gives an ill-defined product of composition [MeCdOC(O)H·CdO].

$$Me_2Cd + t\text{-}BuOOH \longrightarrow MeCd(OO\text{-}t\text{-}Bu) + CH_4 \qquad (16)$$

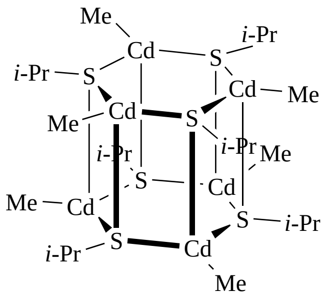
Me_2Cd reacts with H_2O_2 to give a complex that is proposed to be the peroxy-bridged derivative MeCdOOCdMe, but was not isolated (equation 17)

$$2Me_2Cd + H_2O_2 \longrightarrow MeCdOOCdMe + 2CH_4 \qquad (17)$$

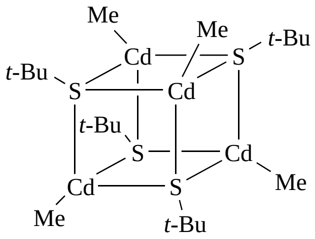
3.5 RCd(SR′)

Alkylcadmium thiolates may be prepared by the reaction of R_2Cd with R′SH (equation 18).[48] As with the alkoxy derivatives, the degree of oligomerization of RCd(SR′) depends upon the R and R′ substituents. For example, the compounds $[MeCd(SMe)]_n$ and $[MeCd(SPh)]_n$ are insoluble and presumably polymeric, whereas $[MeCd(S\text{-}i\text{-}Pr)]_6$ (**13a**) is hexameric and $[MeCd(S\text{-}t\text{-}Bu)]_4$ (**13b**) is tetrameric, with the possible structures shown.

$$R_2Cd + R'SH \longrightarrow RCd(SR') + RH \qquad (18)$$



(**13a**)



(**13b**)

Dialkylcadmium compounds are also reactive towards H_2S. For example, $(Me_3SiCH_2)_2Cd$ reacts immediately with H_2S to give CdS (equation 19).[37] Other organocadmium compounds with Cd–S bonds include the thiocyanate derivatives RCdSCN that are obtained by the reaction of R_2Cd with $(SCN)_2$ (equation 20).[58]

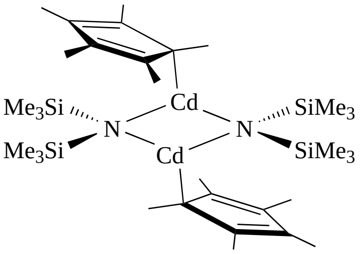
$$(Me_3SiCH_2)_2Cd + H_2S \longrightarrow CdS + Me_4Si \qquad (19)$$

$$R_2Cd + (SCN)_2 \longrightarrow RCd(SCN) + RSCN \qquad (20)$$

3.6 RCd(NR′$_2$)

Alkylcadmium amide derivatives are rare. However, $Cp^*{}_2Cd$ reacts with $Cd[N(SiMe_3)_2]_2$ to give the amide bridged dimer $\{Cp^*Cd[\mu\text{-}N(SiMe_3)_2]\}_2$ (equation 21).[22] The Cp* ligands are bonded in an η^1 arrangement as illustrated in (**14**).

$$Cp^*{}_2Cd + Cd[N(SiMe_3)_2]_2 \longrightarrow [Cp^*Cd\{\mu\text{-}N(SiMe_3)_2\}]_2 \quad (21)$$



(**14**)

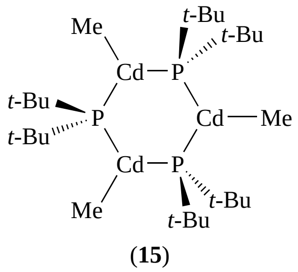
Other alkylcadmium compounds containing Cd–N bonds include the azide derivatives $RCdN_3$, which are obtained by the reaction of R_2Cd with ClN_3 (equation 22).[59]

$$R_2Cd + ClN_3 \longrightarrow RCdN_3 + RCl \quad (22)$$

3.7 RCd(PR′$_2$)

Me_2Cd reacts with $Ga(P\text{-}t\text{-}Bu_2)_3$ to give the phosphido derivative $[MeCd(\mu\text{-}P\text{-}t\text{-}Bu_2)]_3$ (equation 23).[60] The phosphido derivative is trimeric (**15**) and contains planar three-coordinate cadmium centers.

$$12Me_2Cd + 6Ga[P(t\text{-}Bu)_2]_3 \longrightarrow 4[MeCd\{\mu\text{-}P(t\text{-}Bu)_2\}]_3 + 3[Me_2Ga\{P(t\text{-}Bu)_2\}]_2 \quad (23)$$



(**15**)

4 ORGANOCADMIUM ANIONS AND CATIONS

4.1 Organocadmium Anions

As described in Section 2.4.1, R_2Cd derivatives are substantially less Lewis acidic than their zinc analogs. As such, anionic compounds of the types $[R_3Cd]^-$ and $[R_4Cd]^{2-}$ are typically not stable. However, incorporation of electronegative substituents may stabilize such species. For example, $(CF_3)_2Cd$ reacts with alkali metal halides (MX) in polar solvents to give trifluoromethyl cadmate derivatives, for example, $[(CF_3)_2CdX(DMSO)]^-$ (equation 24).[41] Over a period of days, the samples are converted to the species $[(CF_3)_3Cd(L)]^-$ (L = DMSO, glyme, MeCN, py) and $[(CF_3)_4Cd]^{2-}$, on the basis of ^{113}Cd and ^{19}F NMR spectroscopy. For example, the ^{113}Cd NMR resonance of the species $[(CF_3)_3Cd(glyme)]^-$ is a dectet $[^2J(^{113}Cd\text{–}^{19}F) = 281\,Hz]$ owing to coupling to three CF_3 groups.

$$(CF_3)_2Cd(DMSO)_2 + MX \longrightarrow [M][Cd(CF_3)_2X(DMSO)] + DMSO \quad (24)$$

Organocadmate derivatives of the type $[RCdX_2]^-$ (R = Me, Et, Bu, CF_3, Ph, C_6F_5; X = Cl, Br, I) have been obtained by the direct electrochemical oxidation of cadmium metal in the presence of RX and $[Pr_4N][X]$ (equation 25).[61] Other organocadmate derivatives, for example, $[(CF_3)CdI_2]^-$ and $[(C_6F_5)CdBr_2]^-$, are also known.

$$RX + Cd + [Pr_4N][X] \xrightarrow{\text{Cd anode}} [Pr_4N][RCdX_2] \quad (25)$$

4.2 Organocadmium Cations

Brightly colored (yellow to red) π-arene compounds (*see Arene Complexes*) of cadmium $[(arene)Cd]^{2+}$ (e.g. arene = C_6H_6, C_6Me_6) have been obtained by the reactions of $Cd(AsF_6)_2$ or $Cd(SbF_6)_2$ with the arene in SO_2 (equation 26).[62] The structures of the compounds $[(arene)Cd]^{2+}$ are not known with certainty.

$$Cd(EF_6)_2 + arene \longrightarrow [(arene)Cd][EF_6]_2 \quad (26)$$

$$2Ph_3P{=}CH_2 + CdCl_2 \longrightarrow [Ph_3PCH_2CdCH_2PPh_3][Cl]_2 \quad (27)$$

Other cationic compounds that have been isolated include ylide derivatives of the type $[Ph_3PCH_2CdCH_2PPh_3]^{2+}$ (equation 27).[63]

5 ORGANOCADMIUM COMPOUNDS IN ORGANIC AND ORGANOMETALLIC SYNTHESIS

As with organozinc reagents, one of the main uses of organometallic cadmium compounds in organic synthesis derives from their relatively low reactivity (compared with their magnesium, lithium, and aluminum analogs), which thereby often allows them to be more selective reagents.[17,64]

The principal synthetic use of organocadmium reagents in organic chemistry is the preparation of ketones from RCOCl

and $(RCO)_2O$ (equations 28 and 29).

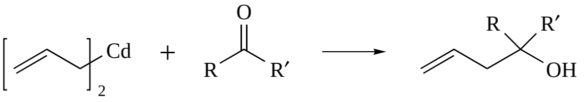
$$\text{RCOCl} \xrightarrow{R'_2Cd} \text{RCOR}' \quad (28)$$

$$(\text{RCO})_2\text{O} \xrightarrow{R'_2Cd} \text{RCOR}' \quad (29)$$

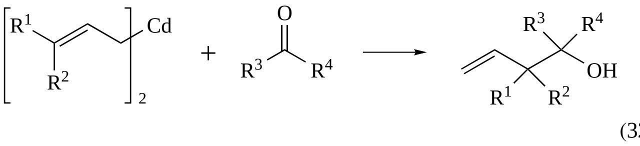
A common misconception concerned with the synthetic applications of organocadmium derivatives is that they are unreactive towards aldehydes and ketones.[17] This misconception has arisen because the reactivity of an organocadmium reagent depends markedly upon its method of preparation. Thus, in situ reagents, obtained by addition of RMgX or RLi to a cadmium salt without further purification, are reactive towards carbonyl derivatives (equation 30), whereas isolated pure R_2Cd compounds are inert. The difference in reactivity between the pure and the in situ reagents may be traced to the presence of certain metal halides, for example, MgI_2, which facilitate addition to the carbonyl group.[65,66] Two possibilities for the function of the metal halide include (i) activation of R_2Cd by forming a complex such as $[R_2CdX_2Mg]$, or (ii) activation of the carbonyl group to nucleophilic attack by coordination to the oxygen atom $[R_2C{=}O\cdots MgX_2]$.

$$\text{ArCHO} \xrightarrow[2.H_2O]{1.R_2Cd/MgX_2} \text{ArC(H)(OH)R} \quad (30)$$

In contrast to dialkylcadmium compounds, allylcadmium derivatives react readily with aldehydes and ketones in the absence of metal salts (equation 31).[17,64] Substituted allylic derivatives undergo rearrangement upon addition (equation 32).

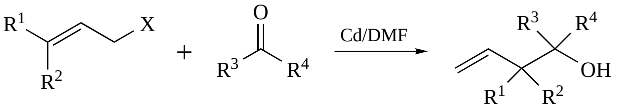


(31)



(32)

In a modification of the above procedure, the direct reaction of cadmium powder with an allylic halide in the presence of an organic carbonyl gives homoallylic alcohols in good yield (equation 33).[67]



(33)

Dialkylcadmium derivatives readily partake in exchange reactions with other metal compounds. NMR studies on the degenerate alkyl exchange reactions between Me_2Cd and itself, and also between Me_2Cd and Me_nM ($Me_nM = Me_2Zn$, Me_3Ga, or Me_3In), demonstrate that the exchange reactions occur via rapid bimolecular processes.[68,69]

In some cases, alkylation may be accompanied by oxidation of the metal center (equations 34 and 35).[70,71]

$$Me_2Cd + 2Cp^*{}_2TiX \longrightarrow 2Cp^*{}_2Ti(Me)X + Cd \quad (34)$$

$$R_2Cd + Cp_2V \longrightarrow Cp_2VMe_2 + Cd \quad (35)$$

$(CF_3)_2Cd$ has been used as a reagent to prepare other trifluoromethyl compounds, for example, $(CF_3)_3Ga(DMF)$, $(CF_3)_3In(MeCN)_2$, and $(CF_3)_3Tl(DMF)_2$ (equations 36–38).[72]

$$GaCl_3 \xrightarrow[DMF]{(CF_3)_2Cd} (CF_3)_3Ga(DMF) \quad (36)$$

$$InCl_3 \xrightarrow[MeCN]{(CF_3)_2Cd} (CF_3)_3In(MeCN)_2 \quad (37)$$

$$TlCl_3 \xrightarrow[DMF]{(CF_3)_2Cd} (CF_3)_3Tl(DMF)_2 \quad (38)$$

^{1}H and ^{19}F NMR studies of the reaction between $(CF_3)_2Cd$ and Me_2Zn have also demonstrated that ligand exchange occurs to give $MeZn(CF_3)$ and $(CF_3)_2Zn$.[73] A summary of trifluoromethyl compounds that have been prepared from $(CF_3)_2Cd$ is provided in Table 4.[74]

Fluorinated alkyl vinyl and aryl cadmium reagents can be prepared in excellent yields just by stirring the fluorinated halides with activated cadmium metal.[75] These reagents can then be used to prepare the corresponding fluorinated stannanes, which are versatile synthetic intermediate, by reacting them with tri-*n*-butyltin chloride at room temperature.[76] Similar methods have been used to synthesize fluorinated copper reagents.[77]

Heterocyclic derivatives of cadmium compounds can be easily prepared by reacting the corresponding Grignard reagent

Table 4 Trifluoromethyl compounds prepared from $(CF_3)_2Cd$[74]

Product	Starting material
$P(CF_3)_xI_{3-x}$	PI_3
$Sn(CF_3)_xBr_{4-x}$	$SnBr_4$
$Ge(CF_3)_xI_{4-x}$	GeI_4

Scheme 3

with cadmium(II) chloride. Cadmium derivatives of heteroaryls such as thiophene, benzothiophene, N-methylindole and pyridine have been successfully used to attach these heterocycles to riboses with good stereoselectivity.[78,79]

Naturally occurring quinones and hydroquinones have been reported to have antitumoral, HIV transcriptase inhibiting, and immunomodulating properties.[80] Alkylation of quinones is one of the important routes to prepare biologically active substituted quinones. A series of substituted quinones was alkylated using diethyl cadmium (Scheme 3). The regiochemistry of the addition shifted from quinol formation to conjugate addition as a function of the steric and electronic effects of the substituents.[3,80]

1 INTRODUCTION

Ca^{2+} is an important second messenger in the regulation of cell life cycle in addition to being an essential component in biomineralization (*see* ***Biomineralization***).[1–3] For eukaryotic systems, different intracellular compartments exhibit different ionized Ca^{2+} concentrations that vary from millimolar concentrations in the endoplasmic reticulum (ER) to submicromolar concentrations in the cell cytoplasm. As shown in Figure 1, for eukaryotic cells, Ca^{2+} signaling is affected by a change in cytoplasmic ionized intracellular Ca^{2+} concentration ($[Ca^{2+}]_c$) that is mediated by the entry of Ca^{2+} across the cell membrane from the extracellular space or the release of Ca^{2+} from the major internal store, the ER. This is mediated via second messengers, including IP_3. The Ca^{2+} concentration in the cytoplasm is maintained by membrane-bound ATP-dependent Ca^{2+} pumps. Ca^{2+} mediates its action in regulation by binding to Ca^{2+} receptors/proteins that in turn regulate signal transduction, enzymatic activity, and protein stability. Ca^{2+}-binding proteins are divided into several major classes: trigger/sensors or regulators, buffer proteins, and stabilizing proteins with Ca^{2+} affinities that vary by 10^6-fold or more. The increase of cytosolic free $[Ca^{2+}]_c$ leads Ca^{2+} sensing (trigger) proteins, such as calmodulin (CaM), to bind Ca^{2+} and undergo a conformational change, which, in turn, regulates numerous cellular events and processes.[4–7] Ca^{2+} also directly regulates enzyme activities (e.g. proteinase calpain). Buffer proteins (e.g. calbindin$_{D9k}$ (CBD) and parvalbumin) act as intracellular Ca^{2+} buffers, modulating the free cytosolic Ca^{2+} levels, which are thought to prevent cells from Ca^{2+} overload and apoptosis.[8] Ca^{2+} also contributes to the folding and stability of proteins (e.g. thermitase and thermolysin).[9] A number of transmembrane spanning Ca^{2+} binding proteins (e.g. cadherins and integrins) support the structural integrity of cells and tissues and contribute to the transduction of signals.[10,11]

Although bacterial cells do not have complex subcompartments or organelles, there is strong evidence that Ca^{2+} plays an essential role in bacterial signaling, communication, and stability similar to the role it plays in eukaryotic cells. Bacteria cells also have a well-regulated cytosolic free Ca^{2+} concentration (approximately $0.1-2\,\mu M$) that remains significantly below that in the extracellular medium (mM) owing to Ca^{2+} transporters and channels.[12–14] While voltage-gated Ca^{2+} channels have been characterized in eukaryotic cells, their counterparts in bacteria remain to be elucidated. Recent developments have led to the hypothesis of nonproteinaceous Ca^{2+} channels in the cytoplasmic membrane.[15] While the function of these putative Ca^{2+} channels remains to be solved, a Ca^{2+} transporter of *S. pneumoniae* is involved in Ca^{2+}-DNA uptake, lysis, and competence.[16,17] Uptake of Ca^{2+} and other divalent cations can also accompany uptake of phosphate by the phosphate transport system of *E. coli*. Similar to the eukaryotic systems, P-type ATPase Ca^{2+} efflux pumps have been characterized from *Synechococcus* and *Flavobacterium*. The ChaA Ca^{2+}-proton antiporter from *E. coli* has been characterized for

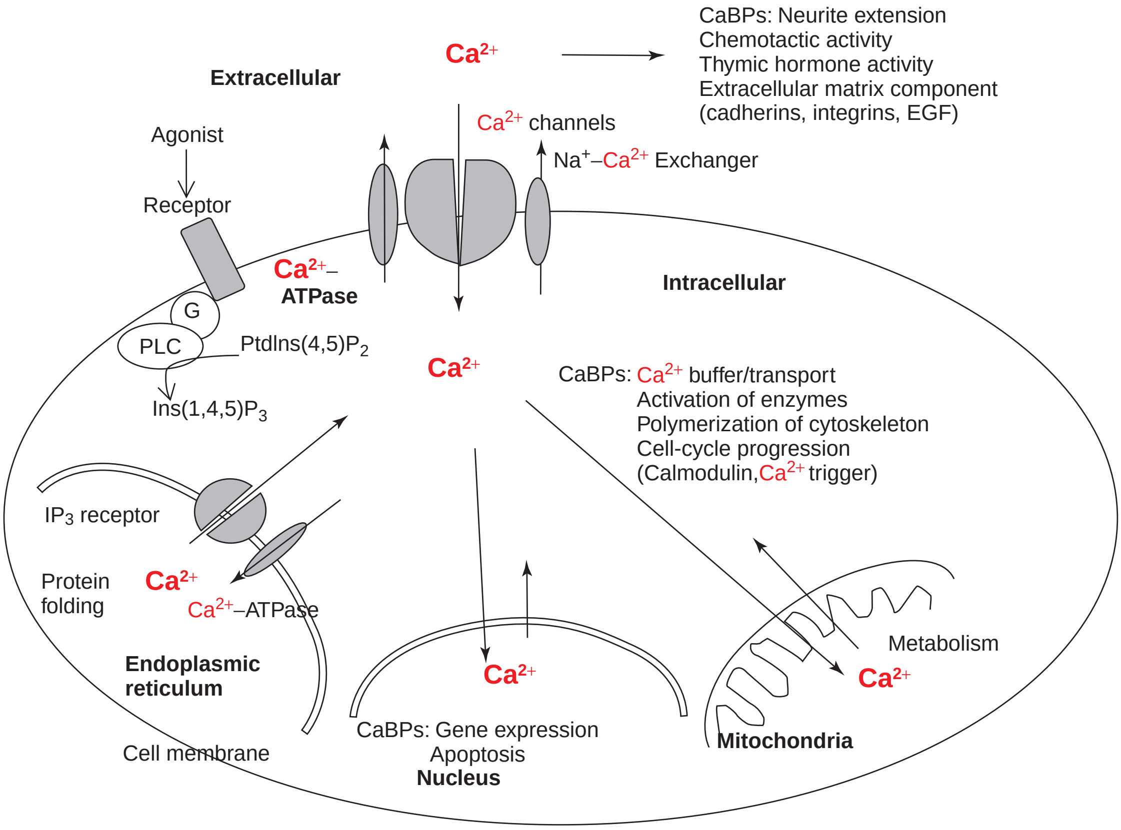

Figure 1 Ca^{2+} signaling and Ca^{2+} binding proteins in a eukaryotic cell. (Reprinted from B.W. Schafer and C.W. Heizmann, *Trends Biochem. Sci.*, 1996, **21**, 134. [© 1996, with permission from Elsevier])

Ca^{2+} circulation at alkaline pH and possession of a sequence domain similar to the eukaryotic Ca^{2+}-binding proteins, such as calsequestrin (CSQ). ChaA homologues and proteins similar to the eukaryotic Na^+/Ca^{2+} antiporter are widely present in the bacterial world. Further, it has been reported that bacteria contain Ca^{2+}-binding proteins are essential for cell adhesion, communication, and differentiation.[18–21] Some of the highly conserved ABC transporters are regulated by Ca^{2+} with Ca^{2+} binding proteins/domains and Ca^{2+}-dependent proteinase. Additionally, previous investigations described CaM-like proteins, such as calerythrin, with EF-hand Ca^{2+}-binding motifs of helix-loop-helix in many bacteria.[22–24] Reddy *et al.* recently reported that a calcium-binding protein CAMLP (calmodulin-like protein) was identified in *Mycobacterium smegmatis*.[25]

Calcium-binding proteins have also been reported for archaea. A calmodulin-like protein with a molecular mass of 24 kD was first found in an archaeon, *Halobacterium salinarium*. This protein is able to stimulate cyclic nucleotide phosphodiesterase in a calcium-dependent manner and can be suppressed by calmodulin inhibitors.[26] In addition, the extremely heat-stable pullulanase from *Pyrococcus woese*i binds two Ca^{2+} ions. Calcium plays essential roles in activation and stabilization of this protein against thermal and guanidinium chloride-induced unfolding.[27] NMR structural studies of the elongation factor, aEF-1β, from *Methanobacterium thermoautotrophicum* reveal that this protein binds calcium in the groove between helix $\alpha 2$ and strand $\beta 4$. Calcium may play either a structural role for protein stability or a functional role in archaeal protein translation.[28]

During the past few years, owing to the rapid progress in genomic information and structural biological studies, our understanding of calcium-binding proteins has been greatly expanded. Since 1991, the structures of calcium-binding proteins have been extended to more than 500 today and they are found in every cellular compartment. In this article, we will first summarize the current knowledge about the common properties of calcium-binding proteins. We then will highlight recent developments in structural biology and biological functions of several classes of calcium-binding proteins.

2 GENERAL PROPERTIES OF CALCIUM-BINDING PROTEINS

Calcium-binding sites are generally classified into three types.[29–31] Class I includes proteins whose Ca^{2+} binding

pockets are formed by a stretch of amino acids in the primary sequence (e.g. EF-hand proteins or α-lactalbumin). EF-hand proteins have a conserved motif of a Ca^{2+}-binding loop flanked by two helices. All of the Ca^{2+} ligand residues of α-lactalbumin are composed of a 10-residue loop flanked by two helices, C and D, plus two water molecules. This type of Ca^{2+} binding site does not belong to the EF-hand family owing to different ligand arrangements and the packing of flanking helices (Figure 2). Class II sites have one ligand supplied by a part of the amino acid sequence far removed from the main binding sequence. D-galactose binding protein (GBP) belongs to this family. Several ligand residues in a short loop with a Glu 63-residue apart form a calcium-binding pocket with the geometry very similar to that of EF-hand proteins (Figure 2). Class III sites are created by amino acids remote from one another in the sequence. Proteins in this group, such as cadherins, C_2 domains, Site I of thermitase, and Phospholipase A_2, have a Ca^{2+} binding site formed by the ligand residues located remotely from one another in the protein sequence.

Detailed analysis for the coordination properties of calcium versus magnesium in proteins and small molecules have been carried out by Einspahr and Bugg,[31] MacPhalen,[29] Glusker,[9] and Natalie *et al*.[36] in the past. An average coordination of 7 for calcium-binding sites in proteins has been identified for several databases containing the structures of calcium-binding proteins. Recently, Pidcock and Moore have carried out surveys of X-ray structures of Ca^{2+}- and Ln^{3+}-containing proteins and coordination complexes.[30] To avoid biasing general conclusions concerning the coordination chemistry of protein-bound calcium, they selected a data set that contained only 44 structures and 60 Ca^{2+} binding sites with a total of 323 ligands from a total of 515 structures of Ca^{2+}-containing proteins. There was only one EF-hand site in this data set. Pidcock and colleagues have found that the average coordination number for Ca^{2+} was 6.0.[30] Calcium-binding sites of EF-hand proteins have a coordination number of 7, which is consistent with previous findings.[36–40] The calcium-binding sites in different classes of proteins can be identified using the structural parameters by a computational program, which is also further used for de novo design of calcium-binding proteins.[41] Among 162 calcium sites surveyed within the Cambridge Structural Database, an average of coordination number of 6.9 was found for small calcium chelators.[30] A polydentate ligand with 3–6 oxygen atoms is able to form calcium complexes with higher coordination numbers. The constraints of the backbone of proteins may be responsible for the relatively low coordination number.

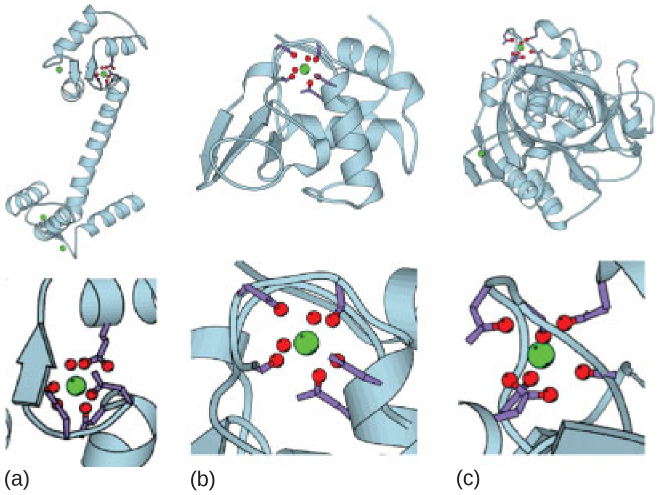

Figure 2 Calcium-binding sites of (a) calmodulin, (b) α-lactalbumin, and (c) thermitase are shown (top) and the pentagonal bipyrimal geometry of calcium-binding sites in each protein is enlarged (bottom). There are one, two, and zero water molecules in the enlarged binding geometries, respectively.[32–34] The structure figures in this article are prepared using the program MOLSCRIPT[35]

A turn or loop structure was found to provide the bulk of the ligands to Ca^{2+}, but helix and sheet secondary structures are slightly better providers of bidentate carboxylate ligation than turn or loop structures. In the database analyzed by Pidcock and Moore, the relative populations of all protein-derived calcium ligand residues are 72.5, 13.4, and 13.5% for turn/loop, helix, and sheet, respectively.[30]

Table 1 shows the relative population of amino acids used in the coordination for calcium binding. Asp has the highest calcium-binding preference as revealed in the all CBP database by Pidcock and Moore[30] and the EF-hand database by Falke *et al*.[42] The relative calcium ligand population is acidic residues > water > mainchain carbonyl > Asn > Ser > Thr > Gln > Tyr. Carboxylate ligand residues of Asp and Glu form the major class of calcium ligands from the protein frame. It is interesting to note that Glu is a preferred bidentate ligand for EF-hand proteins while Asp is commonly used for non-EF-hand proteins.

To understand metal selectivity of proteins, Dudev *et al*. have analyzed the first-second shell interactions in metal binding sites in proteins.[43] As shown in Figure 3, both calcium and magnesium sites prefer carboxylates Asp and Glu as metal ligand residues. On the other hand, magnesium strongly prefers water in the first-shell coordination compared to calcium sites in proteins. Peptide backbone groups were found to be the most common second-shell ligand for calcium-binding sites. The relative orders follow Asp/Glu > Lys/Arg > Asn/Gln > Ser/Thr sidechains.[43] Nayal and Di Cera have found that the bond-strength contribution of each ligating oxygen atom in the inner shell can be evaluated by using an empirical expression successfully applied in the analysis of crystals of metal oxides. The sum of such contributions closely approximates the valence of the bound cation.[44]

A detailed survey of 276 sequences of EF-hand proteins has shown that 64% of the calcium-binding loops have four acidic residues and 27% of the loops have three acidic residues at the ligand positions.[45] Four acidic residues were

Table 1 Amino acids observed as calcium-binding ligands in 567 EF-hand sequences. (Reproduced from J.J. Falke, S.K. Drake, A.L. Hazard, O.B. Peersen, Molecular tuning of ion binding to calcium signalling proteins. *Q, Rev. Biophys.* **27**(3): 219–90 by permission of Cambridge University Press)

Amino acid	Preferences for calcium all type (%)	Preferences for calcium side chain (%)	Preference as bidentate (%)
Asp	45	65	8
Glu	18	21	92
Asn	9.2	14	0
Ser	8.2	11	0
Thr	6.4	3.9	0
Phe	2.6	0	0
Lys	2.1	0	0
Gln	1.9	0.4	0
Gly	1.9	0	0
Tyr	1.5	0	0
Arg	0.79	0	0
Cys	0.50	0.2	0
Leu	0.32	0	0
Ile	0.32	0	0
Val	0.32	0	0
Ala	0.24	0	0
His	0.18	0	0
Met	0.15	0	0

Modified after Falke *et al.*, 1994. Asp has the strongest calcium-binding preference among all residue types. Glu is predominantly used as a bidentate ligand.

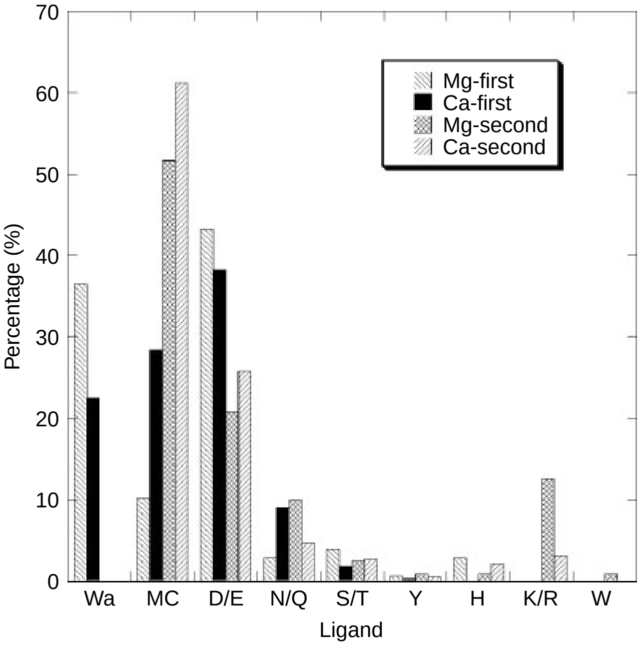

Figure 3 Percentage frequency distribution of the first-shell and the second-shell ligands observed in the 3D structures of proteins bound to Mg^{2+}- and Ca^{2+}-binding proteins. (Adapted with permission from Ref. 43. © 2003 American Chemical Society)

postulated to provide the most stable arrangement of anionic charges.[46] Reducing or increasing the number of acid residues at chelating positions will decrease the stability of the calcium-binding complex.[42,46] Electrostatic distribution outside of the coordination shell of the metal binding site has also been shown to have a strong contribution to calcium binding. Charged side chains that are present on the surface of the proteins can exhibit strong influences on metal binding affinity even if they are not directly involved as ligands.[47,48] As shown in Figure 4, the protein surface of calcium-binding protein α-lactalbumin is mostly negatively charged. In contrast, the non-calcium-binding protein lysozyme has a highly positively charged surface. The X-ray structure of bovine calbindin$_{D9k}$ reveals a cluster of negatively charged amino acid sidechains on the protein surface around the calcium sites. Linse and Forsen and their coworkers have shown that removal of three negative surface charges Glu, Asp, and Glu at positions 17, 19, and 26 in the vicinity of the calcium-binding sites of CBD (6.2, 6.4, and 11.1 Å) leads to a 45-fold decrease in average affinity (per site) at low ionic strength and a five-fold reduction at 0.15 M KCl.[49] The shifts in binding constants due to the reduction in affinity by the substitution of Asp with Asn and Glu with Gln in seven surface charge mutations have been accurately reproduced by Monte Carlo simulation.[50–53] Several other global factors, such as hydrophobic properties and hydrogen-bonding networks have been reported to contribute to calcium affinity.[44,54,55] These factors have less defined roles compared to the electrostatic interaction. They are likely to contribute to the dielectric environment that serves to shape the local electrostatic field.[42,44,47,54,55] Unfortunately, the estimation of the charge contribution to calcium affinity and selectivity in natural calcium-binding proteins is complicated by the interference of cooperative binding, calcium-dependent conformational change, and electrostatic interaction between multiple calcium ions.[9,38–40]

3 EF-HAND CALCIUM-BINDING PROTEINS

3.1 EF-hand Calcium-binding Proteins: Overview

An EF-hand motif with a conserved continuous calcium-binding loop flanked by two helices (helix-loop-helix)[29,37,42] was first described by Dr. Robert Kretsinger, who also described the continuous calcium-binding loop in parvalbumin (Parv).[59] EF-hand calcium-binding proteins are found in prokaryotes to eukaryotes throughout the entire plant (Fungi included) and animal kingdoms. Rapid progress in genome research demonstrates that the EF-hand motif is one of the

(b)

Figure 4 The electrostatic distributions of α-lactalbumin (1ALC)[56] (a) and chicken egg-white lysozyme (1LZ1)[57] (b) calculated by Delphi and presented by Grasp.[58] Both surfaces of calcium-binding protein α-lactalbumin are mostly negatively charged (a) (in red) while the surfaces of noncalcium binding protein lysozyme (b) are mostly positively charged (in blue)

five most common protein motifs in human. Up to 600 entries in animal cells have been identified in all eukaryotes.[59,60] Day *et al*. have identified a maximum of 250 putative EF-hand proteins in the plant Arabidopsis.[61] According to the sequence similarity, EF-hand proteins are classified into 77 distinct subfamilies that contain two to twelve copies of the EF-hand. These include CaM, Parv, troponin C (TnC), sarcoplasmic calcium-binding protein, the essential and regulatory light chains of myosin, CBD, and the S100 and visinin or recoverin (VIS) subfamilies.[62] One of the 77 EF-hand subfamilies is found in viruses and five are found in bacteria.[62]

Transient change of intracellular calcium concentration is sensed primarily by EF-hand calcium-binding proteins such as calmodulin (CaM) and TnC located in the intracellular environment.[63] In addition to EF-hand proteins in the cytoplasm, this highly conserved EF-hand motif was also found in other subcellular compartments and associates with membranes.[64–66] S100, a multigenic family of nonubiquitous calcium-modulated proteins of the EF-hand type expressed in vertebrates exclusively, has been implicated in intracellular and extracellular regulatory activities.[67] Although more analysis of other genomes such as Archaea and virus is needed, given the important function of calcium signaling in cell development and proliferation, it will not be surprising that EF-hand proteins are found in all kingdoms and in every cellular environment.

There are several major functional classes of EF-hand proteins. In the first class, trigger proteins like CaM and TnC bind calcium with a large change in protein conformation, which allows them to regulate target proteins. The second manifests direct calcium-dependent enzymatic activities. Examples include aequorin, calcium-dependent protein kinase, calcineurin, calpain, and CaM domain protein kinase.[68,69] The third type of proteins do not interact with other proteins but act as intracellular calcium buffers modulating the free cytosolic calcium levels and preventing cells from calcium overload and apoptosis.[70] Buffer proteins like CBD and Parv bind calcium without a significant change in the protein conformation. The calcium affinities for EF-hand proteins vary by 10^6-fold or more according to their biological roles. Trigger proteins have affinities with K_d of 10^{-6} M. Parv has the highest affinity of K_d (about 10^{-9} M). Calpain, on the other hand, has a K_d of mM.

As shown in Figure 5, EF-hand motifs can be divided into several major classes: canonical (classical), pseudo-EF-hand motifs, essential light chain (ELC), and BM40.[37,62] The canonical EF-hand consists of α-helix E (helix I, residues -9 to -1), 12-residue calcium-binding EF-loop (1–12) and α-helix F (or Helix II, 10–20).[62] The loop sequence positions 1 (x-axis), 3(y), 5(z), 7($-y$), 9($-x$), 12($-z$) coordinate the calcium ion in a pentagonal bipyramidal geometry. The statistic data shows that the side chain of Asp almost always (99%) serves as the ligand at position 1, and the glutamate side chain at position 12 ($-z$ axis) binds in a bidentate mode to calcium (92%).[47] The $-x$-axis (position 9) is filled by a bridged water molecule connecting the side chain of aspartic acid, serine, or asparagine. The pseudo EF-hand motif has two additional residues with mainchain carbonyl oxygen at positions 1, 4, 6,

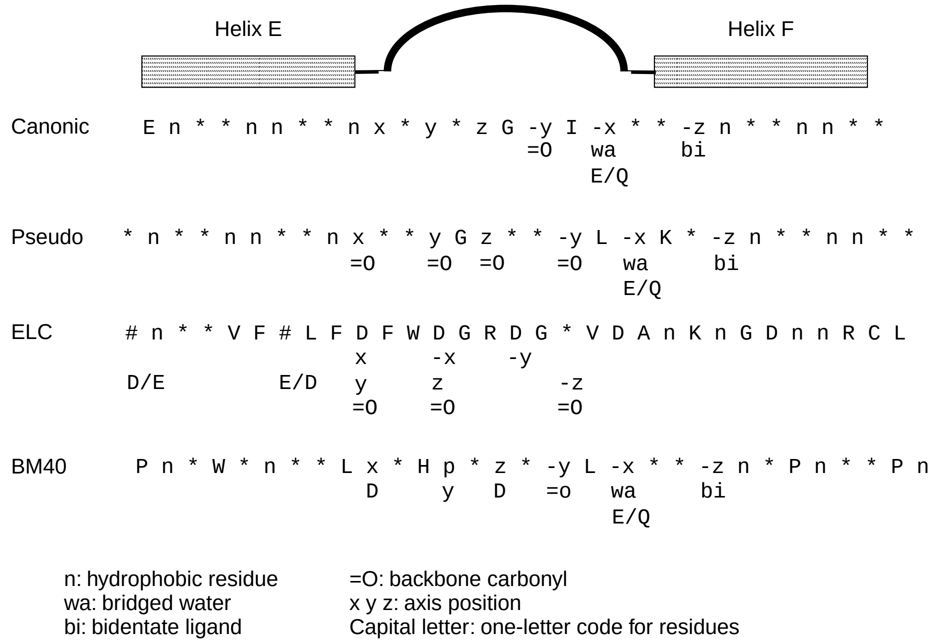

Figure 5 The sequence patterns of four different types of EF-hand motifs. (Ref. 62. Reproduced by permission of Springer Verlag)

and 9 and bidentate carboxyl side chain Glu at position 14. All proteins from the S100 family including CBD have the pseudo EF-hand motif in Site I. Position 6 has a conserved Gly for flexibility and hydrophobic residues such as I, V, L and M are found at loop position 8 and flanking helices −9, −5, −4 for Helix I and 13, 16, 17 and 20 for Helix II. Molluscan ELC and BM40 families have several additional insertions of the loop.[62] Slt35, a soluble fragment of the outer membrane-bound lytic transglycosylase B (MltB) from *E. coli*,[71] contains a 15–16 residue Ca^{2+} binding loop flanked by two helices.

The published structural studies show that nearly all the EF-hand proteins contain at least two interactive calcium-binding sites with average metal–metal distances of about

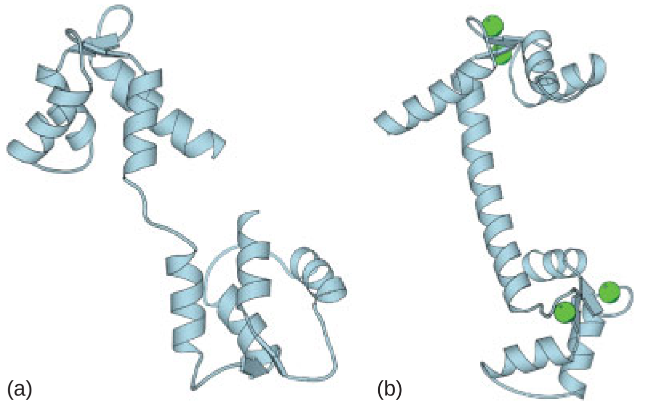

Figure 6 The structures of calcium free (a, 1CFD) and loaded (b, 3CLN) forms of calmodulin[33,78]

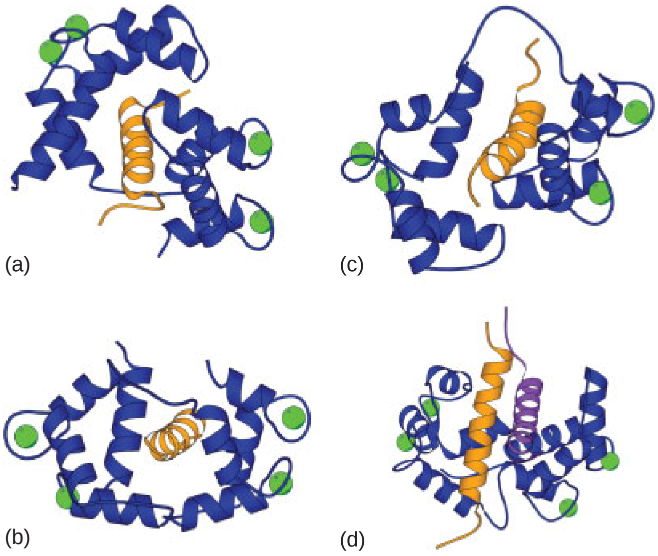

Figure 7 Structures of calmodulin (blue) complexed to a peptide (yellow) from (a) CaMKK (1IQ5),[79] (b) CaMKII (1CM1),[80] (c) rabbit skeletal myosin light chain kinase (SLMK) (2BBM),[74] and (d) glutamate decarboxylase (1NWD)[81]

11–12 Å within a domain with strong cooperativity for calcium binding.[72,73] For example, trigger proteins CaM and TnC have four EF-hand motifs in two tightly packed domains (Figures 6 and 7).[74,75] A few exceptions contain an odd number of EF-hand motifs in which the hydrophobic residues of the flanking helices either are buried by another helix as seen in Parv with three EF-hand motifs or form an

intermolecular dimer with five mutated EF-hand motifs as seen in calpain.[76] Almost all the members of S100 proteins such as S100B, calcyclin, psoriasin, p11, as well as calpain and neurocalcin form homodimer or heterodimers. It is clear that dimerization is one of the essential mechanisms that enable EF-hand proteins to effectively regulate multiple target proteins. In the past few years, significant progresses have been achieved in structural analysis of EF-hand proteins both in apo- and holo-forms.[76,77]

3.2 Calmodulin

Calmodulin (CaM) is a ubiquitous intracellular protein that mediates more than 100 different biological systems in both calcium-free and -loaded forms. CaM has 148 amino acids and its primary sequence is highly conserved in all cell types. It shares strong sequence and structure homology to TnC, which is involved solely in the Calcium-dependent regulation of skeletal and heart muscle contraction. Yeast (yCaM) is ∼60% identical in sequence to vertebrate CaMs and contains only three functional sites. Several labs have shown that the prokaryotes have several CaM-like proteins containing two or more authentic EF-hand motifs.[21,82]

As the major calcium-signaling molecule, calmodulin relays initial calcium signals to a large number of functional proteins in various physiological activities. This signal mediation is carried out by calmodulin-target protein interactions. Calmodulin binds to different target molecules at different calcium concentrations and results in different effects.[83] Some proteins, such as phosphorylase kinase, bind to CaM all the time but are only activated in the presence of calcium. Similar to phosphorylase kinase, myosin light chain kinase (MLCK), or calcineurin bind to CaM at both high and low calcium concentrations. This binding process is reversible possibly owing to its relatively weaker affinity to CaM. The binding of CaM either inhibits the protein functions, such as in some of the G-protein-receptor kinases and type-I IP3 receptors, or activates the protein function, as in protein kinases I and II. In protein kinases I and IV, the binding of CaM to two proteins (CaMK and CaMKK) simultaneously is required for the activation. Some proteins, as neuromodulin and neurogranin, bind to calcium-free CaM instead of the calcium-loaded form.[83,84] In the past few years, significant progress has been achieved in understanding calcium-dependent conformational changes and the several different interaction modes of calmodulin-target protein have been reviewed. The calmodulin-target protein interaction is studied mostly by CaM-peptide complex. The peptides for CaM binding share no primary sequence homology. However, some features are observed in many but not all cases, such as the potential to fold into a basic, amphiphilic α-helix, and the large hydrophobic residues at positions 1–5–10 or 1–8–14.[84] Here, we will first briefly discuss calcium-dependent conformational changes of calmodulin. We will then discuss some of the proteins involved in important activities including recent advances in structural information.

3.2.1 *Calcium-induced Conformational Change of Calmodulin*

High-resolution methods, especially the newly developed residual dipolar coupling (RDC) NMR in a dilute liquid crystalline phase (lipids or phage) have been shown to be a powerful method for monitoring the structural properties of calmodulin upon calcium binding.[74,77,78,85–87] As shown in Figure 6, in the apo-state, CaM is in a closed form and the two flanking helices are in an antiparallel position. Calcium binding to the EF-loop results in the movement of bidentate Glu at position 12 to form a better-defined calcium-binding pocket. Concurrently, this move of Glu 12 pulls residues of the attached helices closer together. Residues on the opposite end of the attached helices move away to each helix with a greater difference in the orientation of Helix I (26°) and IV (22°) in the N-terminal than in that of helices V and VIII in the C-terminal (for 15 and 10°) suggesting that the N-terminal is more open than the C-terminal. This movement of helices results in the exposure of the hydrophobic residues required for the binding of the target molecule (in the open conformation) and the helices become more perpendicular.[74,78,85] A harmonic oscillation of the central helix is observed across an arc with ±20°. Residues 77–81 are located in the middle of this central helix and act as a flexible tether, allowing conformational changes and cooperativity between the two domains in both the calcium-bound form[88] and the calcium-free form.[78,85] Significant backbone plasticity also was revealed by high-resolution 1.0 Å X-ray structure of the calcium-loaded form of CaM from *paramecium tetraurelia*.[89] Finally, Fallon and Quiocho reported that the 1.7 Å X-ray structure of a new native calcium-CaM is in a compact ellipsoidal conformation and shows a sharp bend in the linker helix and a more contracted N-terminal domain.[90]

3.2.2 *Calmodulin-dependent Proteins*

Calmodulin-dependent Kinases. Calmodulin-dependent kinases further relay and amplify the calcium signal from calmodulin to their target proteins. In animals, the identified calmodulin-dependent kinases include CaM-dependent kinase kinase (CaMKK), CaM kinase I-IV (CaMKI-IV), in which CaMKII is also known as elongation factor-2 kinase (eEF-2K), MLCKs and so on.[84] CaMKK, CaMKI, CaMKII, and CaMKIV have multiple targets that involve them in multiple activities, while eEF-2K and MLCK have much more restricted targets. CaMKK is at the upstream of the CaMKI and CaMKIV kinase cascade. CaMKK activates CaMKI and CaMKIV through the phosphorylation of these two kinases. The other substrate for CaMKK is protein kinase B (PKB). The activity of CaMKK itself is inhibited by protein

kinase A (PKA) that phosphorylates two sites in CaMKK.[84] Figure 7(a) shows a 26-residue peptide from CaMKK that binds to calmodulin (1IQ5).[79] This peptide forms an α-helix at the N-terminus and a β-hairpin at the C-terminus. The peptide is engulfed between the two lobes of CaM and its C-terminus interacts with the C-terminal lobe of CaM. Two major CaM-peptide contacts are located at Trp-444 in the α-helix and Phe-459 in the β-hairpin of the peptide, which has a 14-residue gap, longer than the normal 8- or 12-residue space. This binding mode is different from other peptides from CaMKII (Figure 7b) and MLCK (Figure 7c), which bind the C-terminal lobe of CaM with the N-terminus of peptide.

CaMKI is located in cytoplasm and nuclei and is likely to participate in regulation of gene transcription. In vitro CaMKI phosphorylates substrates such as synapsin and the cystic fibrosis transmembrane regulator although its in vivo substrates are yet to be identified. CaMKI is activated by phosphorylation by CaMKK when both kinases are calcium and CaM bound. The 25-residue CaM-binding peptide of CaMKI forms an α-helical structure. Two hydrophobic residues are located at positions 1 and 14 (Trp-303 and Met-316). The peptide induces the bending of the central helix with the interaction of both the N- and C-domains of CaM (pdb 1MXE).[84,91]

The CaMKII family phosphorylates numerous substrates including NR1, NR2A, NR2B, F-actin, α-actinin, densin-180, synGAPb, and cdk5.[92] CaMKII is not a substrate of other kinases. However, with the binding of calcium/CaM, it rapidly undergoes autophosphorylation at Thr-286 to activate itself. Once phosphorylated, the kinase activity is partially retained even after the calcium/CaM dissociates from the protein. Figure 7(b) shows that the binding of CaMKII peptide to CaM unwinds the central helix of CaM (Figure 6). The C- and N-lobes of CaM are bent by 100° and rotate by 120° relative to the substrate-free calcium-bound CaM. Thus, the N- and C-lobes of CaM close together to form a hydrophobic pore that holds the peptide. The binding is mainly driven by the hydrophobic forces where the methionine residues in CaM play a critical role. MLCK has as substrate the regulatory light chain of myosin II. A 25-residue peptide interacts with CaM in a manner similar to that of the other kinase peptides. It bends the central helix of CaM to enable interaction with both lobes of CaM. The peptide forms α-helical structure and the Trp-4 and Phe-17 (positions 1 and 14) of the peptide anchor the peptide to the C- and N-terminus of CaM, respectively (Figure 7c).[80,84]

CaMKIV is responsible for calcium-dependent gene transcription through the phosphorylation of transcription factors cAMP response element-binding protein (CREB), serum response factor (SRF), and myocyte enhancer factor-2 (MEF2). Oncoprotein 18 in the cytoplasm is also a substrate of CaMKIV. The activity of CaMKIV is activated by CaMKK and autophosphorylation. The elongation factor-2 is the only known substrate of CaMKIII (eEF-2K) at present. The phosphorylation of elongation factor-2 inhibits its functions. eEF-2K can be regulated by autophosphorylation and PKA. Other kinases regulated by calmodulin include phosphorylase kinase, phosphatidylinositol 3-kinase, and a series of plant kinases such as cabin1, MCKs, CCaMKs, and CBKs, and so forth.[83,84,93–95]

Calmodulin-regulated Ion Channels. Calmodulin regulates different ion channels including calcium channels. Here we briefly discuss the CaM-regulated potassium channel and sodium channel. All calcium channels and calcium pumps will be discussed in Section 5 in this article. The voltage-gated sodium channel has been shown to be regulated by the CaM-dependent pathway.[96] The calcium-activated potassium channel transports potassium from the cytoplasm to the extracellular environment with a high selectivity for potassium over sodium. Its function is dependent on the cytoplasmic calcium concentration instead of the membrane potential. Calcium increases the frequency of channel opening rather than the duration time of each opening. The potassium channel functions as a homo-tetramer. Each monomer contains six transmembrane segments (TMS) and a pore between TMS-5 and TMS-6. Both the N- and C-termini are located on the cytosolic side. CaM binds to the C-terminus of the protein.[95,97]

Figure 8 shows the structure of the CaM complex with a 96-residue fragment of the C-terminal cytosolic region of the channel with a different protein–protein interaction compared to the CaM-peptide structures.[98] This complex forms a dimer over two extended CaM molecules. The potassium channel

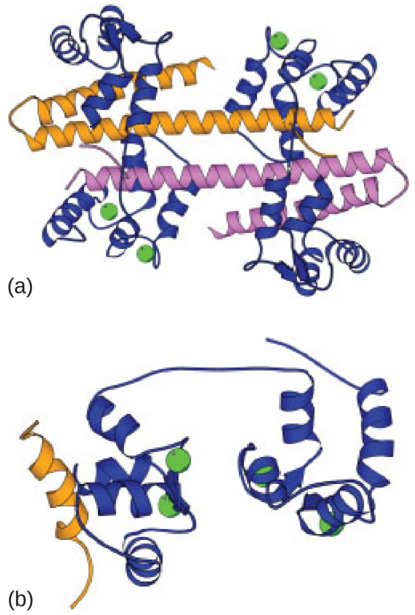

Figure 8 The structures of CaM complex with the peptides from (a) a 96-residue fragment of the C-terminal cytosolic region of the potassium channel (1G4Y) (yellow and pink)[98] and (b) calcium pump (yellow, 1CFF)[99]

fragment forms two antiparallel α-helices with the shorter one binding to the C-terminal lobe of CaM only. On the other hand, the N-terminus of the longer α-helix binds to the C-terminal lobe of CaM and the C-terminus of this helix protrudes to bind to the N-terminal lobe of another CaM. In this structure, CaM is half saturated. Two calcium ions are bound at the N-terminus of CaM. Surprisingly, the C-terminal lobe with a higher calcium affinity is free.[95,98]

Nucleotide Cyclases. Calmodulin regulates the activity of different nucleotide cyclases such as adenylyl cyclase that catalyzes the formation of cAMP from ATP. cAMP is another important molecule in the cell functioning as a second-messenger like calcium. The calmodulin-adenylyl cyclase interaction links these two second messengers together.[83,95]

Edema factor of anthrax is one of the three exotoxins produced by the bacteria. The primary sequence is only slightly homologous to other adenylyl cyclases. When it enters the host cells, edema factor acts as an adenylyl cyclase and transforms ATP to cAMP efficiently. The structure of CaM-edema factor of anthrax complex has been obtained (Figure 9).[100] In the CaM-edema factor complex, only the C-terminal lobe binds two calcium ions while the N-terminal lobe is empty. CaM remains extended and is deeply inserted between the catalytic and the α-helical domains of this exotoxin with a large number of residues of CaM involved in the interaction. CaM binding results in a large domain reorientation of edema factor. The helical domain of edema factor undergoes a 15 Å translation and a 30° rotation. The CaM inserted site is far from the catalytic site and the catalytic site alone has no obvious difference between the CaM-free and – loaded forms. Nevertheless, CaM binding enhances the activity of edema factor 1000-fold.[100] Further, an α-helical peptide of exotoxin contains a typical CaM-binding hydrophobic pattern at positions 1-5-10. The NMR and Fluorescent resonance energy transfer (FRET) studies demonstrated that upon binding to this peptide, CaM is bent with both the N- and C-lobes moving close together in a manner similar to that of CaM-dependent kinases (Figure 7). It is possible that CaM binds to the short peptide and the full-length protein in different topologies.[95,100]

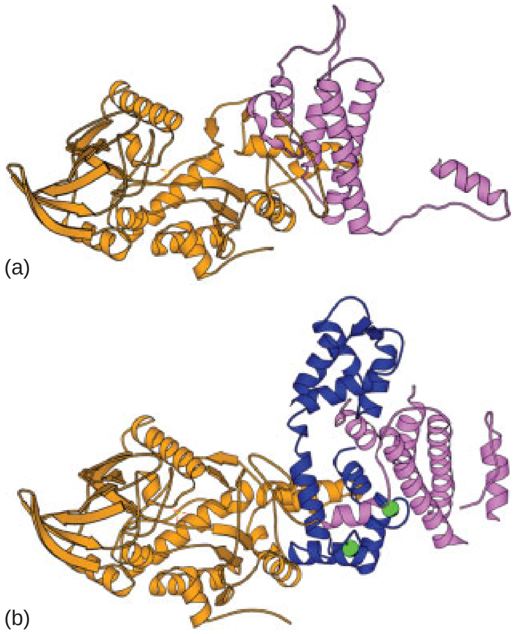

Figure 9 The structures of (a) calmodulin-free (1K8T) and (b) calmodulin-bound (1K93) forms of Edema factor[100]

Other Enzymes and Proteins. In addition to the kinases, cyclases, and ion channels, CaM interacts with and regulates a large, growing number of target proteins from almost every physiologic event of life. These target proteins include enzymes such as phosphodiesterases or phosphatase and other proteins such as gap junction protein connexins or β-2-glycoprotein.[83,95] Recently, the structures of CaM-peptide complexes from two enzymes have been solved, one is glutamate decarboxylase and the other is Nitric oxide synthase (NOS). NOS catalyzes the synthesis of NO, an important physiological messenger and cytotoxin. The 20-residue peptide from NOS binds to CaM to form a structure similar to that of CaMK peptide. The NOS peptide is α-helical and contains a classical pattern with hydrophobic residues at positions 1–5–8–14. Phe-496, Ala-500, Val-503, and Leu-509 in this pattern form critical interactions with CaM. In addition, Ile-505 interacts with several CaM residues such as Met-76, Phe-12, and Ala-15. The central helix of CaM is bent to wrap the peptide inside the pore.[101]

Glutamate decarboxylase in plants is a necessary enzyme for plant growth. It regulates glutamate metabolism and converts the glutamate into CO_2 and γ-aminobutyrate (GABA). The 26-residue peptide from glutamate decarboxylase is predominately unstructured in the absence of CaM. It becomes α-helical upon binding CaM (Figure 7d). Instead of a 1:1 binding, glutamate decarboxyase peptide binds to CaM in a 2:1 ratio. The N-terminal and C-terminal domains of CaM each bind one peptide. The two peptides are antiparallel forming an X-shape with an angle of about 60°. Trp-485 and Ile-482 are the two anchor residues and are critical for peptide-CaM interaction. CaM also bends and the two lobes move close together in this structure with a domain orientation different from that of CaMK peptide-CaM complex. For example, the interhelical angle between CaM helices 4 and 5 is from 114.2° to 123.2° in CaMK peptide complex while in glutamate decarboxylase peptide complex it is 17.2°.[81]

3.3 Troponin C

Tropinin C is a trigger protein that responds to the intracellular calcium concentration in striated muscle cells. An increase in calcium concentration up to 10^{-5} M results in calcium binding to TnC. The binding of calcium to TnC allows

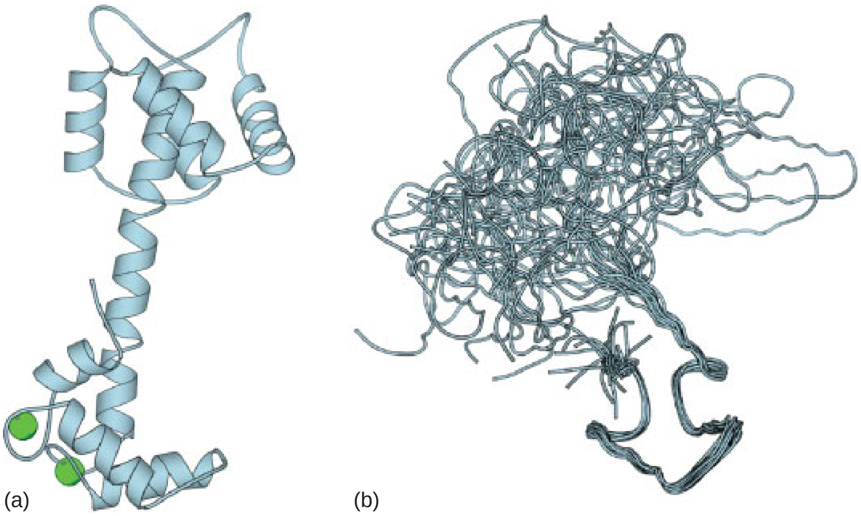

Figure 10 (a) The structures of sTnC with two calcium ions bound.[103] (b) The NMR structures of four-calcium-bound cTnC with the C-terminal of the protein superimposed[104]

it be recognized by the thin filament proteins to regulate muscle contraction. The thin filaments contain tropomysin, actin, and troponin. Troponin is a complex of TnC, troponin I (TnI), and TnT. The thick filaments are composed of myosin and a large ATP binding multi-subunit. Calcium binding to the low affinity of the N-terminal domain of TnC results in a conformational change, which, in turn, causes an alteration in the TnC/TnI/TnT interaction. The signal is then transmitted to other members of the thin filament. The interaction between the thin and the thick filaments are modified and muscle contraction is initiated.[102]

TnC has two isoforms of sTnC in fast striate muscle and cTnC in slow skeletal-cardiac muscle. Both isoforms contain four EF-hand calcium-binding sites. Site I of cTnC is inactive for calcium binding. Like calmodulin, EF-hand motifs I and II are paired in the N-terminal domain and III and IV are paired in the C-terminal domain. The 3D structures of sTnC from both chicken and turkey were first solved in 1985 and refined in 1988. As shown in Figure 10, the calcium-binding sites in the C-terminal domain are occupied while two calcium sites in the N-terminal domain are empty. The apo-N-terminal has different interhelical angles. Based on these observations and molecular modeling, Herzberg *et al*. proposed the HMJ model for the conformational change that occurs in the N-domain of TnC upon calcium binding. In the model, calcium binding leads TnC to change from a closed form to an open structure. The B/C pair of the helices is moved away from the A/D pair, which, in turn, exposes a hydrophobic patch. Since then, many structures of TnC with zero, two and four calcium ions bound have been solved. There are several surprises. First, the NMR structures of the calcium-loaded form of sTnC have a large flexibility in the interdomain linker. Hence the relative orientation of both domains is not fixed (Figure 10b). Second, both the N-terminal domain in isolation and the intact protein of cTnC remain in a predominantly closed conformation upon calcium binding.[102]

3.4 Calcium-buffer Proteins: Parvalbumin and Calbindin$_{D9K}$

Different from trigger proteins, parvalbumin and calbindin$_{D9k}$ function as calcium-buffer proteins. Calcium binding to both proteins does not lead to conformational change with an exposed hydrophobic surface. The structure of a carp parvalbumin was the first structure in the EF-hand protein family.[59] It has two isoforms (α and β) with very similar structures. Oncomodulin is the mammalian beta linkage parvalbumin. The structure of parvalbumin comprises three helix-loop-helix motifs, called AB, CD, and EF initially (Figure 11). The calcium-binding loop in the first

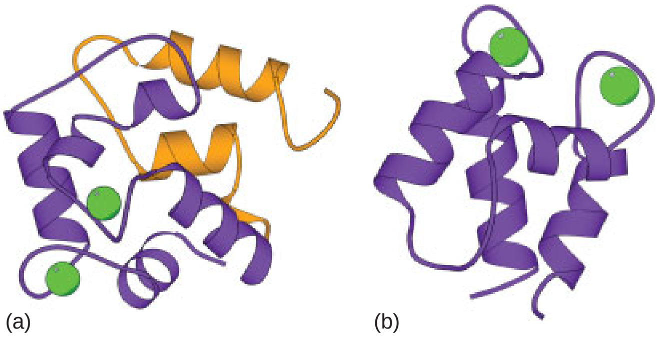

Figure 11 Structures of (a) parvalbumin and (b) CBD. Parvalbumin contains three EF-hand motifs, two of them bind to calcium (purple) and one loses the calcium-binding ability (orange).[105] CBD is monomer while the other S100 proteins are dimer[106]

calcium-binding site has a deletion of two residues. Hence this protein binds two calcium ions in the tightly coupled CD and EF calcium-binding sites. Although the AB site does not bind calcium, it is not 'nonfunctional' since it stabilizes the calcium-loaded form by covering its hydrophobic surfaces and the calcium-binding affinity is dramatically reduced once the AB site is deleted. The role of parvalbumin is proposed to relax muscle after calcium-simulated contraction. Recently parvalbumin has also been shown to play a role in neuron cells.

CBD is the smallest EF-hand protein with two EF-hand motifs. As a member of the S100 protein family, CBD contains one canonical and one pseudo-EF-hand motif at the C-terminus and N-terminus of the protein, respectively (Figure 11). Unlike other S100 proteins, CBD remains monomeric in solution. Chazin and Forsen's groups have carried out extensive structural studies of CBD at different conditions. Like parvalbumin, no significant structure changes have been observed upon calcium binding.[77,107]

3.5 S100 Proteins

The S100 (initially named after soluble in 100% ammonium sulfate) proteins are a group of low molecular weight, soluble calcium-binding proteins.[108] Currently there are more than 20 members in this family. Members of the S100 family often have more than one name. Genes encoding S100A1–14 are clustered together at the human chromosome region 1q21. All S100 members form dimers or oligomers except CBD. The tendency of dimerization is very strong with a K_d in the nanomolar range. This dimerization or oligomerization is critical for S100 proteins to interact with target proteins. It is interesting to note that CBD is the only monomeric S100 member that does not mediate any protein–protein interactions; instead it functions as a calcium-buffer protein. Most of the S100 members are observed in homodimers while S100A8 and S100A9 prefer to interact specifically with each other to form a heterodimer. The S100 family was first identified as intracellular functional proteins expressed in specific cells; for example, S100A8/A9 are mainly expressed in myeloid cells. Some S100 proteins have been shown to function extracellularly.[67,108–111]

The intracellular functions of S100 proteins can be summarized as follows: First, the interactions between S100 proteins and their target proteins result in either stimulating or inhibiting enzyme activities. The enzyme stimulation effects have been observed in cases of S100A1 and S100B binding to fructose-1,6-bisphosphate aldolase, phosphoglucomutase, twitchin kinase, and membrane-bound guanylate cyclase and S100B binding to Ndr. The enzyme inhibition effects have been observed in the process of S100A11 binding to actomyosin ATPase, S100A10 binding to phospholipase A2, S100A8/S100A9 complex binding to casein kinase I and II, and S100A1 binding to phosphoglucomutase and glycogen phosphorylase. Second, S100 binding inhibits protein phosphorylation by blocking the access of kinases to the phosphorylation positions. For example, S100 members regulate the annexin-membrane association by preventing annexin phosphorylation. The inhibition of p53 protein phosphorylation by S100A4 and S100B affects cell growth and tumor occurrence. The phosphorylations of myristoylated alanine-rich C kinase substrate (MARCKS), myosins, caldesmons, and τ protein are also regulated by their S100 partners. Third, S100 proteins control cell morphology, motility, and the dynamics of certain cytoskeleton elements. The components of the cytoskeleton system are a target for many S100 members. For example, microtubules interact with S100A1/S100B. Type-III intermediate filaments (IFs) interact with both the S100A1/S100B and S100A8/S100A9 complex. Caldesmon interacts with S100B and S100A6. Myosin interacts with S100A4. Tropomyosin interacts with S100A4 and S100A2. Microfilaments interact with S100A4 and S100A1. CapZa interacts with S100A1. F-actin interacts with S100A11. Keratin IFs interact with the S100A8/S100A9 complex and three other S100 members, profilaggrin, trychohyalin, and repetin.[67,109,111] Fourth, S100A1 has also been suggested to have chaperone activity as Hsp70/Hsp90.[112] Fifth, monomeric CBD buffers cellular calcium concentrations (Section 3.4).[67,109]

Many S100 proteins function extracellularly although the secretion mechanism is not quite clear. S100B stimulates neurite extension at nM concentration but inhibits it at µM concentration. S100B also induces neuronal apoptosis, IL-6 secretion, and NO secretion, modulates synaptic plasticity, and inhibits myogenesis. The S100A8/S100A9 complex plays a role in the immune system. It has cytostatic and antimicrobial activities. At the same time, it inhibits the activity of macrophage and the synthesis of immunoglobulin. S100A8/S100A9 complex also stimulates CD11b expression and inflammation response. S100A12 stimulates neurite growth at µM concentration and causes monocyte migration at nM concentration. The other extracellular S100 functions include S100A10 inhibiting the extrinsic pathway of blood coagulation, S100A2 inhibiting tumor cell motility, S100A4 stimulating neurite extension, and S100A2 and S100A4 mediating chemotactic processes.[67,109,113]

S100 proteins contain two calcium-binding sites, one canonic EF-hand site at the C-terminus (helix III-loop-helix IV) and one pseudo-EF-hand site at the N-terminus (helix I-loop-helix II) (Figure 5). Calcium binds to these two sites cooperatively.[62,109,111] The majority of the S100 functions are calcium-dependent, but calcium-independent S100-target protein interactions have also been observed.[111] The apo-, holo-, and target-binding-S100 triggers have been studied by NMR and X-ray crystallography. Figures 12 and 13 illustrate the calcium-induced conformational change of S100A6 and S100B.[114–117] The interaction surface of the dimeric structure has small changes. The relative orientations of helices I, IV, I', and IV' are almost the same before and after calcium binding.[67,111]

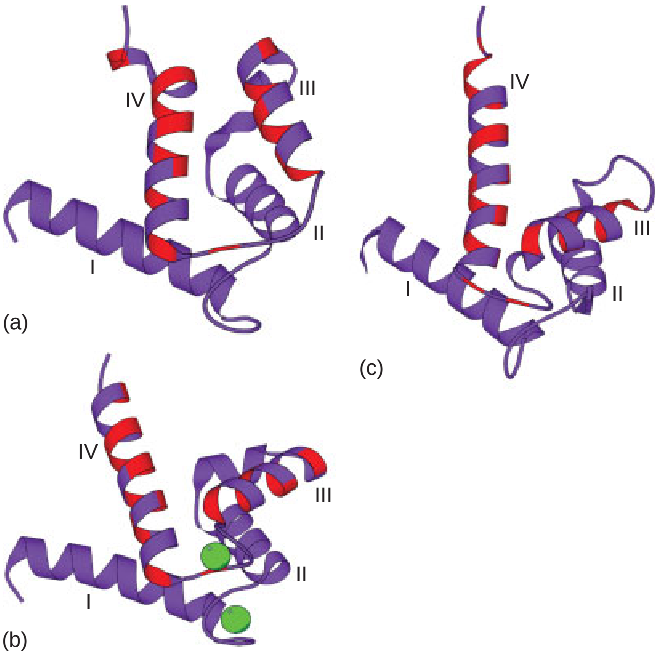

Figure 12 The conformational changes of S100A6 induced by calcium binding. Upon calcium binding (b, 1K96) helix III reorients from that of the calcium-free form (a, 1K9P) and the hydrophobic residues at the second helix-loop-helix motif (red) are exposed.[114] The structure of non-calcium-binding S100 member S100A10 (c, 1A4P) is similar to the calcium-loaded S100A6[118]

The major calcium-induced conformational change occurs in each S100 monomer. In this process, helix III (E-helix in the EF-hand motif II) undergoes reorientation and the hinge region between helix II and helix III reorients as a consequence. This process is different from that of calmodulin and TnC in which the F-helix (corresponding to helix IV here) in the EF-hand motif undergoes the largest reorientation upon calcium binding. Calcium binding exposes the buried hydrophobic residues at helices III and IV of S100 proteins. These exposed hydrophobic residues, together with the residues at helix II and the residues at helix I of the other monomer in the dimeric structure provide the binding surface for the target proteins. As shown in S100B structures (Figure 13), the target peptide binds to the cleft formed by helices III, IV, and the end of I', and the hinge loop between helices II and III. The binding of the target peptide slightly alters the orientation of helix IV, which makes the apparent calcium-binding affinity increase.[67,111,114–117]

In addition to calcium, several S100 proteins bind zinc ion with a K_d at micromolar or submicromolar level. Some S100 proteins, for example, S100B, have zinc-dependent target protein interactions. The zinc-binding and calcium-binding sites in S100 are not clustered together. The zinc-binding site in S100A7 is located between two monomers. It uses two histidines (His-86 and His-90) from one polypeptide chain and one histidine (His-17) and one aspartate (Asp-24) in another polypeptide chain as the ligands. These residues are conserved in other S100 members including S100A8, S100A9, S100A12, and S100B. Copper binding is also observed in S100A12.[67,108,111]

S100A10 is the only S100 member that does not bind calcium. Both calcium-binding sites in S100A10 are missing and the function of S100A10 is calcium-independent. The structure of S100A10 (Figure 12) is closer to the structure of calcium-loaded S100 proteins than the calcium-free proteins. For example, the interhelical angles between helices III and IV of S100A10 is about 120°, close to that of calcium-loaded S100B (105°) and S100A6 (135°) but far from that of calcium-free S100B (−166°) and S100A6 (150°).[111,118]

3.6 Penta-EF-hand Proteins

Most of the naturally existing EF-hand proteins contain an even number of EF-hand motifs although the group of proteins containing an odd number of EF-hand motifs is growing. Currently identified proteins belonging to this group include calpain, sorcin, grancalcin, ALG-2 (apoptosis-linked gene 2 product), peflin, and yeast protein YG25. Among these, calpain is the first penta-EF-hand protein revealed.[119,120]

3.6.1 Calpain

Calpain is a calcium-dependent cysteine protease that regulates many different functions in the cell through cleaving substrate proteins (>100 reported by in vitro test). These substrate proteins mainly belong to four groups: cytoskeletal proteins, kinases and phosphatases, membrane-associated proteins, and transcription factors. For example, calpain regulates the cytoskeletal-membrane attachment by the cleavage of cytoskeletal proteins. The cleavage of kinases and phosphatase such as protein kinase C (PKC) affects the signal transduction pathways in the cell. Calpain also is involved in cell cycle regulation, gene expression, apoptosis, and the long-term potentiation of synaptic transmissions. As a protease, calpain is quickly autolyzed in the presence of calcium, which hampers the study of calcium-binding properties of this protein.[119,120]

There are two types of calpains, μ-calpain and m-calpain, which require an in vitro calcium concentration at µM and mM level, respectively. This calcium-binding affinity is too low to bind calcium at cytoplasmic calcium concentration. However, an in vivo target molecule or other factors that enhance the calcium binding of calpains have not been identified. It is interesting to note that m-calpain is able to function at calcium concentrations less than 10 µM in the presence of excess high concentration of isovalerylcarnitine (a ratio of 20 000 mol isovalerylcarnitine to 1 mol calpain).[120]

Both μ- and m-calpain comprise two chains, one light chain (domain VI) and a heavy chain (domain I-IV). Sequence analysis has revealed a possible EF-hand motif located

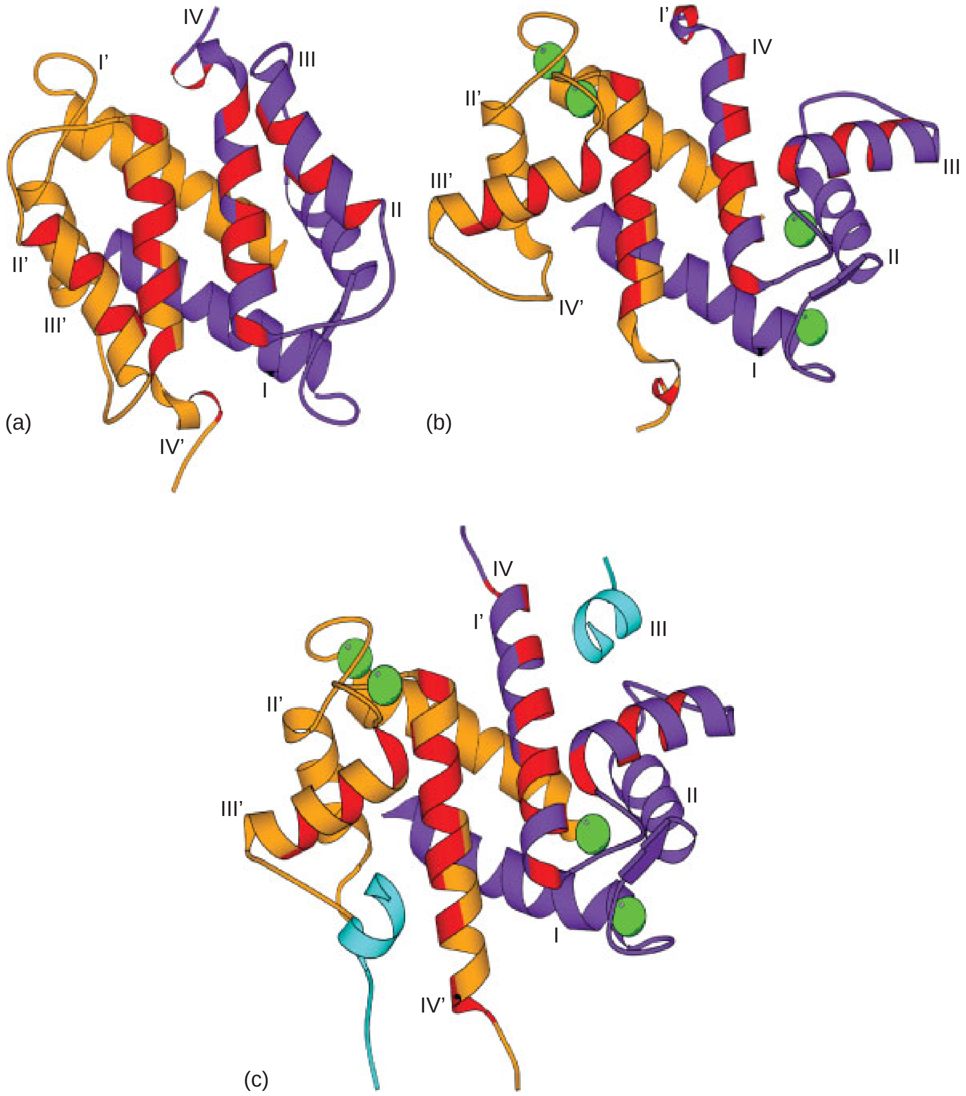

Figure 13 The structures of the calcium-free (a, 1SYM)[115] and the calcium-bound (b, 1QLK)[116] of S100B dimer (c). The structure of S100 dimer complexed to the target peptide (cyan in bottom figure, 1MWN)[117] at the cleft of helices III, IV, I', and the helices II-III hinge

between domain II and domain III. However, the X-ray structure of *m*-calpain indicates this EF-hand motif is not formed and does not bind to calcium. Instead, other loops coordinate two calcium ions. Both domain VI (light chain) and IV (heavy chain) contain five EF-hand helix-loop-helix motifs with mutations. For example, EF-1 (termed from N- to C-terminal) in both domains IV and VI has only 11 residues. The first two side chain ligands in typical EF-hand are missing and a mainchain carbonyl from Ala is used as a ligand. EF-5 is two residues longer than the normal EF-loop. The EF-5 of domain VI lacks the bidentate Glu at the C-terminal.

As shown in Figure 14, domain VI of calpain (1ALV) has eight α-helices forming five helix-loop-helix motifs.[121] Of the eight helices, helix-4 is shared by EF-2 and EF-3 and helix-7 is shared by EF-4 and EF-5. Under the crystal experimental conditions, three calcium ions (green ball) bind to EF-1, EF-2, and EF-3. The other calcium (orange ball) located in EF-4 is not chelated by the typical EF-hand residues. Instead, it uses bidentate Asp-225 and Asp-223 together with Asn-226 and Asp-135. Additional studies suggest that calcium may bind to different loops dependent on protein species and conditions. For example, a mutagenesis study has suggested that the EF-2 and EF-5 of domain VI bind calcium ions. A truncated calpain domain VI structure (removal of EF-5, 1NP8) shows all four remaining EF-hand motifs are occupied by cadmium ions. The removal of the EF-5 of calpain domain VI abolishes the hetero-dimerization ability with the intact calpain domain IV suggesting that EF-5 is responsible for the dimerization. On the other hand, the truncated protein forms homodimer through different contact surfaces.[120,122]

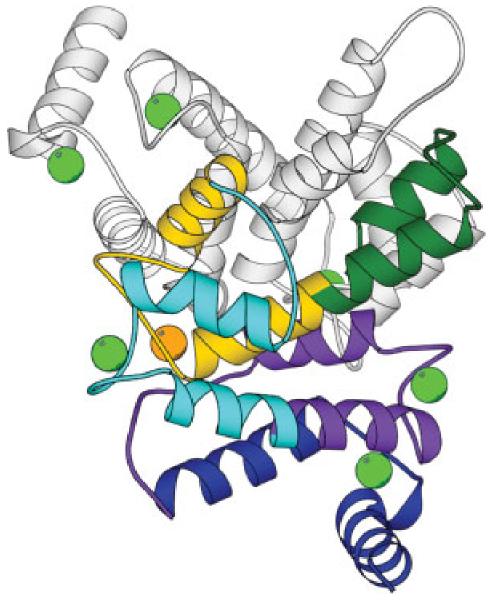

Figure 14 The structure of calpain domain VI dimer (1ALV)[121] with one chain in light gray and the other in color. Each EF-hand motif is in a separate color. From EF-1 to EF-5 they are in blue, purple, cyan, orange, and dark green. Helices 4 and 7 are shared by two EF-hand motifs. The calcium bound to the EF-loop is represented by green balls and that bound to other positions is represented by orange ball

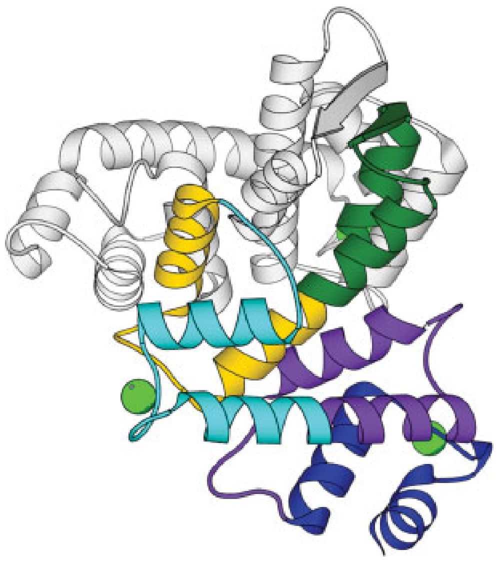

Figure 15 One chain in the dimeric structure of grancalcin (1K94)[125] is shown in light gray and the other in color. Each EF-hand motif is in a separate color, that is, from EF1–5 in blue, purple, cyan, orange, and dark green, respectively. Helices-4 and 7 are shared by two EF-hand motifs. The calcium (green ball) binds to the EF-1 and EF-3 in the colored chain and to the EF-3 in the gray chain

3.6.2 *Grancalcin and Sorcin*

Sorcin is a 22-kDa small protein modulating the sarcoplasmic reticulum (SR) calcium channel ryanodine receptor (RyR). It also interacts with annexin A7. Grancalcin is a 28-kDa protein with unknown functions. It displays a calcium-dependent translocation to the granules and plasma membrane of neutrophils. Both proteins are reported to form homodimers.[119] However, recent studies indicate that sorcin and grancalcin can also form heterodimers and can be coimmunoprecipitated, suggesting that they may function together.[123]

Sorcin and grancalcin contain five EF-hand motifs in each protein. Like calpain, some EF-hand motifs in sorcin and grancalcin are not intact. EF-1 of both proteins comprises only 11 residues, missing the first two Asp/Asn residues. Similar to calpain EF-1 the Ala carbonyl at the beginning of the EF-loop is used as the ligand. EF-2 of grancalcin lacks the bidentate Glu at the end of the loop. EF-4 of both proteins loses two to three side chain ligands at the beginning of the loop and the bidentate Glu is replaced by an Asp. Furthermore, EF-5 also loses the bidentate Glu and side chain ligand at loop position-3. Therefore, it is understood that the calcium-binding affinities of these EF-hand motifs are very low because of the broken patterns.[119,124]

X-ray structures of grancalcin and sorcin show that the overall structure of the proteins is similar to that of calpain domain IV and VI, which contains eight α-helices to form five helix-loop-helix motifs (Figure 15). EF-5 is responsible for the dimerization. When the intact protein is crystallized with 5 mM calcium only one calcium ion is bound to the grancalcin dimer located at one of the two EF-3 motifs. When the calcium concentration is increased to 100 mM three calcium ions are observed in the dimeric structure, two are located at the EF-3 motifs and one is found at one of the EF-1 motifs of the N-terminal truncated grancalcin.[124–126]

3.6.3 *ALG-2 and Peflin*

ALG-2 and peflin are another pair of penta-EF-hand proteins that can form heterodimers and function together.[127] ALG-2 plays a role in cell death. The biological function of peflin currently is not clear. Similar to calpain, sorcin, and grancalcin, the EF-hand motifs in ALG-2 and peflin are also incomplete. This time the EF-1 and EF-3 in both proteins are intact while all the other EF-hand motifs lack one or more calcium ligand residues.[119,124] The structure of ALG-2 (1HQV) shows that two calcium ions bind to two proposed high affinity calcium-binding sites EF-1 and EF-3. The third calcium binds to the EF-5 with the canonic EF-hand ligand residues at Asp-169, Asp-171, Asp-173, and the main chain of Trp-175 without the bidentate Glu. The homodimer shown in the same structure forms a V-shape geometry that is clearly different from that of the calpains and grancalcin. The dimerization surface is again located at the EF-5 region similar to calpain, sorcin, and grancalcin.[128] Unlike the typical

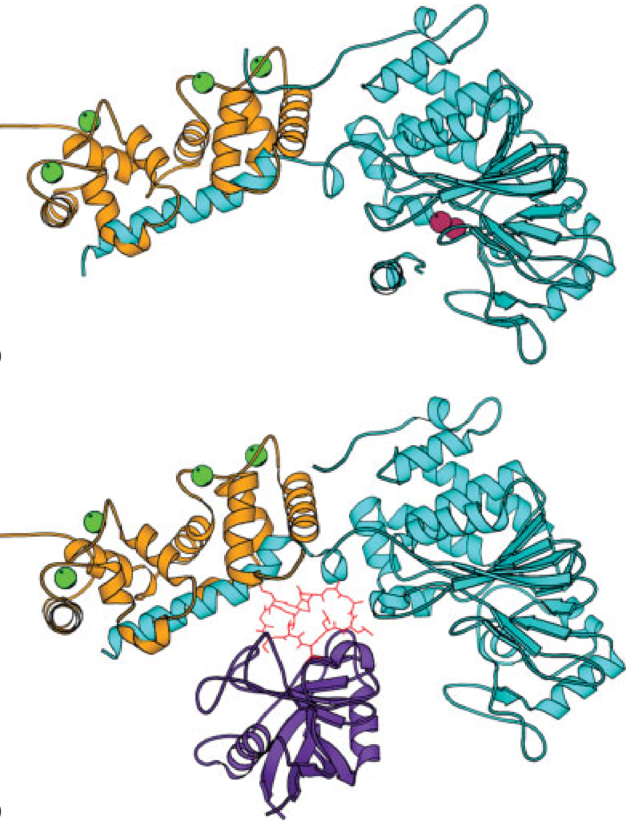
EF-hand proteins, each EF-hand motif of the penta-EF-hand proteins functions separately without cooperativity. Even if even-numbered calcium ions are bound, it is not necessary that they are paired. For example, in grancalcin and ALG-2, two calcium ions bind to EF-1 and EF-3 while the paired partners EF-2 and EF-4 are empty.[121,124,125,128]

3.7 Calcineurin and DREAM

Calcineurin and Downstream regulatory element antagonist modulator (DREAM) are two proteins that are involved in calcium-regulated transcription control pathways. There are several such pathways. One is through calmodulin-dependent kinase, such as CaM kinase I, CaM-kinase IV, or CaM kinase kinase. The other is through S100B that interacts with the tumor suppressor p53 to regulate its transcriptional activity.[93] Both the CaM kinases and S100B have been discussed earlier. Here we will focus on calcineurin and DREAM.

3.7.1 Calcineurin

Calcineurin is a serine/threonine phosphatase (also called protein phosphatase 2B, PP2B) with two subunits calcineurin A and calcineurin B. The catalytic site of calcineurin is located at subunit A, where a Zn–Fe binding site mediates the dephosphorylation reaction. Calcineurin A directly binds to the cytoplasmic subunit of NF-AT (NF-ATc) (nuclear factor of activated T-cell) to dephosphorylate serines in the serine-proline repeats. Only the dephosphorylated NF-ATc can be translocated into the nucleus to form the intact NF-AT complex, which binds to DNA to regulate transcription. The other transcription factors including NF-κ B, Ets1, and MEF2 are regulated by calcineurin.[93,129] The activity of calcineurin is regulated or inhibited by several molecules including FK506 binding protein (FKBP) and FK506, cyclophilin and cyclosporin A, cabin1 (cain), A238L, AKAP79, Csp1, and the calcipressins family. The activity of calcineurin A requires the binding of CaM to calcineurin B.[93,129] Calcineurin B is an EF-hand protein with a structure similar to calmodulin. Four canonic EF-hand motifs are located at residues 30–41, 62–73, 99–110, and 140–151, respectively. The structures of free calcineurin (1AUI) and calcineurin complexed with the inhibitors cyclosporin A/cyclophilin (1MF8) in Figure 16 have revealed that the calcineurin A-calcineurin B interaction is different from the typical known calmodulin-target interactions.[130,131] Calcineurin B uses both domains to interact with the same helix from calcineurin A while calmodulin interacts with its central helix between EF-2 and EF-3 or one of the domains at the N- or C-terminal. Cyclosporin A, as the inhibitor, binds to the interaction surface of calcineurin A-calcineurin B. As shown in Figure 16, the attached cyclophilin blocks the access of protein substrates to the catalytic site of calcineurin.[130,131] The structure of calcineurin complexed with another inhibitor, FK506/FKBP12, reveals a very similar inhibition mechanism (pdb 1TCO).[132]



(a)

(b)

Figure 16 (a) The structure of calcineurin with subunit A in cyan. The catalytic site containing a Zn–Fe binding site is in dark red. Subunit B in orange contains four calcium (green) ions bound to the EF-hand motifs. Both N- and C-terminal domains of calcineurin B interact to the same extended α-helix of calcineurin A.[130] (b) The inhibitor complex cyclosporin A (red) and cyclophilin (violet) interacts with both calcineurin subunits and blocks the catalytic site of calcineurin[131]

3.7.2 DREAM

DREAM (calsenilin, KChIP3) has multiple functions including interacting with presenilin to regulate calcium signals and modulate the activity of A-type voltage-gated potassium channels. In transcription control, calcium-free DREAM directly binds to the downstream regulatory element to block gene expression. DREAM is also essential in sensing pains. DREAM knockout mice display a reduced response to pain.[93]

DREAM is a calcium-binding protein that belongs to the recoverin EF-hand subfamily. One feature of the recoverin subfamily is the CPXG sequence at the beginning of the EF-1 motif. This sequence abolishes the calcium-binding ability of EF-1. As a result, DREAM binds three calcium ions, two at EF-3 and EF-4 with higher affinities (~5 μM) and one at EF-2 with lower affinity (~50 μM). Compared to the other recoverins, DREAM has a long N-terminal sequence but loses the N-terminal myristoylation.[93] No X-ray or NMR structure is available for DREAM at present, but the structural information is available for other recoverin members, such as

recoverin (e.g. 1REC, 1OMR, 1IKU, and 1JSA), neurocalcin (1BJF), and frequenin (1FPW and 1G8I).[133–137]

DREAM dimerizes and tetramerizes through a calcium-dependent mechanism. The calcium-free DREAM forms tetramer at protein concentrations higher than 20 μM. The calcium-bound DREAM forms dimer at low protein concentrations and tetramer when protein concentration is higher than 200 μM. There are other recoverin-like proteins with calcium-dependent dimerization with different responses. For example, calcium-free neurocalcin is a monomer while the calcium-loaded one forms a dimer. Conversely, guanylyl cyclase activating protein 2 (GCAP-2) forms a dimer in the calcium-free state and becomes a monomer in the calcium-bound state.[93]

To repress transcription, the calcium-free DREAM tetramer binds to DNA. Upon calcium binding, DREAM becomes a dimer and leaves the DNA to allow the RNA polymerase to perform transcription.[93] URE3-BP is another EF-hand protein that directly interacts with DNA at the upstream regulatory element-3 of the lectin heavy subunit gene. This protein has two EF-hand motifs.[138]

4 EXTRACELLULAR CALCIUM-BINDING PROTEINS

There are several types of extracellular calcium-binding proteins. The majority of these proteins such as cadherins, integrins and growth factors, are from eukaryotic systems. Below we will present how different extracellular calcium proteins carry out their unique biological functions.

4.1 Cadherins

Cadherin family refers to a group of calcium-dependent homophilic cell–cell adhesive molecules (Figures 17–18). Typical cadherins are named based on their expression locations, such as E-cadherin (epithelial), M-cadherin (muscle), and N-cadherin (neuron). Atypical cadherins include T-cadherin (truncated) and protocadherins.[11,139,140] Cadherins are the major constituent of the cell–cell adhesive junctions, functioning together with numerous other proteins such as catenins.[11,139–141] The property of homophilic recognition of cadherins and the formation of adhesive junctions play a key role in morphogenesis. For example, selective expression of different cadherins controls selective cell aggregation, which refers to the suspended cell re-aggregation with only homotypic cells.[140] This process is important in tissue and organ development. Cell condensing, another process in morphogenesis, also requires cadherins. Central nervous system development represents one of the most striking examples of cadherin-regulated morphogenesis. More than 20 different cadherins, involving all key events of neuron formation from the beginning stage of cell aggregation to the formation of synapses, are expressed at different stages and structural layers. Neurite outgrowth is also activated and regulated by cadherin expression. The formation and regulation of junctions between two neurons or neuron-muscle

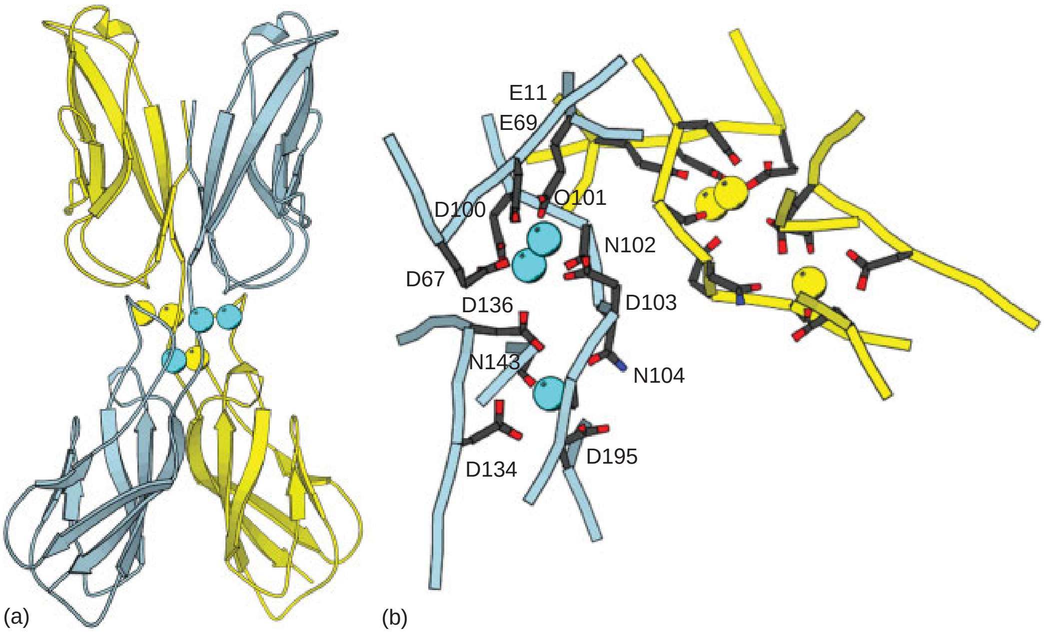


Figure 17 The dimeric structure of E-cadherin EC1–2 (1EDH) (a).[142] Two polypeptide chains and their bound calcium are shown in different colors. (b) A close-up view of the calcium-binding sites. The calcium ligand residues on chain A are labeled. Several ligands are shared by different calcium ions. All calcium binding in cadherin belongs to the discontinuous site class

are also cadherin-dependent. The role of cadherins, especially that of E-cadherins, in cancer growth and tumor invasion, has been investigated. Abnormal expression or abnormal distribution of E-cadherins has been observed in several cancers.[140]

Classical cadherins comprise three different parts, an intracellular C-terminal tail, a transmembrane segment that spans through the cell membrane once, and a long extracellular N-terminal chain.[139,140] The extracellular chain contains five domains termed EC1–5 (Figure 18). Each domain is ∼110 residues. The extracellular five domains are highly homologous to each other. The first domain at the N-terminus (EC1) is directly involved in cell–cell interaction. Domain exchange experiments have shown that the homophilic adhesive properties are encoded in the EC1 domain. Substitution of E-cadherin EC1 domain with P-cadherin (placental) EC1 domain leads the protein to bind selectively with P-cadherin. The four repeated domains EC2–5 are required for the maintenance of normal cadherin function. On the other hand, atypical cadherins of T-cadherin (truncated) and protocadherin subfamily have different structural properties.[140,144] T-cadherin (truncated) expressed in the neuronal system does not have the transmembrane and intracellular parts. It is anchored on the cell membrane via glycosylphosphatidylinositol (GPI). The extracellular part still contains five domains but without the conserved HAV sequence in EC1. The protocadherin subfamily has six or more extracellular domains. The sequences of EC3 and EC5

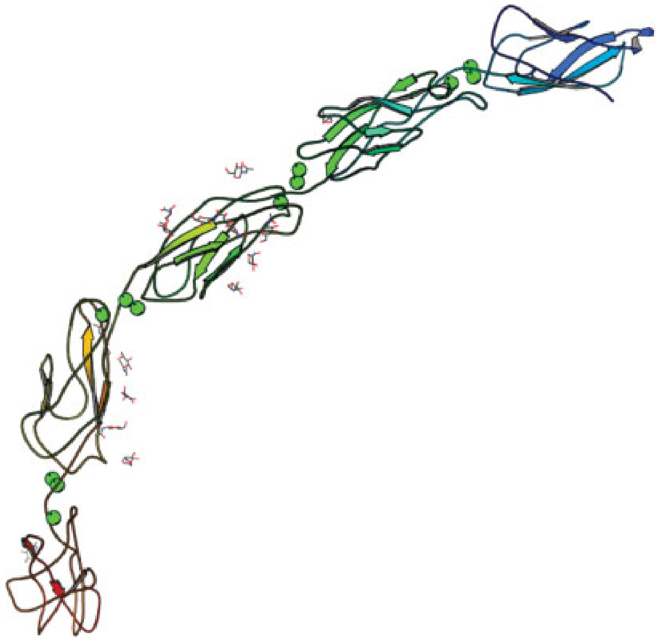

Figure 18 The structure of the extracellular region of Ep-cadherin (1L3W).[143] Calcium ions bind to the loops between each two adjacent domains and the whole protein in the structure forms a curvature. N-acetyl-D-glucosamine molecules attached to the cadherin surface are in gray

domains are also different from those of classical cadherin. Furthermore, they have different intracellular tails that do not interact with catenin.[140,144]

The intracellular tail of classic cadherin interacts with β-catenin or γ-catenin directly.[139,140] α-Catenin interacts with the cadherin tail through the mediation of β-catenin. Catenins then interact with the cytoskeleton protein actin. Through this cadherin-catenin-actin complex, cell–cell adhesion is linked with the cytosolic signal pathway. The cadherin-catenin complex regulates the outside cell–cell interaction. The expression level of cadherin also affects the expression of catenins. Another group of cadherin tail binding molecules is the p120 subfamily, which has a structure similar to catenins.[139] Extracellular cell adhesion is regulated by modifying the intracellular cadherin tail and its target. Stimulated by different signals, such as epidermal growth factor (EGF), transforming growth factor β, platelet-derived growth factor, hepatocyte growth factor, hormones, signals from gap junctions, and cholinergic receptor agonists, catenins or p120 will be phosphorylated directly or indirectly. Phosphorylation and dephosphorylation states of catenins or p120 alter the cadherin-target complex and further control the extracellular function of cadherin. This process is controlled by PKC, several signal receptor tyrosine kinases, Src tyrosine kinase, and several protein tyrosine phosphatases.[139,141]

The 15 solved structures of cadherins are mainly E- and N-cadherin. The X-ray structure shows seven β-strands in the EC1 domain. As shown in Figure 17, the EC1–2 domains of E-cadherin form lateral dimers in a calcium-dependent manner. There are three calcium ions bound between EC1-EC2 domains in each monomer in the crystal structure of E-cadherin EC1–2 dimer (1EDH).[142] Some ligands are shared by different calcium ions (Figure 17). The residue ligands for Ca1 are from the side chain of Glu-11, Asp-68, Glu-70, and Asp-103. The side chain carboxyl oxygen atoms of Glu-11, Glu-70, and Asp-103 are used as the ligands for Ca2. Ca2 also shares ligand Asp-136 with Ca3. The additional residue ligands for Ca2 are the side chain of Asp-100 and the mainchain of Gln-101. In addition to Asp-136, the ligands of Ca3 include bidentate Asp-134, the side chain of Asn-102, Asp-195, and the mainchain of Asn-104 and Asn-143.[142] Boggon *et al.* recently reported the structure of full-length ectodomain of the C-cadherin (EC1–5) (Figure 18).[143] Twelve calcium ions bind to the linkage region between neighboring domains, three in each of the four regions to sequentially organize the protein. The HAV tripeptide sequence in EC1 domain has been shown to be important for homophilic recognition.[143] The binding of calcium induces the conformational change of cadherin, including the important process of the Trp-2 in EC1 docking into the HAV sequence, which is believed to be important in exposing the homophilic recognition region. Trp-2 is observed both in cis dimerization and trans orientation (Figure 17). The structure of the five domains has a gentle bend without applied forces. This orientation corresponds to the distance of adhesion junctions revealed by EM. Cadherin monomers on opposed

cell membranes forming lateral or cis dimers are likely to mediate cell adhesion by forming trans adhesive interactions with cis dimers on the opposed membrane. The trans binding is proposed to be involved in interactions between the outmost domains or interactions between completely interdigitated proteins from both membranes.[143]

4.2 Integrins

Integrins are transmembrane proteins that mediate divalent cation-dependent cell–cell and cell matrix adhesion through tightly regulated interactions with ligands.[145,146] Integrins are involved in the formation of extracellular matrix by fibronectin binding and translocation and plays very important roles in various cell functions and processes such as secretion, phagocytosis, and migration. The extracellular proteins laminin and collagen also interact with integrin. Integrin mediated signals control the cell cycle by suppressing cyclin-dependent kinase inhibitors and integrins regulate the cell polarity and migration through the Rho-family GTPase pathway.[146,147] Several proteins are colocalized with integrin to function together. For example, secreted matrix metalloproteinases (MMPs) degrade the extracellular matrix via binding to integrin. Membrane growth factor receptors, including insulin receptor, EGF receptor, platelet-derived growth factor (PDGF) receptor, form supramolecular complexes for cooperative functioning. Other proteins associated with integrin include CD16, CD14, CD47, TM4, and P2Y. The biological functions of integrin are also regulated by other factors and proteins, such as intracellular calcium concentration, calpains, TM4, syndecans, and focal adhesion kinase.[146,147]

Integrins are $\alpha\beta$ heterodimers. Each type of integrin is defined by its components, for example, $\alpha 2\beta 1$ or $\alpha \mathrm{v}\beta 3$. Currently 18 α-subunits and eight β-subunits have been identified in mammals. Integrin α-subunit contains a transmembrane domain and a short intracellular tail at the C-terminus.[148,149] As shown in Figures 19 and 20, the extracellular region of the α-subunit contains four domains: a β-propeller structure with seven homologous repeats (blades), one C2-like 'thigh' domain, and two β-sandwich like domains (calf-1 and calf-2).[150,151] Some α-subunits contain an approximate 200-residue length A-domain (von Willebrand factor A domain) inserted into the N-terminal β-propeller domain. This inserted A-domain (αA, also named αI as inserted) forms a separated domain without disrupting the β-propeller structure.[148] Integrin β-subunit also contains a short intracellular tail and a transmembrane domain. The extracellular region comprises eight domains: an A-domain (βA), an Ig-like hybrid domain, a PSI domain (plexins, semaphorins, and integrins), four EGF domains (EGF1–4), and a β-tail domain (βTD).[148,149]

At micromolar concentration range, calcium enhances the integrin functions while calcium inhibits integrin function in the mM concentration range. Magnesium and manganese

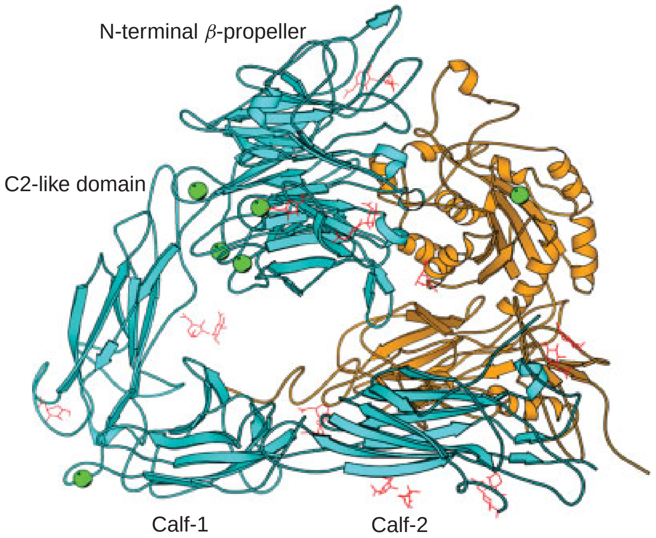

Figure 19 The structure of extracellular regions of integrin $\alpha 3\beta \mathrm{v}$ (1JV2).[151] The α-chain is in cyan, β-chain is in orange, and calcium ions are in green. Four domains of the α-chain are labeled

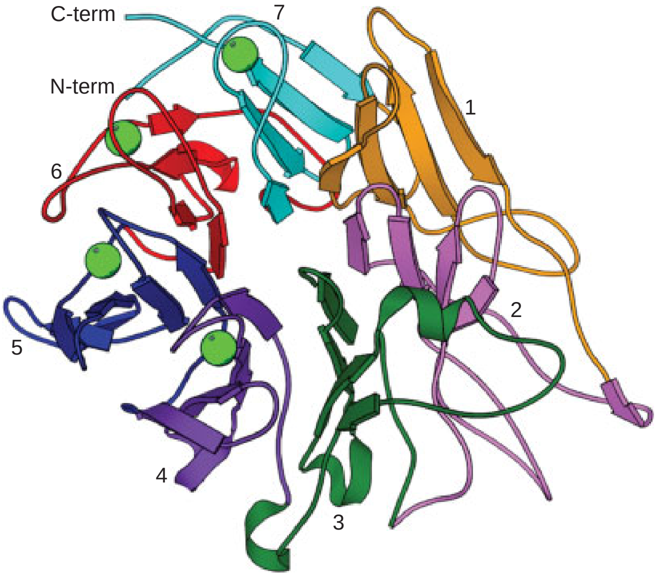

Figure 20 The N-terminal β-propeller domain of α-chain in integrin $\alpha 3\beta \mathrm{v}$ (1JV2)[151] contains seven repeated blades. Each blade (shown in one color) comprises four aligned β-strands. Four calcium ions bound in this domain are located at blades 4–7

facilitate the association of integrin with its ligands at a broad range of concentrations.[145] The integrin-recognition sequence with exposed acidic residues also contributes to integrin-ligand binding. Integrins that contain αA-domain recognize glutamate-based sequences while integrins without the αA-domain recognize aspartate-based sequences.[149] Integrin $\alpha \mathrm{v}\beta 3$ recognizes the RGD sequence in the target molecules.[150]

Before 2000, only structural information of the A-domain was available. Several X-ray and NMR structures of the extracellular integrins have been obtained after 2001 and they revealed detailed metal ion and peptide binding information.[145,150,151] These structures include the $\alpha v\beta 3$ with (1L5G)[150] and without (1M1X and 1JV2)[150,151] RGD sequence, the NMR structures of the N-terminal domain of αIibβ3 (1KUP and 1KUZ),[152] and the NMR structure of β2 subunit EGF-like domain (1L3Y).[153] The overall structure of the extracellular segments of integrin is like a head with two legs. The head consists of a β-propeller domain, including αA domain also in some types, of the α-subunit and the βA hybrid domains of the β-subunit. These two legs can be bent or extended depended upon different ligand and metal ion binding. The transition positions of these two conformations (bent and extended) are located between the 'thigh' and calf-1 domain in the α-subunit and PSI, EGF1, and EGF2 region in the β-subunit. The crystal structure 1M1X (3.3 Å, Mn-loaded) and 1JV2 (3.1 Å, Ca-loaded) revealed six divalent ion-binding positions.[150,151] As shown in Figure 20, four calcium-binding sites are found at the repeated blades 4–7 of the β-propeller structure at the N-terminal of α-subunit. They are exposed to the solvent with a continuous calcium-binding loop similar to the EF-loop of glactose-binding proteins, where a conserved nine-residue segment of D-h-D/N-x-D/N-G-h-x-D contains all the calcium-binding ligands at the side chain of positions 1, 3, 5, and 9 and the mainchain of position 7. The h here refers to hydrophobic residue and x refers to any residue. Another calcium ion binds to α-subunit between the bottom of the 'thigh' domain and the top of the calf-1 domain. βA-domain holds calcium at the ADMIDAS (adjacent to metal-ion-dependent adhesion site (MIDAS)) region, which coordinates the calcium by the mainchain carbonyl of Ser-123 and Met-335 and the side chain carboxyl of Asp-126 and Asp-127. When the protein is exposed to the manganese buffer, all six calcium-binding sites can be occupied by manganese.[150,151]

A MIDAS has been proposed in the αA-domain in the αA-containing integrin, as also in the βA-domain, which is the recognition location for the ligand molecules. The MIDAS motif of αA binds magnesium or manganese with high affinity and binds calcium with low affinity.[145,150,151] The RGD peptide binds to the βA and β-propeller structure of $\alpha v\beta 3$ resulting in the disruption of a hydrogen bond between Asp-119 and Glu-220 to allow the Glu-220 function as a ligand for the additional metal binding at the MIDAS motif.[150,151] This metal ion is coordinated with the carboxyl of Asp-119, Asp-251, and Glu-220, and the hydroxyl of Ser-121 and Ser-123. The binding of the short peptide RGD resulted in the binding of a second metal ion. This second metal ion is also located around the MIDAS motif with the ligand oxygen atoms from the side chain of Glu-220, Asp-158, Asn-215, and Asp-217, and the mainchain of Asp-217 and Pro-219. Glu-220 provides its two side chain carboxyl oxygen atoms to both metal ions. Although these two sites are revealed in the manganese bound structure, all the ligands are popular in calcium binding.[150,151]

4.3 Calcium-dependent Epidermal Growth Factor (EGF)

A large protein family that contains extracellular domains homologous to EGF is called the EGF-domain proteins. EGF-like domains or modules are often found in many extracellular and membrane proteins (>70). They are involved in blood coagulation, fibrinolysis and the complement systems, matrix proteins, cell surface receptors, the low-density lipoprotein receptor and the developmentally important receptor, Notch. EGF-like domains may exist as multiple copies within proteins such as in the Drosophila protein Notch with 36 copies or as a single copy as in EGF itself. It can also be found in conjunction with other modules.

EGF-like domains usually contain 40–50 amino acids with 6 conserved cysteine residues that form three disulfide bonds pairing in the pattern of 1–3, 2–4 and 5–6. These three disulfide bonds stabilize their common structure of two regions of double-stranded antiparallel beta sheets (Figure 21). More than 25% of EGF modules bind calcium. They are called calcium-binding EGF (cbEGF) and form one of the most popular extracellular calcium-binding sites. cbEGF is usually phlogenetically related and clusters together in a dendrogram. Fibulins, a newly recognized family of extracellular matrix proteins, have tandem arrays of EGF-like domains.[154]

The coagulation and anticoagulation proteases, factors VII, IX, and X, and protein C, have a common domain structure with an N-terminal gamma-carboxyglutamic acid (Gla)-containing domain that is followed by two EGF-like modules, whereas the C-terminal half of each protein is occupied by a trypsin-like serine protease domain. Prothrombin also has an N-terminal Gla domain and a C-terminal serine protease

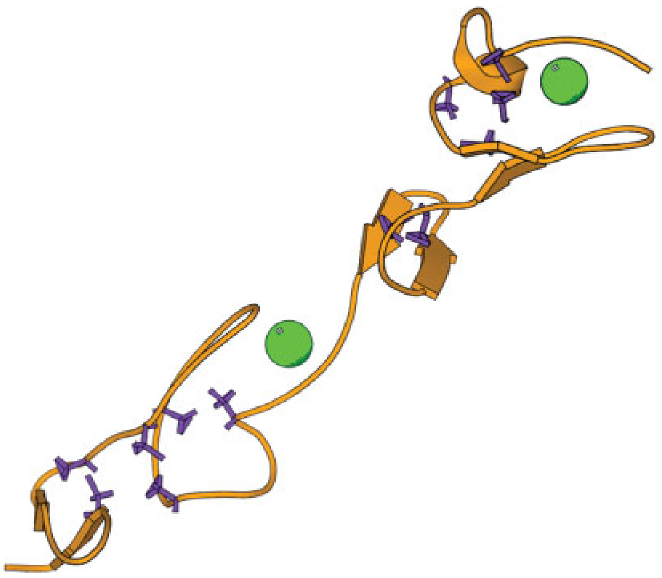

Figure 21 The structure of two EGF-like domains in human low-density lipoprotein receptor is shown with the Cys (violet) highlighted[155]

domain, but they are separated by two so-called kringle domains rather than EGF-like domains.

A protein S, the cofactor of activated protein C, has four EGF-like modules in tandem. The structure of N-terminal EGF modules is very similar to that of non-calcium-binding modules. Calcium binding only results in a limited local conformational change. The N-terminal loop is better defined and moves toward the major β-sheet. The N-terminal non-catalytic Gla and EGF-like domains provide coagulation serine proteases with different calcium affinities for certain biological membranes, and also mediate protein–protein interactions.[156,157]

Fibrillin-1 is composed of 43 cbEGF-like domains.[158] Calcium binding of fibrillins stabilizes interdomain cbEGF interactions and has been shown to be responsible for the formation of a rod-like linear arrangement. In addition, calcium binding significantly protects full length or recombinant fragments of fibrillin-1 from proteolysis by trypsin, elastase, endoproteinase Glu-C, plasmin and matrix metalloproteinase. cbEGF contains more than 60% of the identified mutations of the connective tissue disease Marfan syndrome and related disorders. Mutations at calcium-binding consensus residues on cbEGF such as N2144S in cbEGF32 significantly reduce calcium affinity. Recently NMR studies of the solution structure and dynamic properties of the cbEGF pairs such as cbEGF12–13 reveal a correlation between calcium-binding affinity and backbone dynamics. Calcium plays a key role in stabilizing the rigidity of the domain pair on the pico-to-millisecond timescale.[159,160]

The calcium-binding site in EGF domain is characterized by a consensus D/N-x-D/N-E/Q-x_m-D/N-*-x_n-Y/F (where m and n are variable and $*$ represents beta-hydroxyaspartic acid (Hya) or erythro-beta-hydroxyasparagine (Hyn). Hydroxylation is carried out by Asp/Asn-beta-hydroxylase. Factors IX and X and protein C all have one Hya in the N-terminal EGF module. There are two types of calcium-binding sites. Calcium sites largely locate between domains involved in conserved acidic residues in one EGF-like module and a single calcium ligand from a neighboring repeat. In Class I of repeat pairs, one ligand is donated by the N-terminal adjacent EGF-like domain[161] while for Class II, this ligand is from a repeat on an adjacent molecule.[10] Calcium-binding sites are usually pentagonal bipyrimidal. Usually isolated domain modules have low calcium affinity ($\sim$1–6 mM). The calcium affinity of the module pair was shown to be increased by 10–20-fold (K_d is about 0.1 mM).[162] N-terminal neighbor usually influences the calcium affinity of cbEGF modules.[163]

4.4 C-type Lectins

Lectins refer to all of the proteins that have carbohydrate-binding abilities.[164,165] Carbohydrate recognition domain (CRD) is the functional part in lectins for sugar binding. Based on the structural diversity of CRD, lectins are classified as L-, P-, I-, R-, C-type lectins, and galectins, in which C-type lectins are calcium-dependent lectins. C-type lectins are composed of several different subfamilies, including collectins, selectins, the mannose receptor, and NK receptors and so on. They are normally multiple domain proteins that comprise calcium-dependent CRD domain(s) and other domains performing diverse functions. The CRD domain in C-type lectins adopts a mixed α/β structure.[166,167] This section will briefly discuss the major C-type lectins of collectins, mannose receptor, selectins (CD62), asialoglycoprotein receptor (ASGPR) and GBPs. Calnexin and calreticulin will be discussed in the ER/SR calcium-binding protein section.

4.4.1 Collectins

Collectins are the soluble extracellular members of the lectin family. Collectins are secreted to the extracellular matrix and function as sugar pattern recognition molecules that selectively interact with certain microbial surfaces. It is important for immune responses. Mannose binding lectin (MBL) (mannose binding protein (MBP)), surfactant protein A (SP-A), SP-D, conglutinin, collectin-43, and collectin liver-1 belong to the collectin subfamily.[167–169] The collectins comprise four segments: a Cys-containing N-terminal segment that provides inter- and intrachain disulfide bridges, a collagen-like (-Gly-X-Y)$_n$ repeating sequence, a short linkage between the collagen-like segment to the CRD domain, and the calcium-dependent CRD domain at the C-terminal.[169] As shown in Figure 22, the collectins form trimers in which collagen-like segments wind together and their CRD domains are clustered at the top of the collagen helices. The isolated CRD with linkage segment maintains trimeric structure and the CRD without the linkage segment forms a dimer. Both sugar-selective and calcium-binding properties are encoded in the CRD domain; for example, Glu-185 and Asn-187 in MBP-A are specific for mannose recognition, but when they are mutated to Gln-185 and Asp-187, the protein changes its preference to galactoside.[169]

Calcium binding is required not only for function but also for structure stabilization. Here we use rat MBL–A (1RTM)[170] as an example to illustrate the calcium binding in collectins (Figure 22). Each monomer contains three calcium ions. Each CRD binds two calcium ions specifically (Ca1 and Ca2) and one nonspecifically. As shown in Figure 22(b), Ca1 is coordinated by the sidechains of Asp-161 (bidentate), Asp-188, Asp-194, Glu-165, and the mainchain carbonyl of Glu-193. Glu-193 provides the ligands for both specifically bound calcium ions. Ca2 is coordinated by the protein ligands of sidechains of Glu-193, Glu-185, Asn-187, Asn-205, Asp-206, and also the mainchain carbonyl of Asp-206. The bound sugar provides two hydroxyl oxygen atoms as additional ligands for Ca2. Meanwhile, this bound sugar interacts with Glu-185/Asn-187 pair, Asn-205, and Glu-193 of the protein. Thus, Ca2 directly mediates the sugar binding.[169,170]

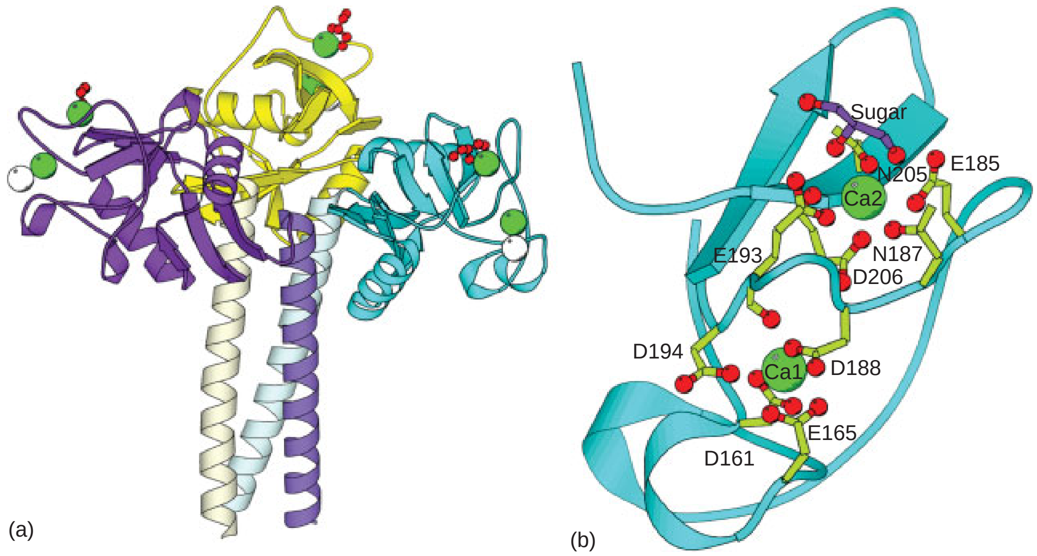

Figure 22 (a) The trimeric structure of MBL-A (1RTM)[170] with each monomer labeled with a different color. The CRDs and the glycan-like domains are labeled in dark and light colors, respectively. Each monomer contains three calcium ions. Two calcium ions (Ca1 and Ca2) that are specifically bound to the CRD are in green. The nonspecific calcium is in the lighter color. The calcium-mediated bound sugars are labeled in red. (b) The local view of the calcium-binding sites of Ca1 and Ca2 of MBL-A with ligand residues highlighted. Several ligands for both calcium ions are highly clustered in the loop from residue 185194, while Glu-193 is shared by two calcium ions. Glycerol is shown in violet

The X-ray structure shows that human SP-D (1PW9),[171] another collectin member, shares the same calcium-binding pattern as rat MBL-A, in which Ca2 binding ligands are encoded in a 22-residue loop E-x-N-5x-E-11x-N-D (Figure 23). The last Asp residue provides both mainchain and side chain ligands. Ca1 binding ligands are encoded in a longer loop D-3x-E-22x-D-4x-E-D, in which the first Asp is bidentate and the second Glu is shared with Ca2. Sequence alignment reveals that similar sequence characteristic properties for calcium binding are also conserved in other collectin members. For example, the Ca1 and Ca2 sharing Glu-residue, the N-D pattern at the end of the Ca2 binding loop, and the Glu-residue at the start of the Ca2 binding loop are conserved in many of the collectin members. Either acidic residue Asp or Glu is used as a bidentate ligand for Ca1.

4.4.2 *Mannose Receptor*

The mannose receptor subfamily is a group of membrane-attached C-type lectins with multiple CRDs. Since most of these domains maintain neither calcium-binding nor sugar-binding properties, the term C-type lectin-like domain (CTLD) is more frequently used lately instead of the term CRD. The mannose receptor subfamily comprises four members including the mannose receptor, the M-type phospholipase A2

Figure 23 Summary of the amino acid sequence patterns that are involved in calcium binding of the subfamilies of C-type lectins. One example in each subfamily is shown and the ligand position is marked black. The last Asp uses both oxygen atoms from the mainchain carbonyl and side chain carboxyl as the calcium ligand atoms

receptor (PLA2R), Endo180/uPARAP, and DEC-205/gp200-MR6/CD205. The first three contain eight CTLDs and the last one contains ten.[172]

The mannose receptor subfamily members contain an N-terminal Cys-rich domain that provides an additional sugar-binding site, a fibronectin type-II domain that binds to collagen, the repeated CTLDs, a transmembrane segment, and an intracellular tail that interacts with the cytoplasmic proteins. The CTLD4 and 5 instead of the CTLD at the end of the mannose receptor are the most critical domains for calcium binding and sugar binding. Endo180 has also been demonstrated to bind monosaccharides. However, CTLD5 within M-type phospholipase A2 receptor mediates protein–protein interactions instead of protein-sugar interactions.[172]

Figure 24(a) shows the structure of mannose receptor CTLD4 (1EGG),[173] which shares a mechanism of calcium-mediated sugar binding that is similar to that in MBL-A. The same sequence pattern for Ca2 binding in MBL-A is conserved in the mannose receptor CTLD4. As shown in Figure 23, mannose receptor CTLD4 has all of the five conserved ligand residues for calcium binding except Glu-733. Glu-733, corresponding to Glu-193 in MBL-A, is replaced by the side chain carbonyl of Asn-728. This Asn is not conserved in CTLD-5; instead it contains a conserved Glu-residue corresponding to Glu-733. The bound sugar provides an additional two oxygen atoms for Ca2. The Ca1 binding site is clearly different from the mannose receptor and MBL-A. In the mannose receptor CTLD4, Asn-728, Asn-731, Glu-737, and Asn-750 coordinate to Ca1.[173] Both CTLD1 and CTLD2 of Endo180 have the conserved calcium-binding pattern as observed in MBL-A. However, the M-type phospholipase A2 receptor and DEC-205 do not have this conserved calcium-binding pattern and their interaction with carbohydrates is independent of calcium binding.[172]

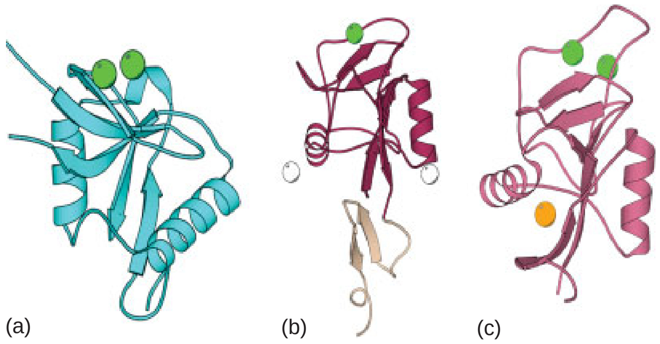

Figure 24 (a) The structure of CTLD4 of mannose receptor (CTLD4, 1EGG)[173] with two bound calcium ions. (b) The structure of CRD (dark red) and EGF-like domain (light colored) of E-selectin with the functional calcium (green) (1ESL).[174] The two nonspecific bound calcium ions are shown in lighter color. (c) The structure of the CRD on H1 subunit of ASGPR with the two calcium ions (green) as in normal C-type lectin (1DV8).[175] The third calcium ion unique to this protein is in orange

4.4.3 Selectins (CD62)

Selectins are cell-adhesion molecules that mediate leukocyte recruitment in immune reactions and signal transduction. Selectins comprise three members termed E-, P-, and L-selectin. The CRD is located at the N-terminus, followed by an EGF-like domain. There are various numbers of consensus repeat sequences following the EGF-like domain. P-selectin, L-selectin and E-selectin contain nine, six, and two repeats, respectively. A transmembrane segment and a cytoplasmic tail are located at the C-terminal. The key domains for target recognition and sugar binding are the N-terminal CRD and EGF-like domain.[167,176]

The CRD of selectins is similar to that of MBL, or MBP. As shown in Figure 24(b), selectins do not have the Ca1 binding site of MBL-A. However, crystal structures of E-selectin (1ESL)[174] and P-selectin (1G1Q, 1G1R, 1G1S, and 1G1T)[177] have revealed that the principal calcium-binding site mediating sugar binding (Ca2) is conserved. Similar to the mannose receptor, selectins contain the five conserved residues of the Ca2 binding pattern of MBL-A but only four of them bind to calcium. Glu-88, corresponding to Glu-193 in MBL-A, is not used for calcium binding. The bound sugar provides additional ligands for this calcium.[174,177]

4.4.4 Asialoglycoprotein Receptor

The hepatic ASGPR is involved in receptor-mediated endocytosis via coated pits. It is a hetero-oligomeric protein with two subunits of H1 and H2. ASGPR contains multiple CRDs and specifically binds to oligosaccharides in glycans.[178]

The structure of the CRD of H1 subunit (1DV8)[175] is shown in Figure 24(c). There are three bound calcium ions, two of which are similar to the Ca1 and Ca2 in MBL-A. As shown in Figure 23, the calcium-binding pattern of Ca2 in MBL-A is almost conserved in ASGPR CRD, including the E-11x-N-D sequence and the shared Glu ligand with Ca1. The differences include the change of E-x-N sequence at the N-terminus of the loop to Q-x-D, which is critical for galactose selectivity in ASGPR. Further, the distance between this calcium binding sequence to the shared Glu increases to 10 residues. The protein ligands for Ca2 are Gln-239, Asp-241, Glu-252, Asn-264, and Asp-265 (main chain and side chain). Ca1 in ASGPR contains four of the five Ca1 ligands of MBL-A. It is coordinated by Asp-215 (bidentate), Asp-242, Glu-252 (bidentate), and Asp-253. ASGPR has a Pro at the corresponding position of Glu-165 in MBL-A. The third calcium ion is unique to this protein. It is coordinated mainly by two glutamate residues, Glu-196 and Glu-227, both of which provide their two carboxyl oxygen atoms as bidentate ligands. The additional ligands come from the mainchain carbonyl of Val-190 and water.[175]

4.4.5 NK Receptor and Other C-type Lectins

Natural killer (NK) receptors are a group of proteins expressed at the surface of NK cells.[167,179] They share some common features including the transmembrane domains, intracellular tails, the formation of homodimers, and the C-terminal CTLD. There are many members, such as Ly49, CD69, and NKG2, in the family of NK receptors. These proteins have reserved the hydrophobic pattern of the C-type lectins such as MBL but lack the conserved calcium-binding residues. Many of them have been shown to function calcium-independently.[167,179] More and more C-type lectins have been discovered as a result of the fast progress in the field. For example, tetranectin and type-II antifreeze proteins are found to be C-type lectins that partially share the calcium-binding geometry and calcium-binding pattern of MBL.

4.4.6 Galactose-binding Protein

Galactose-binding proteins contain a unique calcium-binding site that differs from the general C-type lectins. GBPs are not classified as C-type lectins because calcium binding is not required for their biological function. Figure 25 shows the three-dimensional structure of the galactose-binding protein.[180] The calcium-binding geometry of the GBP is very similar to that of EF-hand motif although it is not completely formed by a continuous calcium-binding loop flanked with both helices. The first four ligands of GBPs are the same as EF-hand proteins with the calcium-binding pattern D-x-N/D-x-D/N-x-Mainchain-x. A water-mediated ligand of Glu/Gln is also located at loop position 9. The bidentate Glu (E203) of the GBP is located 63 residues away from the primary sequence (Figure 25).[180]

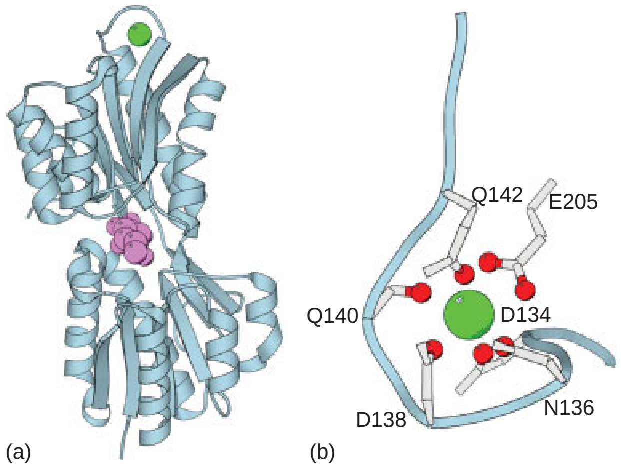

Figure 25 (a) The structure of GBP (1GLG)[180] with the calcium-binding in green and the sugar-binding site in pink. (b) The local view of the calcium-binding site of galactose-binding protein with ligand residues labeled. The calcium-binding geometry of galactose-binding protein is very similar to that of EF-hand motif

4.5 The Extracellular Calcium-sensing Receptor

The extracellular calcium-sensing receptor (CaR) is a detector for the concentration of extracellular calcium in blood and extracellular fluid.[181–184] It is responsible for calcium homeostasis. In this case, calcium functions as a first messenger to activate CaR outside cells. This activation of CaR has several major signal transducing effects. First, it activates phospholipase C (PLC) to generate the second messengers of diacylglycerol (DAG) and inositol triphosphate. Second, it inhibits adenylate cyclase to reduce intracellular cyclic AMP concentration. It can also regulate nuclear function by activating the mitogen-activated protein kinase pathway. Hofer *et al.* have shown that the CaR mediates intercellular communication that allows cells to be informed of the calcium-signaling status of their neighbors.[183]

The CaR is expressed in many cells such as parathyroid cells and C cells in the thyroid gland. It is also expressed in the kidneys, osteoblasts, in the gastrointestinal mucosa, and hematopoietic cells in bone marrow. It has been found that CaR is expressed in different amounts on the cell face of many cell types and in diverse species. CaR is a member of the G protein-coupled receptor family with seven hydrophobic transmembrane helices in the plasma membrane. It has a large N-terminal domain with about 600 amino acids located in the extracellular environment and is essential for sensing extracellular calcium concentration. CaR has a large cytosolic C-terminal domain with about 200 amino acids that is subjected to phosphorylation. A dimeric structure has been proposed based on the known crystal structure of the metabotropic glutamate receptor type 1.

5 CALCIUM PUMPS AND CHANNELS

Calcium pumps, also termed Ca^{2+}-ATPase, are calcium channels that transport calcium from the low concentration cytoplasm to the high concentration extracellular space or ER/SR lumenal side using the energy of ATP hydrolysis. Based on their locations, calcium pumps are classified into two groups, plasma membrane Ca^{2+}-ATPase (PMCA) and sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA).[185–187] Four basic isoforms of PMCA (PMCA1−4) have been identified and the other PMCA isoforms are the alternative splicing products of the basic isoforms. PMCA1 and 4 are ubiquitously expressed in different tissues and PMCA2 and 3 are expressed in nerve cells. Three basic isoforms of SERCA pump and several splicing variants have also been identified.[185]

Both PMCA and SERCA have ten TMS. Several loops are exposed to the extracellular space or the inner

SR/ER lumen. The major parts of the proteins exist in the cytoplasmic solutions to form functional units.[185–187] The PMCA cytoplasmic part comprises four units: the N-terminal unit, the acidic phospholipids binding unit, the ATP-binding unit that contains the catalytic aspartate that is phosphorylated during the ‘pumping’ process, the nucleotide-binding domain containing the ATP-binding motif and a fluorescein isothyocyanate (FITC) binding site, and the C-terminal regulation unit that contains the sites for PKA, PKC, calmodulin, and calcium binding. The calmodulin binding inhibits the protein function. SERCA comprises the first three units similar to PMCA but lacks the long C-terminal sequence. Each ATP is used to pump one calcium ion out of the cytoplasm by PMCA and two calcium ions into SR/ER lumen by SERCA. Two protons are exchanged from SR/ER lumen to cytoplasm at the same time by SERCA.[185–187]

Before 2000, structural information, especially the topology of the pumps was mainly from electron microscopy, structural modeling and low resolution X-ray crystallography.[188] Upon the binding of calcium, a large rearrangement of the cytoplasmic units has been observed. A simple model has been proposed for this observation. The model postulates the existence of two conformations E1 and E2. While in the E1 state the protein has high affinity calcium-binding sites and upon phosphorylation the conformation changes to E2 that has low affinity sites.[185,189] The first high-resolution structure of a P-type ATPase, that of the Ca^{2+}-ATPase of skeletal muscle sarcoplasmic reticulum, was published in 2000.[190] A clearer picture comes from the X-ray structure of SERCA1 protein at the E1 state (1EUL) (Figure 26).[190] Ten TMSs are almost entirely helical with four of them extended into the cytoplasm to form the stalk. Calcium-binding sites are located in these transmembrane domains. The first calcium ion is coordinated by Asn-768 and Glu-771 on TMS-5, Thr-799 and Asp-800 on TMS-6, and Glu-908 on TMS-8. The second calcium ion binds with the side chain of Glu-309 at TMS-4, Asn-796 and Asp-800 at TMS-6 and the mainchain carbonyl of Val-304, Ala-305, and Ile-307 at TMS-4. The phosphorylation position that triggers the calcium transportation is located at Asp-351 in a very conserved sequence of DKTGT, about 40 Å away from the calcium-binding sites.[190] A series of conformational changes are required to mediate these two separated calcium binding and phosphorylation effects and to make them function together.

The structure of the E2 state (1IWO) has also recently been solved by stabilizing the conformation in the calcium-free form using thapsigargin (TG).[191] Consistent with the EM results, a large conformational change has been observed compared to the E1 state. Although the individual cytoplasmic units do not exhibit significant structural change, the overall arrangement of these units is altered. The N-terminal unit rotates about 110° and the phosphorylation domain rotates about 30° with respect to the membrane plane. The nucleotide binding unit rotates 50° further with respect to the phosphorylation unit. This reorientation results in a relatively compact structure in contrast to the relatively open structure in the E1 state.[191] This conformational change also causes the rearrangement of the calcium-binding ligands, such that those at TMS-6 rotate 90° and TMS-4 shifts down 5 Å.[190,191] Unlike the previous postulation that in the E2 state the calcium-binding sites face the SR lumen, the calcium sites in this model face the cytoplasm in both states. The detailed pathway

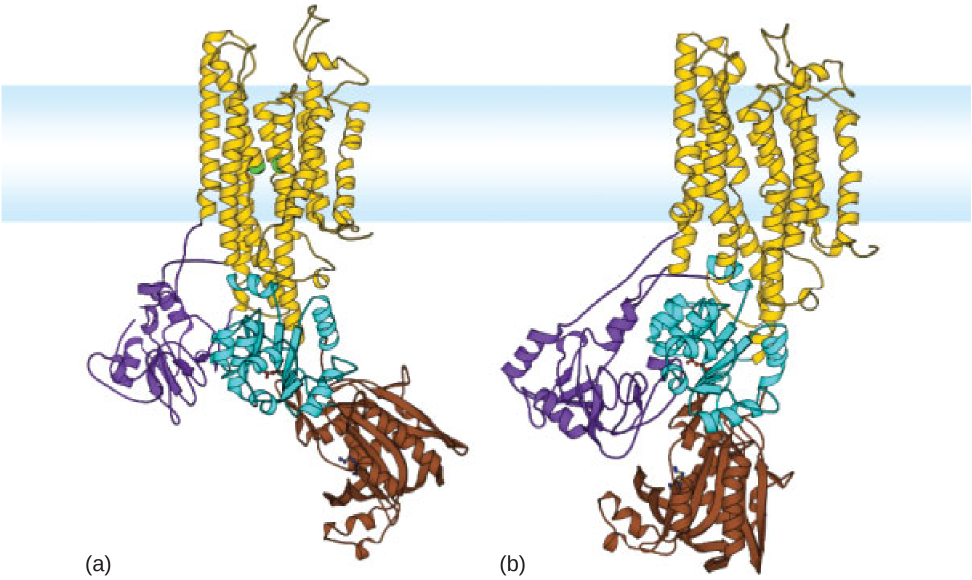

Figure 26 The structures of SERCA at the E1 state (a, 1EUL)[190] and E2 state (b, 1KJU)[191] are shown. The light blue lines represent the phospholipid bilayer membrane. The phosphorylated domain and the ATP-binding domain are labeled as cyan and brown, respectively. Calcium is represented as green ball

of calcium transportation has yet to be identified though some important residue locations (e.g. Glu-309) have been proposed.[186,190,191]

In contrast to SERCA, the Ca^{2+} release channel of the SR (RyR) transports calcium from SR to cytoplasm following the calcium gradient with no specific energy required. RyR has three isoforms. They are activated by low concentration of calcium, adenine nucleotide, and cADP and are inhibited by a high concentration of calcium. Other factors include calmodulin, which is involved in the regulation of RyRs. The protein forms a tetrameric structure and looks like a square prism with several pores.[192] IP_3R (inositol 1,4,5-trisphosphate receptor) is another calcium release channel that transports calcium from ER/SR into cytoplasm. IP_3R is regulated directly by IP3 together with the cytoplasmic calcium concentration and CaM binding.[193]

The other calcium channels that regulate cytoplasmic calcium concentrations include Na^+/Ca^{2+} exchanger and H^+/Ca^{2+} exchanger. Instead of using the energy from ATP hydrolysis, the sodium or proton gradient across the membrane is used to transport calcium. Nine TMS segments and one large cytoplasmic sequence between TMS-5 and TMS-6 are predicted in classical Na^+/Ca^{2+} exchanger. There is no detailed structural information about these families of proteins. The calcium-binding sites are proposed to be located in the cytoplasmic sequence.[187,194]

Voltage-gated calcium-channel and receptor-gated calcium channel are two channels that have the reverse effects of PMCA. They transport the calcium influx following the calcium gradients regulated directly by the electric potential between the two sides of plasma membrane or receptor binding, respectively.[193]

6 MEMBRANE CALCIUM-BINDING PROTEINS: ANNEXINS AND C_2 DOMAIN

6.1 Annexin

Annexin is a family of calcium-binding proteins that bind phospholipid. More than 160 members of this family have been identified. Based on their sources, annexins are classified into five groups. Group A is typically thought to be in vertebrate animals, but studies after 1990 show some of the Group A annexins appear in invertebrates. It is one of the most frequently studied groups of annexins. To date, 13 subfamilies in Group A with different N-terminal tails have been identified. Group B is represented in nonvertebrate metazoans. Groups C, D, and E are annexins in Mycetozoa and fungi, plants, and protists, respectively. Annexin overall is an intracellular protein, but it has also been found in the extracellular matrix (e.g. annexin A1).[195–198]

Annexins play important roles in many cellular processes by binding negatively charged phospholipids in a calcium-dependent manner. As a molecule that binds and aggregates phospholipid vesicles, it frequently accompanies vesicle or membrane fusion. Annexins were shown to be important in membrane organization, membrane transportation, exocytosis (annexin A1, A2, A3, A6, A7, A11, A13, and B7), endocytosis (annexin A1, A2, and A6), and phagocytosis (annexin A1–5, A7, and A11). Annexins A7 and A5 and annexins A2 and A4 regulate calcium and chloride channel activities, respectively.[198] In addition to calcium and phospholipids, several proteins, such as EF-hand proteins S100A6, S100A10, S100A11, and sorcin, and cytoskeletal protein actin, have been identified as interacting with annexins. S100 EF-hand family members S100A6, S100A10 and S100A11 specifically bind to annexins A11, A2, and A1, respectively. Sorcin binds to the GYP-rich N-terminal tail of annexin A7. Several annexins, such as A1, A2, A5, and A6, interact with actin. Other proteins associated with annexin include phospholipase A2, p120 Ras GTPase activating protein (GAP), protein kinase Fyn and Pyk2, and so on, suggesting annexins are involved in many more biological activities that have yet to be explored.[198]

The number of X-ray and NMR structures of annexins exceeds 40, including 23 of annexin A5. Recently, calcium-independent phospholipid binding of annexin has been revealed. Instead of binding calcium, lowering the pH also causes annexin A5 and B12 to interact with the lipid membrane.

All annexins are composed of two principal domains, the conserved C-terminal core and the N-terminal tail unique to their subfamily. The length of the N-terminal tail is shorter than 40 residues in most of the annexins with the exception of the A7 and A11 subfamilies, which have up to 160 and 195 residues, respectively. The current known protein–protein interaction with annexin occurs at the N-terminal tail. The diversity of this small N-terminal tail contributes at least partially to the diversity of annexin functions.[195,198]

Almost all annexins contain a core domain with four subdomains, each with about 70 residues, with the exception of A6 that has eight repeats (Figures 27 and 28).[195,196,198–200] Calcium and lipid binding sites are located at the core domains. As shown in Figure 27, the core domains of A5 are composed of four repeated subdomains. X-ray crystallography has shown that the repeated subdomain contains five α-helices. Two calcium-binding helix-loop-helix motifs (A/B and D/E) are arranged as a four-helix bundle. Helix C crosses over the bundle to hold the two helix-loop-helix structures in the bundle together. The four repeat segments of the annexin core form a planar cyclic structure, in which subdomain 1 interacts with subdomain 4 and all the bundles are lined up in the same orientation, resulting in a hydrophilic pore similar to the ion channels. However, the monomeric annexins are not proposed to be ion channels because of the hydrophilic surface of the helices and the relatively shorter length of the α-helices for spanning through the bilayer membrane.[198,199] The X-ray

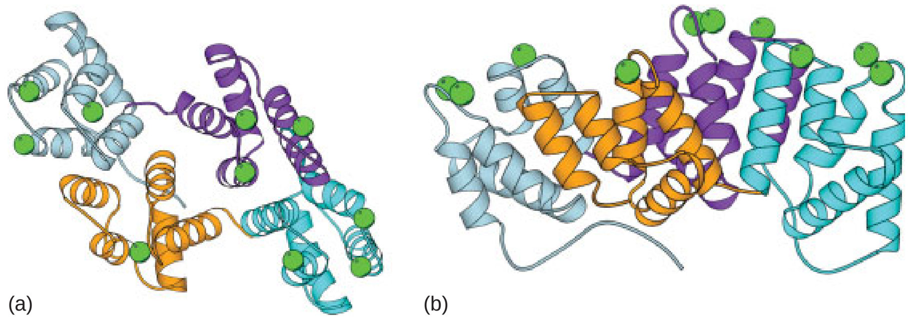

Figure 27 (a) A pore is formed by the four repeated domains of annexin A5 (1A8A)[199] in which the domain I (light blue) interacts with domain IV (orange) directly. (b) The structure of annexin A5 with four domains in which all calcium is bound to the top of the protein

structure of A6 shown in Figure 28 contains eight repeated subdomains that form two regions, each with four domains as in other annexins.[200]

Most of the crystallized structures of annexin contain different numbers of calcium or lanthanide ions. The calcium binds at the AB loop and/or the DE loop in each repeated segment. For example, in annexin A5, the AB-loop calcium-binding site comprises three mainchain carbonyl ligands at the AB-loop and two side chain carboxyl ligands from one bidentate Asp or Glu-residue at the DE-loop. Two solvent molecules are used to obtain the pentagonal bipyramidal geometry. The calcium-binding site at the DE-loop comprises two mainchain ligands at the DE-loop and two ligands from one bidentate acidic residue at E-helix. Up to three solvent molecules are used in this site.[198,199]

The conformational change induced by calcium binding in annexin is relatively small. The largest change that has been detected is the repacking of the repeated segment III D-helix in annexin A1. The X-ray structure shows that without the calcium binding the N-terminal tail of A1 forms an α-helix and replaces the position of the D-helix of segment III, while the D-helix is unwound and partially points out. With the calcium binding, the tail may have to be out of the core domain and the D-helix may have to be switched to a conformation similar to those in the other segments.[198,201]

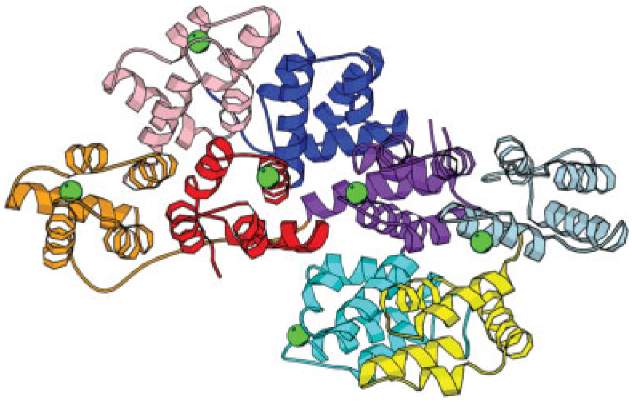

Figure 28 The structure of Annexin A6 (1AVC)[200] with eight repeated domains in different colors

As a protein located at the cytosolic side of the membrane, the calcium-binding affinity of annexin is weak. In vitro measured apparent dissociation constants of calcium are from micromolar to millimolar. Annexins appears to be apo-form at the submicromolar intracellular calcium concentration. Given the fact that the function of annexin is calcium-required in vitro, it is plausible to propose that annexin acts differently in vivo. Either the in vivo function of annexin is calcium independent (less likely), or, more likely, in vivo, by interacting with membrane or target protein ligand, the calcium-binding affinity of annexin increases owing to the environment change. In addition, the calcium concentration near the membrane region may be higher than the average level in the cytosol.[198]

6.2 C2 Domains

The C2 domain was first identified in calcium-dependent PKC isoforms, and refers to the conserved domain 2 in PKC with about 80–160 residues. To date, more than 100 proteins have been identified as containing C2 domains. It is one of the most widely used modules of intracellular calcium-binding proteins. Some proteins contain two or more repeats of the C2 domain in a single peptide chain, such as synaptotagmin, double C2 protein (DOC2), and Munc13.[202,203]

The structural information of C2 domain is primarily from the studies on PLC, PKC, cPLA2 (cytoplasmic phospholipase A2), factors, and synaptotagmin (Figure 29). Synaptotagmin I contains two C2 domains, C2A and C2B, of which C2A is the first C2 domain with a solved structure. Currently, more than twenty structures of C2-domain-containing proteins have been obtained by X-ray and NMR. The C2 domain contains eight β-strands that form a compact β-sandwich structure composed of two layers with four strands in each layer.[202,203] Based on the topology of these β-strands, they are classified as type I and type II C2 domains. In type I C2 domains, such as synaptotagmin and DOC2, β-strands 1, 2, 5, and 8 are in the same layer and β-strands 3, 4, 6,

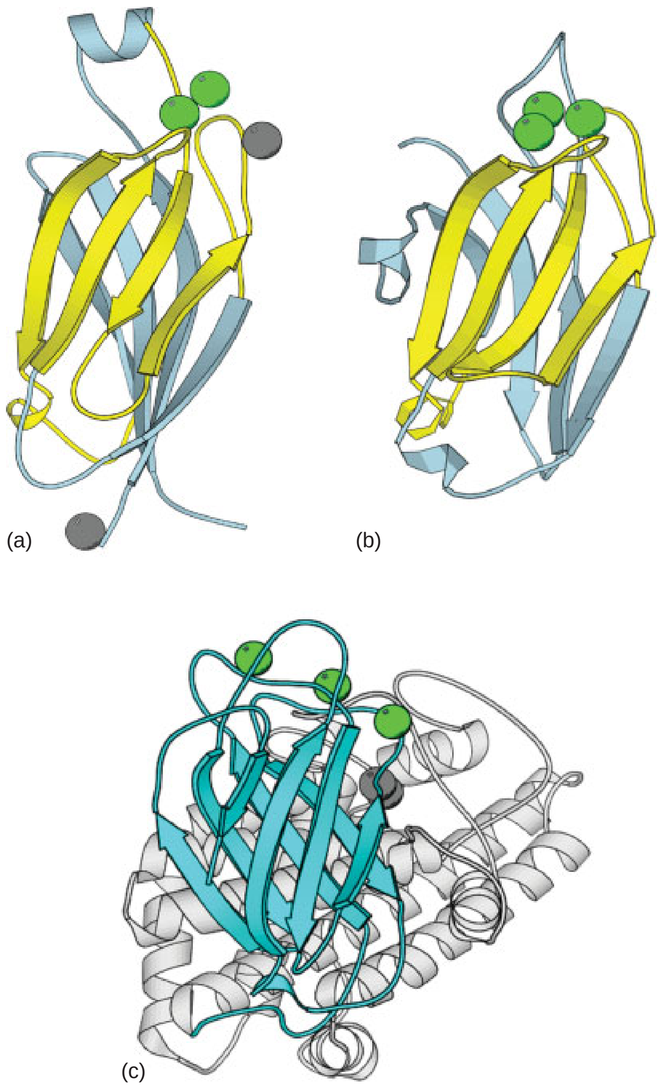

Figure 29 (a) The C2 domain in cPLA2 (1RLW)[205] has type II topology, in which the β-strands 7, 8, 1, and 4 (light blue, left to right) form one layer while the β-strands 6, 5, 2, and 3 (yellow, left to right) form another layer in the β-sandwich structure. (b) The C2 domain in PKCβ (1A25)[206] has type I topology, in which the β-strands 8, 1, 2, and 5 (light blue, left to right) form one layer and the β-strands 7, 6, 3 and 4 form another layer. (c) The C2 domain (blue) in the α-toxin (1QMD)[207] is shown. The calcium ions in all three figures are labeled green and the other metal ions (Zn in α-toxin and Cd in PKCβ) are labeled gray

and 7 are in the other layer. In type II C2 domain, such as cPLA2 and PLC, the β-strands 1, 4, 7, and 8, and 2, 3, 5, and 6 are in two layers, respectively.[202,203] Loops connecting the β-strands are located at the two ends (top and bottom) of the protein. Two or three calcium ions bind to the loop regions located at the top of the protein. The ligand residues of the calcium-binding sites in C2 domain are widely separated in the primary sequence.[202,203] In the X-ray structure of synaptotagmin I C2A domain, three calcium ions (termed Ca1–3) are bound to five Asp, one Ser, and three mainchain carbonyls located at loop 1 and loop 3. Of these ligands, Asp-172 and Asp-230 are shared by Ca1 and Ca2, Asp-238 is shared by Ca2 and Ca3, and Asp-232 is shared by all three calcium ions. The mainchain carbonyl from Leu-171 binds only to Ca2, an Asp-178 side chain and Phe-61 mainchain bind to Ca1, and Ser-235 side chain and Lys-236 bind to Ca3. The substrate phospholipids have been proposed to provide additional ligand atoms to the pentagonal bipyramidal geometry of the calcium-binding sites. In the absence of phospholipids, the calcium dissociation constants of synaptotagmin I C2A domain are low (0.06 mM to >1 mM), a value too weak to bind calcium at the intracellular environment.[203–205]

The calcium binding in PLCδ1 C2 domain revealed by x-ray crystallography has two similar and one distinct site compared to synaptotagmin I. The locations for Ca1 and Ca2 are almost the same, while the ligands for these two calcium ions, Asp-653, Asp-706, Tyr-707, Asp-708, and Asp-714 correspond to Asp-178, Asp-230, Phe-231, Asp-232, and Asp-238 in synaptotagmin I, respectively. The ligands corresponding to Leu-171 and Asp-172 are missing. The ligands corresponding to those for Ca3 are retained and have similar orientation in PLCδ1 but no calcium occupies the pocket. The third calcium in PLCδ1 shares one ligand residue with Ca1 (Asp-653, bidentate in this site) and uses the other three ligands from loop 1 and loop 2 (Asn-677, Ser-650, and Ile-651). Like synaptotagmin I, the additional ligands for pentagonal bipyramidal geometry may come from the target molecule phospholipid.

C2 domain represents a large family of proteins with different functions.[204,208] Most of them bind calcium and phospholipids. Most members of the C2 domain protein family are involved in signal transduction, such as PKC and PLC (phosphoinositide-specific phospholipase C), or membrane traffic, such as synaptotagmin and rabphilin-3.[202,203] To date, several important subfamilies have been extensively studied and their functions are relatively clear. First, the classical PKCs (isoforms α, β, and γ) contains type I C2 domain, and some of the non-classical PKCs (δ, ε, θ, and η) and yeast PKCs contain type II C2 domains. In classical PKCs the C2 follows the C1 domain while for the nonclassical PKC, the C2 domain is before the conserved C1 domain. This family of protein kinases plays important roles in the cell signal transduction pathway by mediating protein phosphorylation. The biological functions of these C2-containing PKCs with a proper calcium-binding pocket are calcium-dependent. Calcium-independent C2-containing PKC does not contain conserved calcium-binding ligand residues.[203,206,209–211] Second, cytosolic phospholipase A2 (cPLA2) cleaves arachidonic acid from glycerophospholipids using the C-terminal catalytic domain. The C2 domain at the N-terminus interacts with neutral phospholipid vesicles containing phosphotidylcholine or phosphotidylethanolamine through a calcium-dependent mode to localize the cPLA2 to its target membrane substrate. The C2 domain

in cPLA2 is of type II topology. Four of the five aspartate ligands in synaptotagmin I are retained in cPLA2 and the fifth is mutated to asparigine.[203,205,212] Third, phosphoinositide-specific phospholipase C (PLC) liberates inositol trisphosphate (IP3) and DAG when activated. Both IP3 and DAG are directly involved in the regulation of intracellular functions (e.g. IP3 regulates several calcium channels and DAG regulates several PKC isoforms). The C2 domain in PLC is of type II topology. It facilitates the catalytic domain's interaction with the substrate. PLC also contains an EF-hand calcium-binding domain and a pleckstrin homology(PH) phospholipid binding domain.[203,208,213] Fourth, α-toxin is a eukaryotic phospholipase C, which is capable of binding to mammalian cell membrane and cleaving membrane-bound phosphatidylcholine (or sphingomyelin) to produce phosphocholine and DAG (or ceramide). X-ray crystallography has revealed three calcium ions in the C2 domain of alpha toxin. Unlike the synaptotagmin or PLC, the three calcium ions are clustered but only share one ligand (Asp-298) that interacts with Ca2 with the side chain carboxyl group and with Ca3 with a main chain carbonyl group. The ligands for Ca2 are located continuously (Asp-293, Asn-294 main chain, Gly-296 main chain, and Asp-298) while the ligands for Ca1 (Asp-269 main chain, Gly-271 main chain, Asp-336, Ala-337 main chain, and Glu-32) and Ca3 (Thr-272 main chain, Asp-273, Asn-297, Asp-298 main chain) are discontinuous.[207,214] Fifth, phosphatidylcholine-specific phospholipase D (PLD) catalyzes the cleavage of phospholipid to produce phosphatidic acid and a free head group such as choline. The putative calcium-binding ligands in the C2 domain of PLD are diverse in different isoforms. The apparent calcium-binding affinity without substrate of PLDα, β, γ and δ varies more than two orders of magnitude.[215] Sixth, phosphatidylinositol 3-kinase (PI3K) and PTEN catalyze reverse reactions on phosphorylation and dephosphorylation of phosphoinositides. The isoforms PI3K α, β, and VPS34P have a type II C2 domain while isoform PI3K 68D has a type I C2 domain. The calcium-binding ligands in PI3K C2 domain are not complete. The functions of PI3K and PTEN as a tumor suppressor are not dependent on calcium.[203,216,217] Seventh, synaptotagmin is a family of transmembrane proteins with two type I C2 domains in the cytosol. It is involved in vesicle fusion and exocytosis events in the cell.[218] Synaptotagmin I–V, X, and XI are expressed in the neuron system and the others (VI–IX) are expressed in other tissues. The C2A domain binds with calcium and triggers calcium-regulated exocytosis and secretion. The C2B domain of synaptotagmin I and II binds inositol high polyphosphates and inhibits the exocytosis and secretion by this binding. Synaptotagmin I is also known to be crucial for neurite outgrowth. Synaptotagmins are involved in constitutive vesicular trafficking in addition to regulated exocytosis. The C2B domain of synaptotagmin III, V, VI, and X lacks the inositol high polyphosphate,for example, IP4, binding ability resulting in the deficiency of IP4 inhibition. C2 domains in synaptotagmins also mediate protein–protein interactions through a calcium-dependent or – independent manner. Some known synaptotagmin target proteins include clathrin-AP2, syntaxin, and PKC and so on. The oligomerization of synaptotagmin is also calcium dependent.[203,205,219] Eighth, double C2 (DOC2) protein plays a role in regulating calcium-dependent exocytosis, particularly in vesicle cycling in response to stimuli or phorbol esters (PE). It comprises two type I topology C2 domains and a Munc13 interacting domain (MID). DOC2 is localized to a pre-synaptic vesicular terminal. It interacts with other exocytotic proteins including the presynaptic PE receptor Munc13-1, syntaxin-interacted protein Munc18, and dynein component Tctex-1. The DOC2-Munc13 complex is required for vesicle maturation in certain glutamatergic synapses.[220] Munc13 comprises two type II C2 domains, one type I C2 domain, and one C1 domain. It is expressed in neuronal cells and functions cooperatively together with DOC2 in regulating exocytosis and neurotransmitter release process.[203,220] Ninth, rabphilin-3A is identified as a protein that interacts with Rab3A, a small ras-related membrane-bound GTPase playing a role in neurotransmitter release and exocytosis, in the GTP-bound form. Other partner proteins such as Rab27 have also been observed for rabphilin. The Rab3A-binding domain is at the N-terminal and two type I topology C2 domains are at the C-terminal of rabphilin-3A. The C2 domains of rabphilin-3A interact with phosphatidylserine in the presence of calcium. The C-terminal C2 domain is critical for secretion functions of rabphilin-3A. Mutations in this domain will impair calcium-dependent vesicle binding.[221,222] Tenth, several GAP have been identified as having a C2 domain, including p120-rasGAP, GAP1m, R-Ras-GAP, BCR, ABR, and BUD2. The C2 domain of p120-rasGAP binds phosphotidylserine and phosphotidylinositol in the presence of calcium. Functionally, p120-rasGAP down-regulates the mitogen-activated protein kinase pathway after epidermal growth factor stimulation and also regulates cell proliferation.[223] Eleventh, human coagulation factors are essential for blood clotting through a thrombin-mediated mechanism. Factor V and VIII share a similar sequence and topology. They are each represented by the domain structure A1-A2-B-A3-C1-C2 and share 40% sequence homology in the A and C domains. After cleavage by thrombin or factor X, the domains A3, C1, and C2 form the light chain. The C2 domain in factors V and VIII is critical for mediating the membrane binding of proteins.[224–226] With the increasing number of C2-containing proteins, the C2 domain has become one of the most popular domains in nature. In addition, the currently known C2 domain members also include perforin, phosphatidylserine decarboxylase, SCH9 kinase, RSP5, Ege A, and so on.

7 CALCIUM-BINDING PROTEINS IN ENDOPLASMIC RETICULUM AND SARCOPLASMIC RETICULUM

ER and SR are the major calcium stores in the cell (Figure 1). They play a vital role in regulating cell functions.

With the proper stimuli, calcium in the ER/SR is released to the cytoplasm activating calcium-signal proteins. To restore the rest state of the cell, calcium is pumped out of the cytoplasm by PMCA, SERCA, and Na^+/Ca^{2+} exchanger. Most of the calcium ion in ER is buffered by many lumenal calcium-binding proteins such as CSQ, calreticulin and calnexin. There are other calcium-binding chaperone molecules in the ER such as grp94, PDI family, and BiP. These proteins are more likely to chaperone the non-glycoproteins. One member of the protein disulfide isomerase (PDI) family, ERp57, cooperates with calreticulin and calnexin.[227–229]

7.1 Calsequestrin (CSQ)

CSQ is the major buffer protein in the lumen of the SR of muscle cells, especially those bound at the calcium release channel, the ryanodine receptor, and through junction and triadin. CSQ was shown to determine the functional size and stability of cardiac intracellular calcium stores.[230] As shown in Figure 30, more than 1/3 of the total residues of CSQ are glutamate or aspartate (a total of 110 carboxylate groups) residues.[231] One CSQ molecule is capable of absorbing 40–50 calcium ions with an average calcium-binding affinity of about 0.6–1 mM. All calcium or metal binding ability is mainly determined by the charge–charge interaction without a defined calcium-binding pocket. The calcium binding of CSQ has both high on-rate ($\sim 10^9\ M^{-1}s^{-1}$) and off-rate ($\sim 10^6\ s^{-1}$), which allows this protein to release and bind large quantities of calcium rapidly. Owing to the highly negatively charged surface, calcium or monovalent cation ions are required for the folding of the CSQ. The calcium-loaded CSQ is dimerized and then polymerized to form a long chain, which further allows even more calcium to be bound intermolecularly. The lined CSQ cooperates with the calcium release channel of SR/ER in regulating the cytoplasmic calcium concentration.[227]

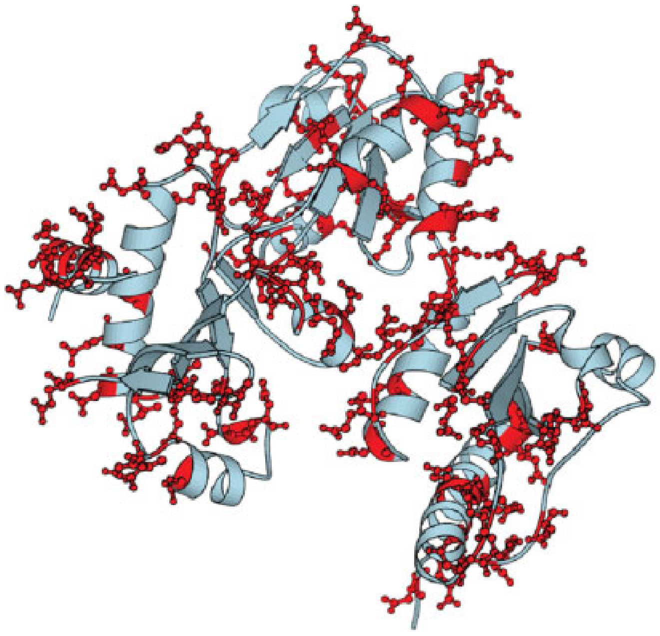

Figure 30 The structure of CSQ (1A8Y)[231] with acidic residues highlighted in red

After more than 10 years of attempting to crystallize CSQ, it was finally accomplished with 0.3 M K^+ in the absence of Ca^{2+} (1A8Y).[231] The solved x-ray structure of CSQ contains three structurally similar domains of a thioredoxin fold although there is no significant repeat sequence in the primary structure (Figure 30). Each thioredoxin-like domain comprises a core that is formed by five β-strands and four surrounding α-helices. The interior of the core is mainly composed of hydrophobic residues. The bulky content of acidic residues is located at the α-helices and the connecting loops. Ca^{2+} ions bind to the protein surface and the spaces between domains (Figure 30).[231] CSQ monomer can associate in 'front to front' and 'back to back' chains to create additional calcium-binding sites in clefts between the individual molecules. These two distinct dimerization contacts in CSQ crystals suggested a mechanism for Ca^{2+} regulation resulting from the occurrence of coupled Ca^{2+} binding and protein polymerization.[232]

7.2 Calreticulin and Calnexin

Calreticulin functions as a chaperone protein for the folding of newly synthesized proteins and glycoproteins.[229,233] It is also a major calcium-buffer protein residing in the lumen of the ER. Calnexin exhibits a high degree of similarity to calreticulin in primary sequence and structure. It also has functions similar to calreticulin such as calcium binding and recognition of misfolded proteins. The major difference between these two proteins is that calreticulin is able to move in the lumen of the ER while calnexin is an integral membrane protein of the ER, interacting transiently with its protein folding intermediates at the stationary phase. Both proteins bind to the monoglucosylated carbohydrate of the glycoproteins. Misfolded non-glycoproteins may also bind to calreticulin and calnexin.[229,234,235]

Both calreticulin and calnexin comprise three domains: a globular N-domain, an extended proline-rich P-domain, and a transmembrane helix in calnexin or an acidic calcium-binding C-domain in calreticulin.[229,236] The structures of the soluble part of calnexin and the P-domain of calreticulin have been reported. The crystal structure of calnexin (1JHN) shows an unusual structure in that the P-domain extends far away from the N-domain like an arm (Figure 31). The glycoproteins interact with the N-domain surface facing the arm. A calcium ion binds to the N-domain using the ligands from the carbonyl of Ser-75 and the carboxyl of Asp-118 and Asp-437 (bidentate).[236] The P-domain (residue 189–288) NMR structure of calreticulin (1HHN, 1K91 and 1K9C) is very similar to that of calnexin.[237,238] This structure shows an extended hairpin topology, with three short antiparallel beta-sheets, three small hydrophobic clusters, and one helical turn

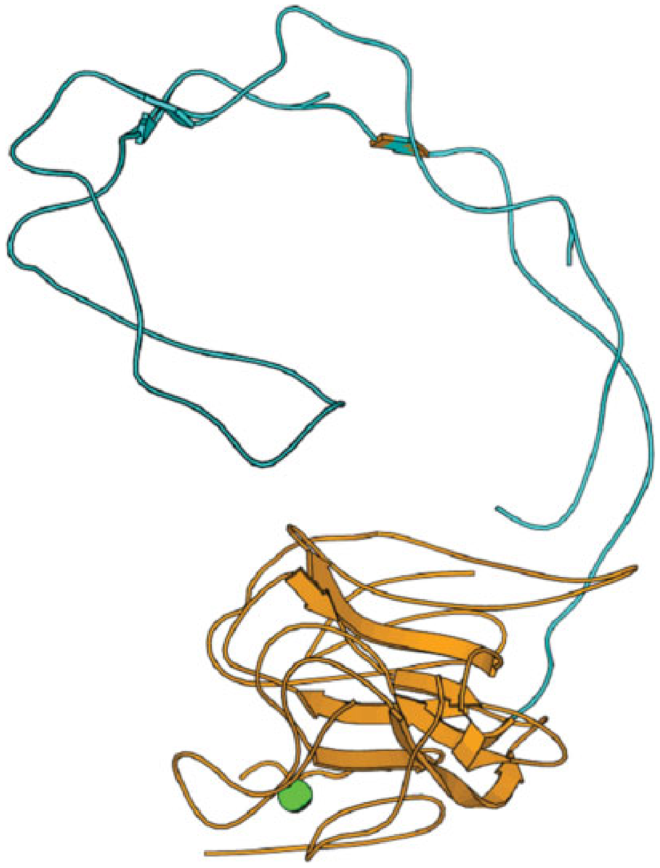

Figure 31 The structure of calnexin (1JHN)[236] with a calcium-binding (green ball) compact domain and a long extended arm. The space between is proposed for the binding of chaperoned proteins

at the top of the hairpin.[236–238] Both calreticulin and calnexin cooperate with an associated co-chaperone, the thiol-disulfide oxidoreductase ERp57, which catalyzes the formation of disulfide bonds in bound glycoprotein substrates.[229,235] Frickel *et al*. demonstrated that the residues 225–251 at the top of the CRT P-domain are involved in direct contacts with ERp57.[239] The CRT P-domain fragment CRT (221–256) constitutes an autonomous folding unit, and has a structure highly similar to that of the corresponding region in CRT (189–288).[234] So far, no structural information is available about the calcium-binding C-domain and N-domain of calreticulin.

8 α-LACTALBUMIN AND LYSOZYME

α-Lactalbumin (α-LA)[240] is a component of mammalian milk. It complexes with β-galactosyl transferase to form lactose synthetase that catalyzes the synthesis of lactose. Unlike most of the other known calcium-binding proteins that have clusters of calcium ions or cooperative calcium binding, only one calcium-binding site with very high calcium-binding affinity ($K_d \sim 10^{-9}$ M) is in this small protein; thus, it has been used as a model protein to study calcium binding. Although recent X-ray studies have revealed an additional calcium-binding site in α-LA, its binding affinity is not comparable to that of the stronger one.[240,241] The following description only refers to the strong calcium-binding site in α-LA.

As shown in Figure 32,[32] the 3D structure of α-LA contains α and β domains. α-Domain is composed of four helices and β-domain is composed mainly of loops and three β-strands. There are four disulfide bridges in α-LA (6–120, 28–111, 61–77, and 73–91), which are shown to be important for the structure and folding of the protein. The disulfide bridge 73–91 links the two subdomains. The ligand residues for the calcium ion are from a continuous loop with residues 79–88 in α-LA. The side chain carboxyl groups from Asp-82, Asp-87, Asp-88, the mainchain carbonyl groups from Lys-79 and Asp-84, and two water molecules form a calcium-binding site with a pentagonal bipyramidal geometry (Figure 2). Removing either residue Asp-87 or Asp-88 eliminates the calcium-binding ability and alters the structure of α-LA.[56,242] Mutation of Lys-79 to Ala destabilizes the protein without significantly reducing the calcium-binding affinity. Mutation Asp-84 to Ala lowers the calcium-binding affinity and destabilizes the protein. The single mutation of Asp-82 to Ala has no obvious effect on the protein structure and calcium binding. Peptide studies show that without the formation of the disulfide bond 73–91, the calcium-binding affinity of the loop decreases several fold. Without the formation of flanking helices after the loop (residue 86–99), the calcium-binding ability is very weak.[243]

The calcium ion in α-LA plays a structural role in stabilizing the protein. The thermal stability of the calcium-bound form of α-LA increases more than 40 °C compared to that of the apo-form. At low pH (e.g. pH 2), α-LA releases the calcium ion and becomes partially unfolded (molten globule state). This partially unfolded protein loses its tertiary structure but retains its secondary structure. Other metals, such as manganese or magnesium, are able to compete with calcium at the same site with a similar stabilizing effect. However, the binding of zinc, which is proposed to bind at different locations, decreases α-LA stability.[240]

Lysozyme is evolutionarily related to α-LA with a divergent function of binding oligosaccharides and cleaving the glycosidic bond. Chicken-type (c-type) lysozymes have a 35–40% primary sequence homology with α-LA. The secondary and tertiary structure are also similar, including overall topology, the two subdomains, and the disulfide bonds (Figure 32).[57,244] Unlike α-LA that has a strong calcium-binding site, most of the members in the lysozyme family do not have any calcium-binding ability despite the high similarity in sequence and structure.[244–247] To date, four lysozymes have been identified as having the calcium-binding site of α-LA. They are canine, equine, pigeon, and echidna. The Asp residues at the ligand positions of α-LA are retained in these lysozymes, while the other members have lost these

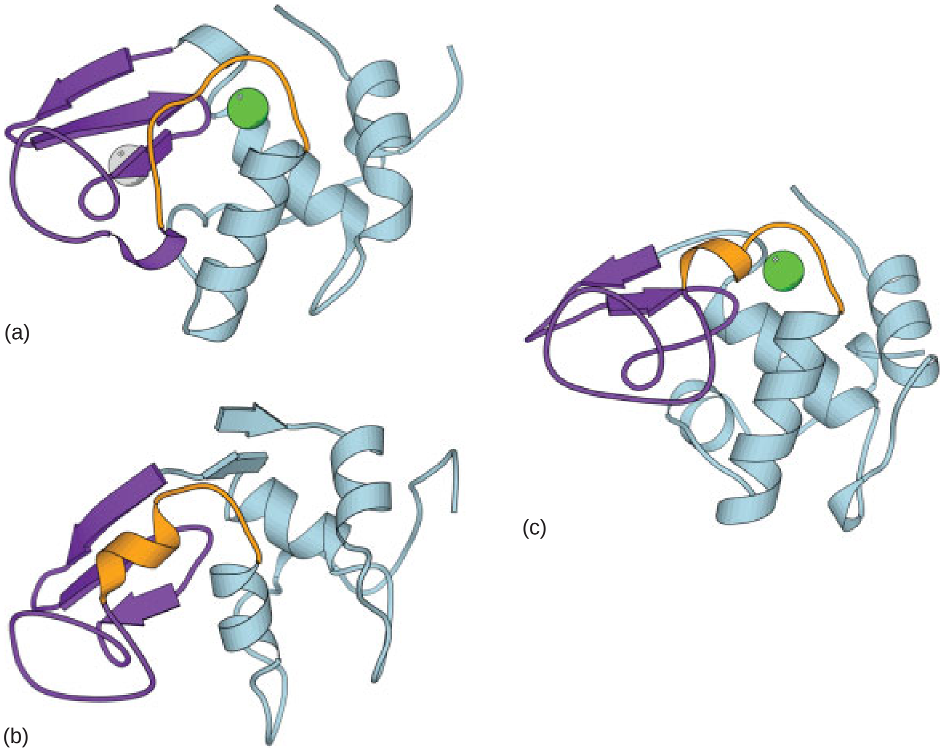

Figure 32 (a) The structure of α-lactalbumin with calcium (green ball) and an additional Zn (gray ball) binding (1HML).[32] (b) The structure of classical lysozyme (1LZ1) without the calcium-binding ability.[57] (c) The structure of calcium-binding echidna lysozyme (1JUG)[244] with calcium binding. All these proteins have similar structures with a flanking loop (orange) located between the α-domain (light blue) and the β-domain (purple)

ligand residues (Figure 32). In addition, the charge and surface electric potential of α-LA and most of the lysozymes are different. α-LA is an overall acidic molecule and lysozyme is basic. As shown in Figure 4, bovine α-LA has a strong negatively charged surface while noncalcium binding protein human lysozyme has a strong positively charged surface. Typical lysozymes also do not have a molten globule state during the unfolding process.[245–249]

To understand the difference between α-LA and typical lysozymes, tremendous work has been done, including peptide analogues, mutagenesis studies, and computational simulations. The calcium-binding loop and the following helix of α-LA have been transported into lysozyme individually or simultaneously. By introducing the Asp residues at the key positions without the following helix, lysozyme gains the calcium-binding ability with a K_d at 10^{-5} M range but not the ability to have a molten globule state. By introducing the helix without the calcium-binding loop, lysozyme can also form the molten globule state without the calcium-binding ability. By introducing both, lysozyme gains both the structural properties of α-LA.[248]

As one of the extensively investigated protein families, hundreds of lysozyme structures are deposited in the Protein Data Bank, including wild type from different sources and numerous mutants. Also available are the structures of antibody binding or substrate binding complexes. The available calcium-binding lysozyme includes X-ray structures of canine lysozymes 1EL1 (holo-form) and 1QQY (apo-form), NMR solution structure of canine lysozyme 1I56, X-ray structures of equine lysozyme (2EQL, apo-form) and echidna lysozyme (1JUG, holo-form).

X-ray structures of apo (1F6R, bovine) and calcium-loaded (1F6S, 1HFY, bovine; 1A4V, 1B9O, human; 1ALC, baboon; 1HFZ, 1FKQ, 1FKV, 1HMK, goat; 1HFX, guinea pig) α-LA are available. The structures of zinc and manganese loaded α-LA are also solved (1HML for zinc and 1PZY for manganese). There are also solution NMR structures (1CB3, human) and complexes with substrate or galactosyltransferase (1NF5, 1NKH, 1NMM, 1NQI, 1NWG, and 1PZY) in the Protein Data Bank.

1 INTRODUCTION

Transition metal carbides[1–4] show a unique combination of solid-state properties such as very high hardness, excellent electrical and thermal conductivities, and very high melting points. TaC and HfC have the highest melting points of all known materials. Against nonoxidizing acids, except hydrofluoric acid, they are chemically very inert but are oxidized in air at moderate temperatures. Table 1 gives a brief survey of solid-state properties of the technologically most important transition metal carbides.

Moissan was the first to synthesize many of the transition metal carbides and to realize their outstanding properties. In the wake of his basic research, some transition metal carbides were used as molded ingots but with little success. Schröter (German Patents 420 689 (1923) and 434 527 (1925)) succeeded in making composite materials by liquid phase sintering of carbides with iron group metals, thereby achieving a singularly successful combination of hardness with toughness; carbides such as WC, TiC, and TaC are the main components in hardmetals.

Many binary transition metal carbides, especially the δ-phases of group 4 elements, exist over a broad range of composition with an upper limit of the carbon to metal ratio near 1. Practically all solid-state properties show a gradual change with the [C]/[T] ratio (T = transition metal). Only some carbides such as tungsten monocarbide, WC, and the chromium carbides have a very narrow homogeneity region.

2 STRUCTURE AND BONDING

The structure of transition metal carbides are closely related to those of the transition metal nitrides. However, transition metal carbides feature generally simpler structure elements as compared to the nitrides. In carbides, the metal atoms are arranged in such a way that they form close-packed arrangements of metal layers with a hexagonal (h) or cubic (c) stacking sequence or with a mixture of these (*see* ***Nitrides: Transition Metal Solid-state Chemistry***). The carbon atoms in these phases occupy the octahedral interstitial sites. A crystallochemical rule[5,6] claims that the phases of pure h type can have a maximum carbon content of [C]/[T] = 1/2 and the c type phases a maximum carbon content of [C]/[T] = 1; hence in structures with layer sequences comprising h and c structure elements the maximum nonmetal content follows suit.

The phenomenon of vacancy ordering is often observed in the transition metal carbides.[6–8] While in the group 4 carbides the tendency towards carbon ordering is weak and can be observed only by extended annealing of δ-TC_{1-x} samples at comparably low temperatures (<800 °C), the tendency becomes more pronounced in the group 5 and 6 carbides. By the ordering of vacancies at low temperatures, even the metal atom positions are affected. In some cases, however, such ordered structures probably cannot be regarded as equilibrium phases nor can an impurity influence on the stability of the structures be ruled out.

An extensive compilation of the crystal structures of transition metal carbides is found in Pearson's Handbook.[9] Ward[10] has discussed the structures of carbides extensively. Epicier[7,11] and de Novion[8] have summarized the results of investigations on ordering in transition metal carbides. Lengauer[12] recently reviewed the knowledge on transition metal carbides and carbonitrides. For a comparison of close-packed transition metal carbides with close-packed transition nitrides, *see* ***Nitrides: Transition Metal Solid-state Chemistry***.

The bonding in transition metal carbides can be described as a mixture of metallic, covalent, and ionic bonding. Energy band calculations performed for a variety of transition metal carbides, nitrides, and oxides[13] have shown a minimum in the density of states (DOS) for a valence electron concentration (VEC) of 8, which in fact is the VEC for the stoichiometric carbides TiC, ZrC, and HfC. At higher VEC, the electrons already have to occupy antibonding states leading to successively pronounced destabilization. Transition metal carbides have a lower DOS at the Fermi Level than the corresponding nitrides; hence the transport properties such as electrical and thermal conductivities and the superconducting transition temperature T_c are lower than those of the corresponding nitrides.

The decomposed DOS resulting from energy band calculations can be used to describe the bonding mechanism in terms of the molecular orbital (MO) scheme for covalent

Table 1 Properties of some important Transition Metal Carbides[a]

Phase	Structure	Lattice parameter (room temperature) (nm)	Density ($g\,cm^{-3}$)	Young's modulus (GPa)	Micro-hardness (100 g load) (GPa)	Heat conductivity (room temperature) ($W\,m^{-1}\,K^{-1}$)	Coefficient of thermal expansion ($10^{-6}\,K^{-1}$)	Electrical resistivity (room temperature) ($\mu\Omega$ cm)
TiC	fcc	0.4328	4.93	450	29	15.5	8.5	100

bonding. Figure 1 shows these MO schemes for bonding in TiC, which were obtained by calculating the electron densities in the (100) plane just below the Fermi energy.[14] The lower part of the figure gives the schematic bond type indicating pd_σ (left), dd_σ (middle), and pd_π (right) bonds. The ionic contribution to the binding mechanism in transition metal carbides originates from a net charge transfer from the metal to the carbon atom.

3 PREPARATION

Transition metal carbides can be prepared by direct combination of the elements, preferably as powder mixtures, at elevated temperatures. If the heat generated by the reaction such as with Ti and C (equation 1) is exothermic enough to keep up the reaction temperature, the process can be carried out in the form of a self-sustaining high-temperature synthesis (SHS).

$$Ti + C \longrightarrow TiC \tag{1}$$

Likewise, carbon-containing gases such as methane or benzene can be utilized as well (equation 2).

$$Ti + CH_4 \longrightarrow TiC + 2H_2 \tag{2}$$

The preparation of TiC, VC, NbC, TaC, Mo_2C, WC, and the chromium carbides are important technical processes for the production of carbide powders for hardmetals. Generally, the carbides are prepared by the reduction of oxides with carbon; only Mo_2C and WC are manufactured by reaction of the metal powders with graphite or carbon black.

Solid solutions of transition metal carbides and carbonitrides, which also play an important role in the hardmetal industry, can be advantageously manufactured by the simultaneous reduction of oxide or oxide-carbide mixtures in the presence of carbon (equation 3).

$$TiO_2 + WC + 3C \longrightarrow (Ti,W)C + 2CO \tag{3}$$

The chlorides of the transition metals can also be employed to obtain transition metal carbides (equation 4). This reaction proceeds in the gas phase at temperatures above approximately 600 °C. Because transition metal halogenides are rather volatile, this reaction is usually used for chemical vapor deposition of carbide layers on solid substrates or to produce carbide powders with very fine (submicron) grain sizes (‘nanopowders’). In the latter case, the nucleation of the

carbide particles must proceed in the homogeneous gas phase.

$$ZrCl_4 + CH_4 \longrightarrow ZrC + 4HCl \quad (4)$$

The oxides of the transition metals can be reduced by carbon according to the following overall reaction (equation 5).

$$TiO_2 + 3C \longrightarrow TiC + 2CO \quad (5)$$

Investigations of this reaction have revealed that there are usually several intermediate steps involving lower oxides and carboxides of the transition metals until the final product is reached. Another process to produce coarse carbide powders from oxidic prematerials makes use of calcium carbide and aluminum as the reducing agent. The heat generated by the exothermic process must be sufficient to reach the reaction temperature, which should be high enough to obtain physical separation of the molten slag and the reaction product. This principle has been used to manufacture coarse WC powders from wolframite, a naturally occurring tungsten ore, according to the following overall reaction (equation 6). In order to obtain conditions under which the reaction becomes self-sustaining, aluminum chips and iron oxides are added to the mixture.

$$FeWO_4 + CaC_2 + 2Al \longrightarrow WC + Fe + CaO + Al_2O_3 + C \quad (6)$$

WC and Fe form a regulus from which WC can be separated by an acid leach process (Macro process[15]).

Coarse chromium carbide powders have been produced by reducing Cr_2O_3 with aluminum powder in the presence of carbon (equation 7).

$$3Cr_2O_3 + 6Al + 4C \longrightarrow 3Al_2O_3 + 2Cr_3C_2 \quad (7)$$

Large single crystals of transition metal carbides can be prepared either by the floating zone technique[16] or by the auxiliary metal bath technique.[17] The first process uses an RF induction heating equipment to form a melted zone in a presintered carbide powder rod of typically 1 cm diameter, which is slowly moved along the rod. The samples so−obtained are typically 10 cm long rods containing single crystals up to the size of ca. 1 cm. The auxiliary metal process takes advantage of the fact that the carbides can be dissolved at high temperature in liquid iron group metals (Fe, Ni, and Co) and are reprecipitated upon cooling in the form of large faceted crystals, which can be separated from the metal bath by an acid leach process.

4 CHARACTERIZATION

4.1 Chemical Analysis of Carbon

Carbon analysis of transition metal carbides is nearly exclusively performed by combustion of the carbide in oxygen and measurement of the volatile combustion products CO_2 or CO. There are several methods whereby this analysis can be carried out:

- volumetrically by absorption of CO_2 in alkaline solutions;
- by measurement of the change in electrical conductivity of an alkaline solution resulting from the CO_2 absorption;
- by amperometric titration of a $Ba(OH)_2$–$BaCl_2$ solution after absorption of the CO_2 content;
- by gas chromatographic analysis of the CO_2 (and N_2) content of the carrier gas.

4.2 Physical Analysis of Carbon

Since carbides are extensively used in spatially restricted sizes (thin films, powder particles in cemented carbides), microanalytical techniques of local carbon analysis are of special interest for sample characterization. Electron probe microanalysis (EPMA) is the most successful method for the quantitative analysis of carbon when the lateral resolution needs not to be better than about 2 µm.

The highest accuracy is obtained by the use of external or internal standards and a wavelength-dispersive spectrometer. Problems arise when the carbon atoms in the standard and sample material are differently bonded. This leads to slightly different peak positions and peak shapes. Errors arising from these effects can be either avoided by using the same type of carbide in standard and sample or by measuring the peak area rather than the peak height. Bastin and Heijligers[18] worked out the area-peak-factor procedure, where the ratio peak area to peak height, in XRD the so-called intregral intensity, is determined for a given compound. After this function has been obtained for a specific carbide and a specific microprobe set up (since the peak area and peak height are a function of the spectrometer) relative to the standard, a simple peak height intensity determination of standard and sample is sufficient for quantitative carbon analyses.

In the preparation of standards, diffusional techniques are of special importance. Using such techniques diffusion layers are formed. With a special modification by use of wedge-type samples, these layers are broadened[19,20] and are thus better accessible for the microprobe.[21–23] The samples consist of several diffusion bands because of the various phases in the respective carbide system. Usually, however, the samples should be single phase and homogeneous in order to make chemical gross compositional analysis applicable. Only with a comparison of different techniques a real standardization is possible. Such transition metal carbide standards have been made from the phases VC, NbC, TaC[22] and Cr_3C_2.[23]

In addition, contamination of the analyzed surface by hydrocarbons may coincide in the measurement. Therefore, anticontamination techniques such as using a cold-trap or an oxygen jet should be applied.

Relief effects owing to insufficient or inapplicable polishing routines can be avoided by lapping of the specimens.[21]

5 THERMODYNAMICS

5.1 Free Energy of Formation

The free energy of formation of transition metal carbides does not change significantly with temperature. Hoch[24] has derived interaction parameters between carbon and the metal atoms in group 4 and 5 transition metal carbides from metal and carbon vapor pressure measurements at high temperatures, which quantitatively describe the partial free energy of carbon within the homogeneity region of the monocarbides. From these values it was concluded that with the heavier elements of group 4 and 5, the stoichiometric composition can more easily be attained than with the carbides of the metals of the first long period. Indeed, vanadium carbide shows a maximum carbon content of $VC_{0.92}$. The thermochemical stability of the carbides decreases with increasing group number. While the monocarbides of groups 4 and 5 can be melted congruently, the carbides of group 6 metals decompose peritectically before their melting points are reached. The monocarbide MoC decomposes in a peritectoid reaction at 1170 °C into $Mo_2C + C$.

5.2 Phase Equilibria

5.2.1 Group 4 Transition Metal–Carbon Systems

Figure 2 shows the group 4 transition metal–carbon systems,[25] which are very similar to each other concerning the carbide phases: the monocarbides δ-TiC_{1-x}, δ-ZrC_{1-x} and δ-HfC_{1-x} show extensive homogeneity ranges and have high congruent melting temperatures. These phases are of the NaCl type and are closely related in structure as well as in properties with the transition metal nitrides.

Carbon does not stabilize the hcp low-temperature modifications of these metals (in contrast to nitrogen) and the solubility of C in the α-phases is much smaller as compared to the group 4 transition metal nitride systems.

Several superstructures have been observed at substoichiometric compositions formed by long-range ordering of carbon atoms in fcc δ-TiC_{1-x}.[8]

5.2.2 Group 5 Transition Metal–Carbon Systems

The group 5 transition metal–carbon systems (Figure 3 shows reinvestigated portions of their phase diagrams by means of diffusion couples, information at high temperature including the liquid phase can be obtained from the ASM Handbook[25]) are again very similar to each other and contain structurally identical subcarbide phases β-T_2C and ζ-T_4C_{3-x} as well as the fcc monocarbide phases δ-TC_{1-x}. All carbides of the composition T_2C have high- and low-temperature modifications that differ only by the arrangement of the carbon atoms[5] on the interstitial positions. Furthermore, a large variety of ordered hemicarbides T_2C have been identified by electron microscopy and/or diffraction[7,11] but have not been included in the phase diagrams because of their dubious phase character. Possibly these structures are affected by impurities.

In these systems, the ζ-phases ζ-V_4C_{3-x}, ζ-Nb_4C_{3-x} and ζ-Ta_4C_{3-x} are observed. These phases have a close-packed metal atom stacking sequence of 12 layers per unit cell (ABABCACABCBC...) and a random occupancy of carbon atoms in the octahedral interstices. Their actual compositions deviate from the ideal crystallochemical C/T ratio of 3/4 (see Section 2), a deviation that is largest for ζ-V_4C_{3-x} where the carbon content is below 40 at%. The stabilities and the homogeneity ranges of these phases were investigated by diffusion couples.[22] Peritectoid decomposition/formation of these ζ-T_4C_{3-x} phases occur in which also the β-T_2C and δ-TC_{1-x} phases are involved. Several ordered compounds have been observed in group 5 carbides[8] even at high carbon contents such as V_6C_5, V_8C_7 and Nb_6C_5. The effect of ordering on the hardness has been investigated for δ-VC_{1-x} (see Section 8.5).

5.2.3 Group 6 Transition Metal–Carbon Systems

The crystal structures of the phases in these systems are characterized by the destabilization of the T_6C octahedral

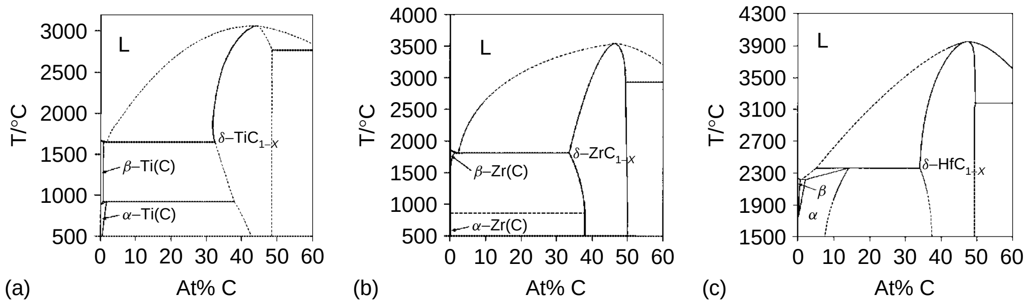

Figure 2 Phase diagrams of the group 4 transition metal–carbon systems. (a) titanium-carbon; (b) zirconium-carbon; (c) hafnium-carbon. (Ref. 25. Reproduced by permission of Materials Information Society/ASM International)

Figure 4(b): Reproduced from Ref. 23 by permission of Materials Information Society/ASM International)

structure elements, which are replaced by T_6C trigonal prismatic structural elements. Cubic monocarbides MC_{1-x} in the Mo–C and W–C systems (Figure 4) exist only at high temperatures and with substoichiometric compositions. The stoichiometric monocarbides WC and MoC are hexagonal with trigonal prismatic structural elements. An additional phase, γ'-Mo_3C_2, has been observed in the Mo–C system with a layer sequence ABAB... and hence is structurally related to some ternary transition metal nitride phases. The carbides Mo_2C and W_2C undergo a phase transition $\beta \rightarrow \beta'$. In the β'-T_2C phase the cell symmetry with respect to carbon is lower than in the β-phase. In Mo_2C a hexagonal to orthorhombic first-order phase transition occurs. Especially in the W-C system, a large variety of possible ordered structures have been found by electron diffraction in the W_2C phase. Whether they are to be considered as stable phases is not yet clear.[7]

The Cr–C system (Figure 4) has been reinvestigated by diffusion couples in which the three chromium carbides form distinct diffusion bands.[23] The system is characterized by the absence of a monocarbide phase. There are three carbide phases ($Cr_{23}C_6$, Cr_7C_3 and Cr_3C_2) with crystal structures that deviate from the simple concept of a densely packed metal atom host lattice with interstitial carbon atoms. Cr_3C_2 has trigonal prismatic structural elements in an orthorhombic lattice. A further orthorhombic chromium carbide phase with the composition Cr_3C is metastable and isotypic to cementite, Fe_3C. The phase Cr_7C_3 has an orthorhombic arrangement of metal atoms and is structurally closely related to the hexagonal T_2C phases. While the hexagonal T_2C do not contain other structural elements than T_2C octahedra, slightly distorted T_6C trigonal prismatic structure groups can be observed in Cr_7C_3. In ternary systems with hexagonal T_2X phases in the boundary system, the solid solubility of Cr_7C_3 in the hexagonal phases is considerable. In $Cr_{23}C_6$, each carbon atom has 8 metal neighbors in the form of a quadratic antiprism. In that respect the structure differs basically from all other transition metal carbides.

5.2.4 The Mn–C and Fe–C Systems

The Mn–C system (Figure 5) has similarities with both the Fe–C and the Cr–C systems with respect to occurring phases. The phase Mn_3C is isotypic with Fe_3C and is a stable phase at high temperatures as opposed to the Fe–C and Cr–C systems. The phases $Mn_{23}C_6$ and Mn_7C_3 are isotypic with the chromium carbide phases of the same compositions. The phase Mn_5C_2 has a monoclinic structure with 28 atoms in the unit cell. As opposed to the above-mentioned manganese carbides, which are line compounds, the ε-Mn_4C has a broad homogeneity region and is a high-temperature compound.

Although in the Fe–C system (Figure 5) no stable carbide phase exists, this system is, nevertheless, the most important system in materials science because on this system the physical metallurgy of steels is based. Cementite (Fe_3C) and several other iron carbides have been reported to be formed in heat treated, quenched, and annealed steels. The broken lines in this figure relate to the metastable Fe–Fe_3C phase diagram. Cementite is metastable but in solid alloys it can persist for very long times even at temperatures up to 700 °C. The decomposition is extremely slow and can be avoided by addition of other carbide forming metals such as Cr and Mn.

5.2.5 The Co–C and Ni–C Systems

In the systems Co–C and Ni–C and in the other transition metal–carbon systems not mentioned so far, no stable carbide phases are observed. The carbon solubilities in the metals are of importance for the fabrication and properties of hardmetals (see Section 9.1.1). The phase diagrams are of the eutectic type. Metastable carbide phases have been reported in rapidly quenched Co–C and Ni–C alloys.

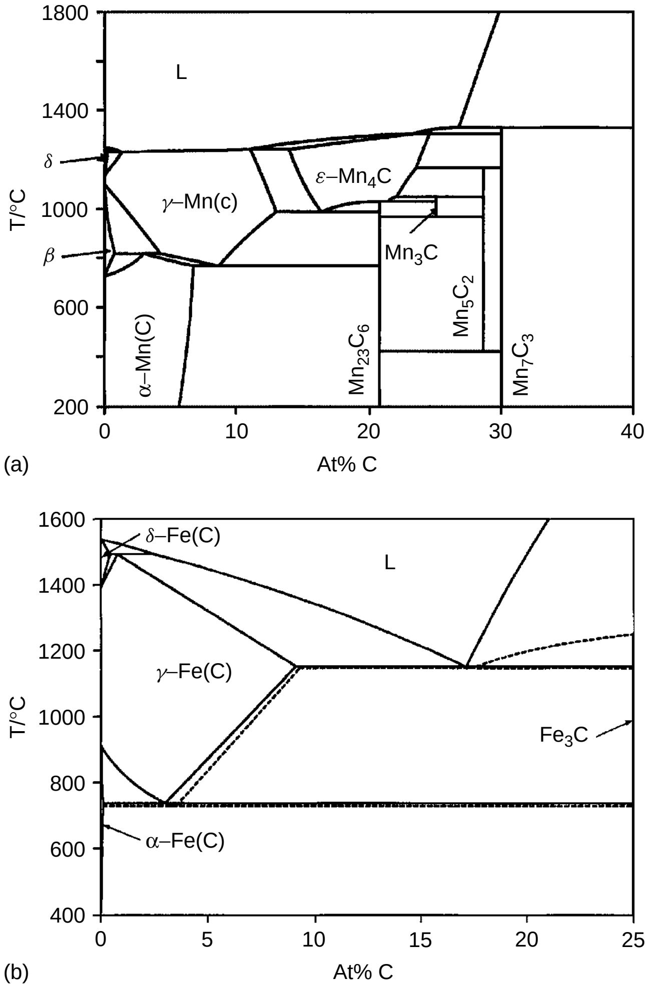

Figure 5 Phase diagrams of the Mn–C (a) and Fe–C (b) systems. (Ref. 25. Reproduced by permission of Materials Information Society/ASM International)

6 TERNARY TRANSITION METAL CARBIDES

Fcc transition metal carbides often form complete solid solutions with each other, particularly at high temperatures and if their lattice parameters do not differ by more than 8–10%. Miscibility gaps have been observed[26] in the quasibinary systems TiC–ZrC, TiC–HfC, VC–NbC and VC–TaC. The solid solubility of 'MoC' and WC in the fcc carbides of Groups 4 and 5 is appreciable, while hexagonal WC does not dissolve any of the fcc carbides except at very high temperatures.

There are several families of ternary carbide phases with transition metals and main group elements. Several of them are of structural interest such as the H-phases, the filled β-manganese type carbides and the κ-carbides. The η-phases are formed in carbon–deficient hardmetals and cause embrittlement.

The H-phases are a large family of ternary interstitial compounds. They have the general formula T_2MX, where T is a transition metal, M is a group 2 or 6 element and X is C or N. The structure can be described as alternating hexagonal layers of octahedra consisting of carbon and main group element atoms (Figure 6). The structure of the H-phases is related to the structures of γ'-Mo_3C_2, η-NbN and η-TaN (*see* ***Nitrides: Transition Metal Solid-state Chemistry***).

The η-phases have the general formula $T1_4T2_2C_x$ or $T1_3T2_3C_x$, where T1 and T2 are transition metals. There are carbides, nitrides, and oxides with the η-carbide structure. Ward[10] has summarized the structure of these phases, which are characterized by T_6C octahedra connected by common faces.

A further group of ternary carbides, T_3MC_2, where T is a transition metal and M is a main group element such as Si or Ge, features a close-packed stacking sequence of Si/Ge and T layers with the sequence $(hhhc)_2$ and where the second h layer in this sequence is the Si/Ge layer. Barsoum *et al.*[27] conducted an intensive investigation of the phase Ti_3SiC_2 in the past years. These phases (also nitride and carbonitride phases belong to this family) show an unusual set of properties (Table 2) owing to the layered structure of the unit cell. They are relatively soft but elastically stiff. Of highest importance is the fact that these compounds can be easily machined by regular tools despite their good high-temperature mechanical properties. They represent a new class of solids that can be identified as thermodynamically stable nanolaminates. A comprehensive treatment of structural aspects in complex carbides has been given by Nowotny and Benesovsky.[28]

7 TRANSITION METAL CARBONITRIDES

Because of the evident structural similarities between transition metal carbides and transition metal nitrides the carbon atoms in group 4 and 5 carbides can be replaced completely by nitrogen without changing the structure of the binary phases. So far only one distinct ternary phase $Cr_2(C,N)_2$ has been reported.[29] Intersolubility between the binary nitrides and carbides in the group 6 carbonitride systems Cr–C–N and Mo–C–N is not complete because of the differences in the crystal structures of the carbide and nitride phases.

Carbonitrides of the type (T1,T2)(C,N) also show complete solid solubility if the lattice parameters of the boundary systems are favorable. In the systems Ti–Mo–C–N and Ti–W–C–N complete miscibility between TiC–TiN, MoC–WC and MoN–WN at high temperatures has been predicted[30] (the fcc MoN and WN corners are experimentally not accessible). At lower temperatures, the homogenous fcc phase is claimed to undergo a spinodal decomposition into a (Ti,Mo)C or (Ti,W)C phase with low N contents and a Ti(C,N) phase with low Mo or W contents. The spinodally decomposed fcc phases have very similar lattice parameters. The driving force for the decomposition is based on the fact that in the 'reciprocal salt pair' TiC + MoN $\rightarrow$ TiN + MoC the Gibbs free energy of reaction is negative. This fact has

been claimed to be of consequence for the sintering behavior and performance of carbonitride hardmetals (see Section 9.1).

8 PROPERTIES OF TRANSITION METAL CARBIDES

8.1 Melting Points

The transition metal carbides are some of the highest melting known materials. δ-$TaC_{0.89}$ melts congruently at 3985 °C and δ-$HfC_{0.94}$ congruently at 3950 °C. The melting temperatures can be read from the phase diagrams presented in Section 5.2.

8.2 Thermal and Electrical Properties

The thermal conductivities of transition metal carbides increase with increasing temperature, an unexpected phenomenon that has been investigated extensively on titanium, zirconium, hafnium and carbides and carbonitrides.[31,32] Previous studies have reported a linear increase of the thermal conductivity with temperature, but more recent investigations have revealed a nonlinear relationship.[32] Carbon deficiency increases the low-temperature thermal conductivity of δ-TiC_{1-x} but decreases the high-temperature thermal conductivity.

Transition metal carbides have generally a significantly lower thermal conductivity than isotypic transition metal nitrides. Some values are given in Table 1 and a comparison between these two groups is given in the article on (*see **Nitrides: Transition Metal Solid-state Chemistry***) as a function of temperature.

The thermal conductivity of WC[33] is much higher than that of the fcc transition metal carbides. The lower thermal conductivity of fcc carbides has been attributed to their generally nonstoichiometric composition and hence the higher concentration of phonon scattering defects in the lattices, but can probably be explained by the stronger covalent bonding in WC and hence the higher efficiency of the heat transport by phonons.

The parallelism in properties between fcc transition metal carbides and nitrides is also valid for room-temperature electrical resistivity, which decreases with increasing carbon content and increases with increasing temperature. Generally the transition metal carbides have higher electrical resistivities than the transition metal nitrides. Figure 7 gives the electrical resistivities of Groups 4 and 5 transition metal carbides as a function of carbon content, as compiled by Storms,[2] compare also Ref. 32. For the electrical resistivity of δ-HfC, values

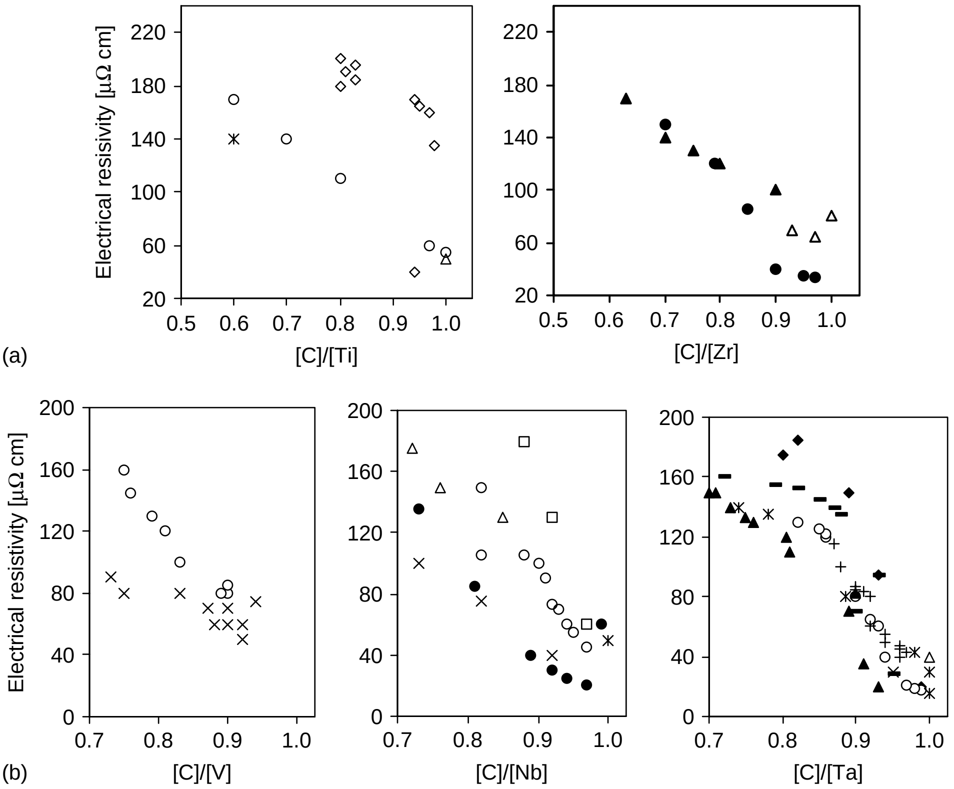

Figure 7 Electrical resistivity versus [C]/[T] ratio for δ-TiC_{1-x}, δ-ZrC_{1-x} (a), and fcc group 5 transition metal carbides (b), from Storms. (Reprinted from Ref. 2. © 1972, with permission from Elsevier)

between 27–51 μΩ cm have been reported, which is probably valid for compositions close to [C]/[Hf] = 1, and where the lower value is most probably due to the purer sample.

Some transition metal carbides are superconducting. The highest T_c values have been reported for δ-NbC (11.1 K), δ-TaC (10.3 K) and hexagonal WC (10.0 K), δ-TiC, δ-ZrC, δ-HfC and δ-VC_{1-x} are not superconducting above 1 K.

8.3 Thermal Expansion

Thermal expansion is an important property of transition metal carbides.[34] They are practically never used in pure form but mostly in composite materials with matrices of other materials (metals). Upon thermal load, the difference in the thermal expansion coefficients of the carbide phase and the matrix may cause degradation of the composite. Generally, the thermal expansion of transition metal carbides is higher than that of the pure metal component. Table 1 gives average thermal expansion coefficients of various carbides. For WC, the thermal expansion has even been measured at various pressures.[33]

The thermal expansion of the group 4 carbonitrides was measured by high-temperature X-ray diffraction[34] and can be expressed as a function of the [C]/([C] + [N]) ratio:

$$\delta - \mathrm{Ti}(\mathrm{C}_x\mathrm{N}_{1-x}): \quad \alpha_{\mathrm{av}} = \{9.9 - 1.4^*[\mathrm{C}]/([\mathrm{C}] + [\mathrm{N}])\}^*10^{-6}\,\mathrm{K}^{-1}$$

$$\delta - \mathrm{Zr}(\mathrm{C}_x\mathrm{N}_{1-x}): \quad \alpha_{\mathrm{av}} = \{7.8 - 0.3^*[\mathrm{C}]/([\mathrm{C}] + [\mathrm{N}])\}^*10^{-6}\,\mathrm{K}^{-1}$$

$$\delta - \mathrm{Hf}(\mathrm{C}_x\mathrm{N}_{1-x}): \quad \alpha_{\mathrm{av}} = \{8.5 - 2.4^*[\mathrm{C}]/([\mathrm{C}] + [\mathrm{N}])\}^*10^{-6}\,\mathrm{K}^{-1} \qquad (8)$$

8.4 Diffusivities

The diffusion of carbon in transition metal carbides proceeds via a vacancy mechanism and thus the diffusivity increases with increasing vacancy concentration in the nonmetal sublattice.[35,36] However, carbon diffusivities versus composition were measured only for very few types of carbides. Diffusivity data are summarized in Figure 8 and Table 3, for which data of Matzke[37] and Lengauer[12] were used. The metal diffusion is even slower and has a higher activation energy. Actual values were obtained for δ-TiC_{1-x} and δ-NbC_{1-x}. A detailed study of concentration-dependent diffusivities was conducted for δ-TiC_{1-x} and δ-ZrC_{1-x} by means of carbon profile measurements in diffusion couples.[38]

Table 3 Diffusivity data for nonmetal diffusivity of transition metal carbides,[12] for compounds with a = 0 no significant concentration dependency is present

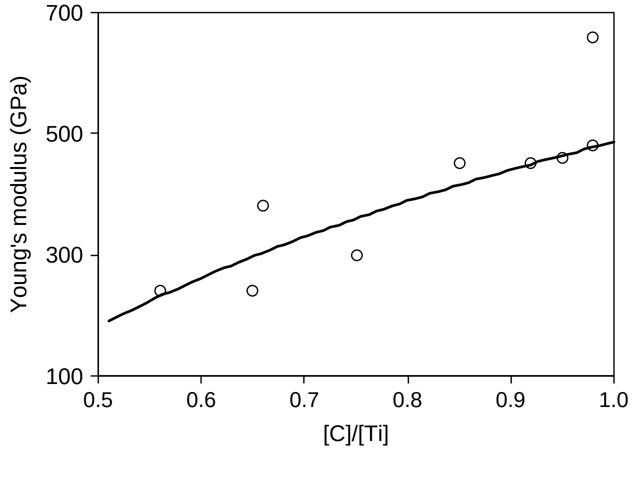

Figure 9 Young's modulus of δ-TiC_{1-x} as a function of carbon/metal ratio, from Török *et al.* (Reprinted from Ref. 39. © 1987, with permission from Elsevier)

8.5 Microhardness and Elastic Properties

The Young's moduli E of group 4 transition metal carbides are on the order of about several hundred GPa (Table 1) and appear to depend on the carbon/metal ratio. This is at least true for δ-TiC_{1-x}, where E increases with increasing [C]/[Ti] approximately linearly from 200 GPa at $TiC_{0.50}$ to 460 GPa at $TiC_{0.98}$ (Figure 9). Values for δ-ZrC_{1-x} and δ-HfC_{1-x} are 370–480 and 420–460 GPa, respectively, for unspecified but probably near-stoichiometric compositions.[39,40] The highest Young's modulus is that of WC (Table 1) and has been measured for temperatures of up to 2200 K.[33] It drops almost linearly from about 710 GPa at room temperature to 557 GPa at 2200 K.

For Ti, Zr, and Hf carbonitrides, including also binary carbides and nitrides, the Young's, shear, and bulk modulus as well as the Poisson number have been measured by ultrasonic measurements as a function of the C/N ratio.[41] The data are given in Figure 10.

Many of the transition metal carbides such as TiC are very hard compounds. In δ-TiC_{1-x} the microhardness increases with increasing carbon content, a phenomenon that is probably closely related to the VEC, with the maximum stability at VEC = 8 at the composition TiC. Figure 11 shows this behavior for δ-TiC_{1-x},[42] other data are contained in Table 1. Both microhardness and nanohardness were recently measured for Ti, Zr, and Hf carbonitrides as a function of the C/N ratio.[41] The data are

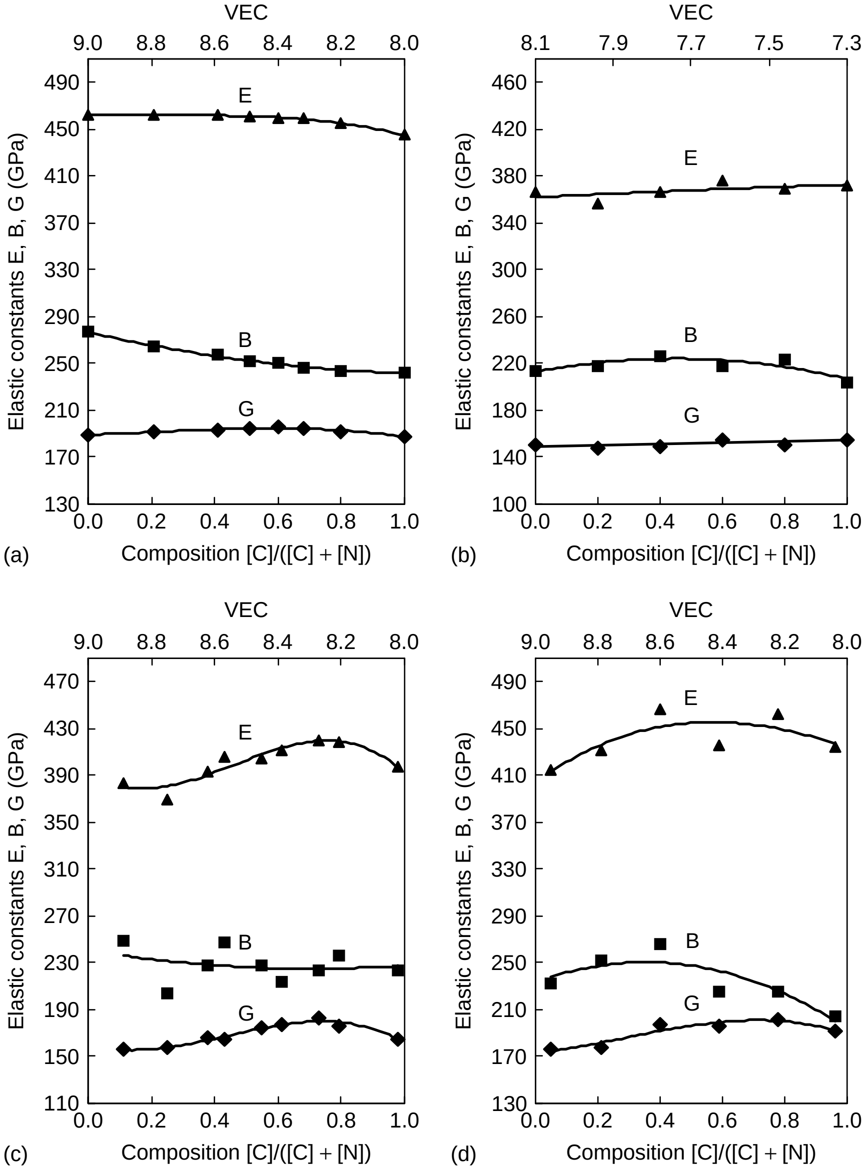

Figure 10 Young's (E), shear (G), and bulk modulus (B) of (a) $Ti(C_xN_{1-x})$, (b) $Ti(C_xN_{1-x})_{0.81}$, (c) $Zr(C_xN_{1-x})$ and (d) $Hf(C_xN_{1-x})$, as a function of the C/N ratio as well as of the VEC. (Reprinted from Ref. 41. © 2000, with permission from Elsevier)

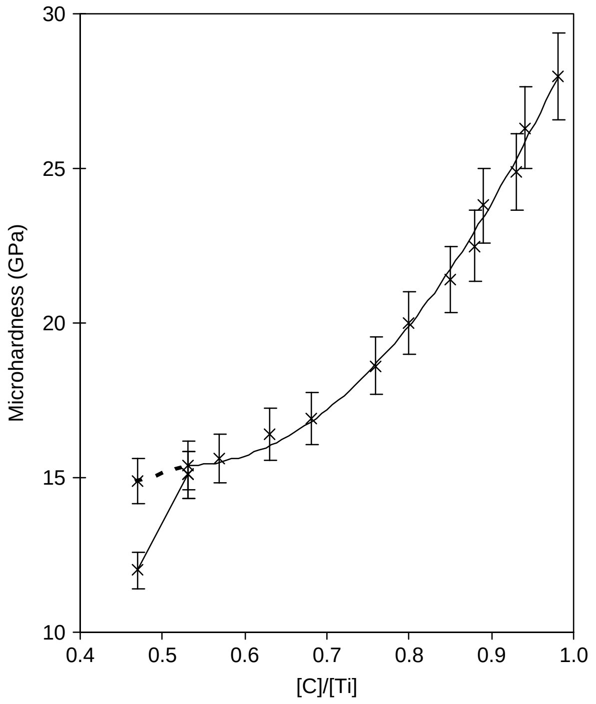

Figure 11 Microhardness of δ-TiC_{1-x} as a function of the carbon/metal ratio, from Chermant *et al.* (Reprinted from Ref. 42. © 1970, with permission from Elsevier)

given in Figure 12 and show a higher nanohardness than microhardness.

Interestingly, as-grown δ-V$C_{0.91}$ has the highest hardness among these compounds ($HK_{0.1}$ = 30.8 GPa). This value corresponds to the ordered state, whereas that of the disordered is 26 GPa, depending on the composition.[43] δ-TiC has the highest hardness for annealed single crystals ($HK_{0.1}$ = 30.4 GPa). Both values correspond to the (100) plane, which has the highest hardness. Generally, the hardness values of annealed crystals (Table 1) are lower than that of as-grown crystals owing to their lower dislocation density. Polycrystalline material has 1–2 GPa higher hardness values than single crystals owing to the grain boundary influence on hardness (Hall–Petch relation).

On single crystals of transition metal carbides it has been shown for hexagonal WC and also for fcc NbC_{1-x} that the microhardness is dependent of orientation.[44,45]

Single-crystal and polycrystalline transition metal carbides have been investigated with respect to creep, microhardness, plasticity, and slip systems. The fcc carbides show slip upon mechanical load within the (111) plane in the {110} direction.[45,46] The ductile-to-brittle transformation temperature of TiC is about 800 °C and is dependent on the grain size. The yield stress of TiC obeys a Hall–Petch type relation, that is, the yield stress is inversely proportional to the square root of the grain size.[47] TiC and ZrC show plastic deformation at surprisingly low temperatures around 1000 °C.

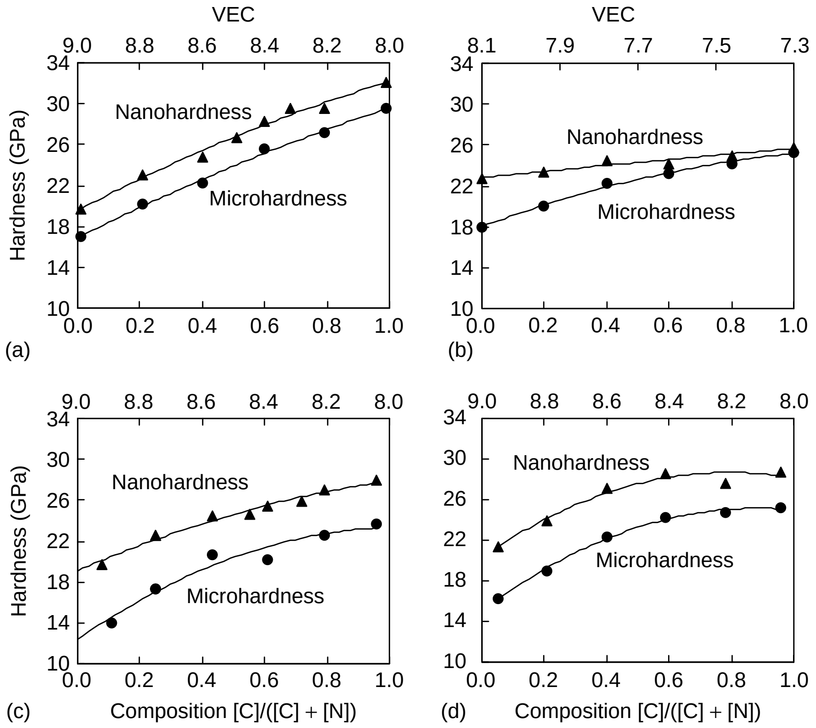

Figure 12 Nanohardness (▲) and microhardness (•) for (a) Ti(C_xN_{1-x}), (b) Ti(C_xN_{1-x})$_{0.81}$, (c) Zr(C_xN_{1-x}) and (d) Hf(C_x N_{1-x}) as a function of the [C]/([C] + [N]) ratio as well as of the VEC. For stoichiometric carbonitrides the two functions are practically parallel, from Yang *et al.* (Reprinted from Ref. 41. © 2000, with permission from Elsevier)

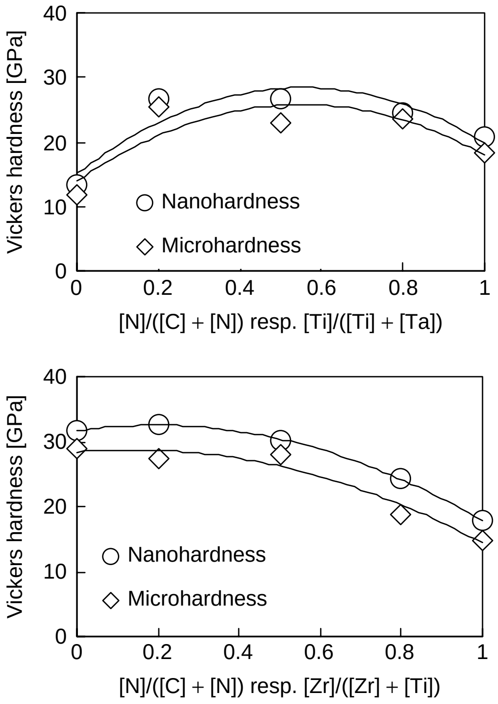

Figure 13 Micro- and Nanohardness of quaternary phases (Ti,Zr)(C,N) and (Ti,Ta)(C,N)

Upon additional alloying ternary carbonitrides quaternary carbonitrides are obtained. The group 4 and 5 transition metal carbides and nitrides are completely miscible except TiN-VC and ZrN-VC. Thus, modified material properties can be obtained (see also Section 9.2). Information on the properties of these carbides are still scarce,[48] a few data are given in Figure 13 and Table 4.

9 USES

9.1 Cemented Carbides (Hardmetals)

9.1.1 Metallurgy of Hardmetals and Cermets

The most widely used transition metal carbide is tungsten carbide, hexagonal WC, which is employed as the hard constituent in WC–Co hardmetals. These hardmetals are sintered composite materials with 80–90% of hard particles such as WC embedded in a ductile binder phase such as Co and/or Ni. For these applications, WC combines a number of favorable properties such as high hardness and wear resistance, exceptional high modulus of elasticity, good electrical and heat conductivities and is readily wetted by the binder metals Co and Ni. The ternary system W–C–Co is shown in Figure 14 for 1350 °C.[49] WC coexists with the Co phase and forms a pseudobinary lower melting eutectic between WC and Co. This eutectic facilitates full densification during liquid phase sintering. The carbon content must be kept close to the theoretical value because a decrease in total carbon content will lead to the formation of η-carbides $(W,Co)_6C$, which are brittle and harmful to the performance of these materials. Modern hardmetals, particularly for metal cutting applications, contain other carbides such as TaC, NbC, and TiC, which are admixed to increase the high-temperature performance and wear resistance. Figure 15 shows a microstructure of a WC–Co hardmetal.

Shortly after the invention of WC–Co hardmetals, TiC–based hardmetals were proposed as cutting tools but have not found extended use because of their comparative brittleness. Only in the last two decades, TiC-based hardmetals have found wider use when titanium nitride, δ-TiN, was

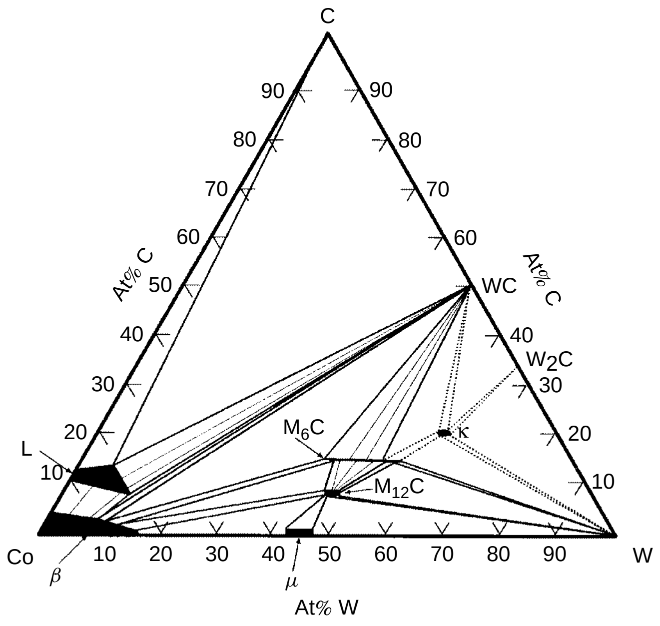

Figure 14 Phase diagram of the W–C–Co system at 1350 °C

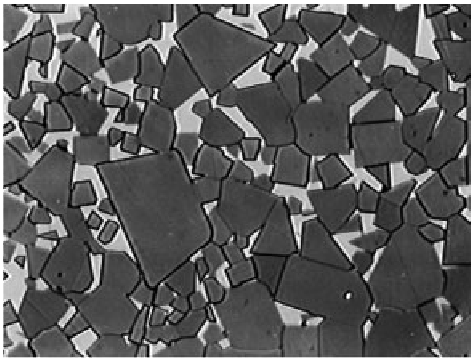

Figure 15 Microstructure of a coarse WC–Co hardmetal with gray WC particles embedded in a Co matrix, the size of the largest grains is about 20 μm

introduced as a further constituent. Generally, these titanium carbonitride hardmetals, often called cermets (an artificial word coined from the words ceramic and metal because of the combination of a brittle ‘ceramic’ component, which, however, has metallic transport properties as shown above, and a binder metal), are comparable with respect to properties and microstructure to WC-based hardmetals.

The compacted powder mixtures of these materials are usually liquid phase sintered with Ni or Ni–Co binder metal alloys. The microstructure features a core-and-rim structure of the hard phase with a molybdenum- and carbon-rich (Ti,Mo)C rim and a titanium- and nitrogen-rich Ti(C,N) core. This microstructure can be made visible in the SEM (Figure 16). The metallurgy of the phase reactions is not

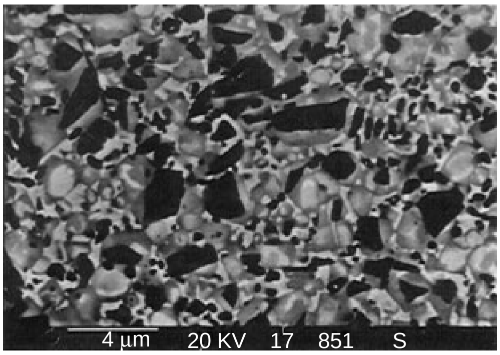

Figure 16 Microstructure of a titanium carbonitride hardmetal (cermet) showing the core-and-rim type structure of hard particles

yet fully understood,[50] because of the complexity of the multicomponent system. The theoretical background of the phase reactions within the system Ti–Mo–C–N was developed by Rudy,[30] who claimed that the quaternary compound (Ti,Mo)(C,N) with a random distribution of the metals Ti and Mo on the metal sites and the nonmetals C and N on the nonmetal sites should undergo a decomposition with the formation of two isotypic fcc phases but with a preferential arrangement of N around the Ti atoms and Mo around the C atoms. This decomposition is of a spinodal type, which is a decomposition induced by local composition fluctuations without any activation energy rather than a classical nucleation and growth process. The question whether the spinodal decomposition is a necessary prerequisite for the core-and-rim formation of the hard component is still the topic of discussions because core-and-rim structures may develop via reactions of the hard constituents with the liquid binder metals as well.

The core-and-rim type structure has been claimed to have a favorable influence on the mechanical properties because the molybdenum-containing rim is much better wetted by the binder alloy than the nitrogen-containing core. Modern Ti(C,N) hardmetals have been successfully applied for finishing operations of high-strength steel grades and ductile cast irons at high cutting speeds but with moderate cross section of the chips. The main advantages of Ti(C,N) hardmetals over conventional hardmetals are the high chemical resistance and the low frictional welding tendency, resulting in longer life of the cutting edge and a good workpiece surface. For some applications, Ti(C,N) cermets do outperform even coated WC hardmetals.

9.1.2 Cemented Carbide Grades

The cemented carbides are used for a variety of different applications ranging from metal cutting, drilling, and milling (steel and nonferrous alloys) over wood cutting to drilling of circuit boards for electronic devices as well as for structural parts such as dies and cutters for the paper

industry. Examples for the tools are given in Figure 17 and 18. Table 5 gives a summary of the various grades in use. One of the most important developments in recent years is the application of submicrometer sized WC powders used for WC–Co hardmetals such as for micro-drilling and wood cutting. Such ultra-fine grained cemented carbides have very high hardness and bending strength. They are doped with VC and/or Cr_3C_2, which serve as a grain-growth inhibitor.

9.2 Wear-resistant Layers

Wear-resistant layers of transition metal carbides that have been deposited by CVD (*see Chemical Vapor Deposition*) and PVD processes on the surface of WC–Co hardmetals further reduce the wear in cutting applications. About 80% of all tool tips for metal cutting are coated. Modern multilayer coating feature a combination of different layers, where TiN is often the base layer adjacent to the substrate, Ti(C,N) is an intermediate layer and TiN is the top layer. This should provide a smooth variation of properties across the layer, from good adherence to the hardmetal to the high chemical inertness and low tool-workpiece frictional welding tendency of TiN. Such layers are usually made by CVD processes where a volatile component such as titanium tetrachloride is reacted with a

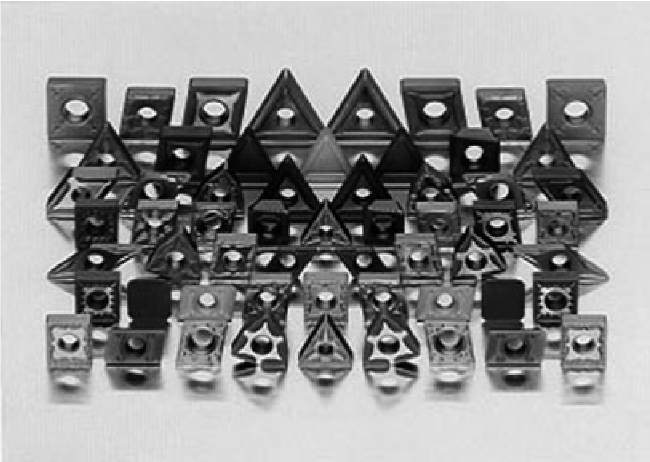

Figure 17 Examples of different cutting inserts used in cutting industry (Kennametal-Widia GmbH)

Figure 18 Microdrills used in electronic industry made of ultra-fine WC

Table 5 Characteristics of hardmetal and cermet grades and their applications

Composition	Grain Size μm	Amount of binder metal wt%	Applications

Cermets	0.5–3	5–20	cutting tools for steel chipping

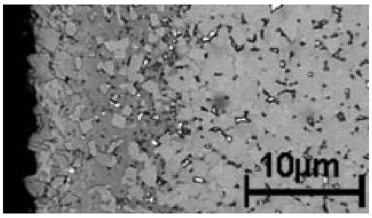

Figure 19 Microstructure of a functionally graded hardmetal

gas, the composition of which is gradually changed from methane-rich to nitrogen/ammonia-rich. The gas pressures are on the order of 100 mbar and temperatures are about 1000 °C. The thicknesses of the coatings are about 1–10 µm. A microstructure of a TiN/TiCN/Al_2O_3/TiN coating is given in the article (*see* ***Nitrides: Transition Metal Solid-state Chemistry***).

Recent developments in the field of CVD and PVD layers are multilayer coatings that consist of carbonitrides, carbides, nitrides, and oxides, whereas the trend goes into the use of ternary and quaternary carbonitrides[51] such as Zr(C,N) and (Ti,Hf)(C,N) as well as mixed oxides such as Al_2O_3/TiO_2, $Al_2O_3/TiO_2/HfO_2$.

PVD (physical vapor deposition) methods can be applied whenever the substrate temperature has to be kept lower than 600 °C (e.g. for quenched-hardened steel items); they make use of a variety of techniques ranging from sputtering to ion beam deposition.

Another recent development on the field of wear-resistant layers is the formation of graded zones in functionally graded hardmetals FGHMs (cemented carbides).[52] These near-surface zones are formed by diffusion of mainly nitrogen into a Ti-containing hardmetal so as to create a Ti(C,N)-enriched surface. Some of these FGHMs show a smooth increase of the nitride phases towards the surface and thus a absence of a macroscopic interface. An example of an microstructure is given in Figure 19. The lifetime of such graded hardmetals is more than tenfold of that of untreated grades. Such FGHMs can be used as a substrate for nitride and carbonitride as well as diamond coatings and outperform hardmetals without graded substrate.

9.3 Diffusion Barriers

Transition metal carbides can be used as diffusion barriers like transition metal nitrides in multilayer metallization schemes for integrated circuits.[53] Layers on the order of 100 nm are applied and are produced by sputtering methods. The high chemical stability of these transition metal carbides, especially those of group 4, are exploited to prevent interaction of metal or component layers such as silicon, aluminum, and silicides upon thermal load in production processes. This load would cause electrical or even structural deterioration of the multilayer packages.

Glossary

Fullerene: closed hollow-cage molecule consisting solely of carbon atoms which are arranged as pentagonal and hexagonal rings
IPR Fullerene: fullerene which satisfies the isolated pentagon rule, i.e. there are no edge-sharing pentagonal rings

Abbreviations

IPR = Isolated pentagon rule; Fc/Fc^{+} = Ferrocene/ferricinium couple (redox potential reference).

1 INTRODUCTION

The fullerene family represents a new *Allotrope* of carbon, which now stands alongside the two more familiar forms: black graphite, with its lubricating properties, and the sparkling gemstone diamond, one of the hardest materials known. The fullerenes are fundamentally different from both these forms of carbon as they are an infinite family of discrete cage-like molecules, of which buckminsterfullerene is the archetype (named after the architect Richard Buckminster Fuller, designer of the geodesic dome). The idealized infinite structures of graphite and diamond are shown in Figure 1, and the 'dangling bonds' at the boundaries of these repeating patterns are usually terminated by another element or group (typically hydrogen and/or oxygen). In contrast, the fullerenes are closed molecules with no edges, and as such they represent a truely 'pure' form of carbon.

1.1 History

The properties of hypothetical closed carbon cages have been the subject of discussion for many years, and the highly symmetric truncated icosahedral (soccer ball) geometry of the archetypal species buckminsterfullerene (C_{60}) had particular appeal. It was suggested that C_{60} would be stable and possibly 'superaromatic',[1] but the deliberate synthesis of such a complex molecule remained too daunting a challenge.[2]

The first major breakthrough in fullerene chemistry occurred in 1985, during an experiment designed to simulate the aggregation of carbon atoms in cool red giant stars. A carbon plasma generated by laser vaporization of graphite spontaneously formed large carbon clusters upon cooling, and mass spectrometric analysis of the products showed that the cluster ions $C_{60}{}^{+}$ and $C_{70}{}^{+}$ were particularly stable (Figure 2).[3] Hollow cage structures were proposed, and subsequent experiments showing that other elements could be encapsulated inside these cages were consistent with these proposals.

The second major breakthrough came in 1990, when the presence of macroscopic quantities of C_{60} in the soot generated by arc vaporization of graphite was established.[4] A mixture of C_{60}, C_{70}, and other larger fullerenes was extracted from this soot and shown to be a new crystalline form of carbon (Figure 3). Chromatographic separation of this mixture gave pure C_{60} and C_{70}, and their proposed molecular cage structures were confirmed by ^{13}C NMR spectroscopy (Section 5.3).[5]

2 STRUCTURE AND BONDING

2.1 General Definitions

Fullerenes are closed hollow cages consisting solely of carbon atoms. Each carbon atom is bonded to three neighbors and is sp^2 hybridized, as in the hypothetical structure of graphite (*see Hybridization*). A 'perfect' graphite sheet, however, is an infinite flat array of hexagonal rings and cannot be closed to a cage structure without the incorporation of defects (disclinations). Euler's equation (equation 1) relates the number of vertices (V), edges (E), and faces (F) of a simple polyhedron, and satisfaction of the condition that each vertex is linked to exactly three neighbors gives equation (2), where n_i is the number of i-sided polygons in the polyhedron. In general, the term fullerene refers to cages comprised solely of pentagonal and hexagonal rings, and although other defects may be envisaged (e.g. smaller or larger rings), these are expected to result in strained structures. Thus it can be seen from equation (2) that incorporation of exactly 12 pentagonal rings is sufficient to effect cage closure, and that the general molecular formula for all fullerenes is C_{20+2n} for integral

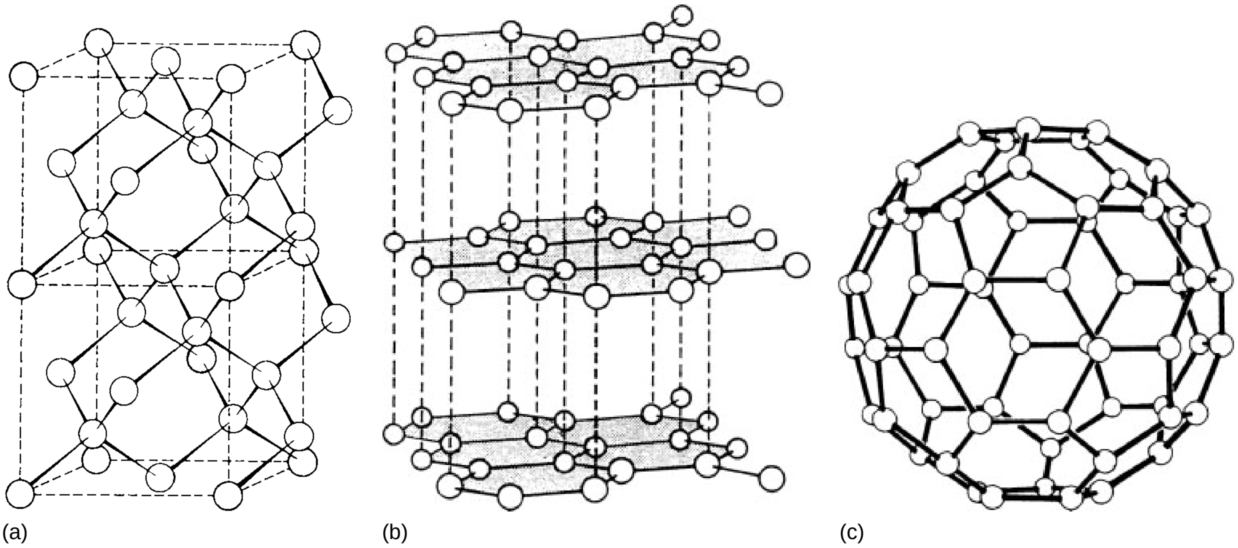

Figure 1 Structures of the three main forms of carbon: (a) diamond; (b) α-graphite; and (c) buckminsterfullerene (I_h-C_{60}), the archetype of the fullerene family

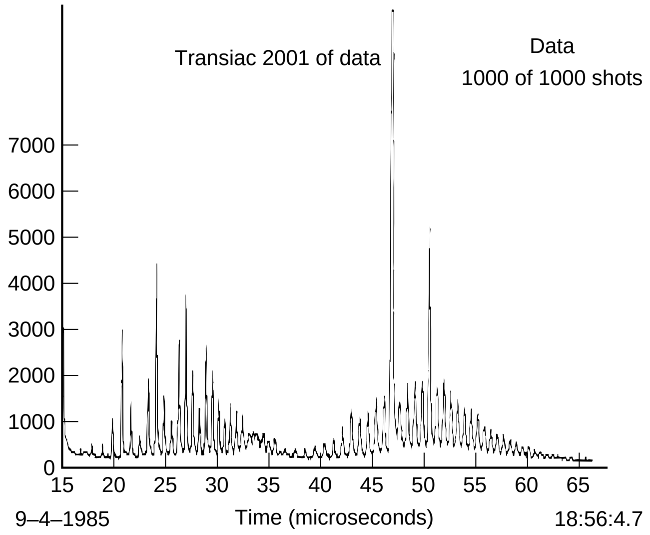

Figure 2 Time-of-flight mass spectrum of carbon clusters produced by laser vaporization of graphite (September 4, 1985) under conditions which first exhibited the dominance of the C_{60} cluster and led to the recognition that 60 might be a magic number. values of n ($n \neq 1$; C_{22} cannot be constructed with only hexagonal and pentagonal rings). Fullerenes therefore contain an even number of carbon atoms arranged as a combination of 12 pentagonal rings and any number n ($n \neq 1$) of hexagonal rings, e.g. the archetypal fullerene, buckminsterfullerene (I_h-C_{60}), consists of 12 (isolated) pentagons and 20 hexagons (Figure 1(c)). Buckminsterfullerene is the only fullerene to have acquired an accepted trivial name, albeit a slightly long one. In general the simpler fullerenes are referred to by their symmetry and size, e.g. I_h-fullerene-60, although for convenience and brevity the fullerene cage structure is often assumed and the molecular formula used, e.g. I_h-C_{60}, D_2-C_{76}, or simply by the molecular formula alone if only one cage symmetry is known, e.g. C_{60}, C_{70}.

$$V - E + F = 2 \tag{1}$$

$$3n_3 + 2n_4 + n_5 - n_7 - 2n_8 - 3n_9 - \cdots = 12 \tag{2}$$

Heterofullerenes are derivatives of fullerenes in which one or more carbon atoms have been replaced by a different

element without disruption of the basic cage structure, e.g. $C_{59}B$.

Endohedral fullerenes are molecules in which an atom or group of atoms is encapsulated within the cage. In the case of metal encapsulation the compounds are commonly referred to as endohedral metallofullerenes. The accepted symbol to indicate encapsulation is @, e.g. U@C_{28}, La@C_{82}.

2.2 Fullerene Structure

As the general formula for a fullerene is C_{20+2n} ($n \neq 1$), the three simplest fullerenes are I_h-C_{20}, D_{6d}-C_{24}, and D_{3h}-C_{26} (Figure 4), and there is only one isomer for each of these. For the larger fullerenes more structures are possible, the number of which increases rapidly with cage size and can be calculated using the Ring Spiral Algorithm.[6] For fullerenes up to C_{380} this algorithm generates all isomers and reduces each to a unique sequence of numbers and therefore provides an unambiguous (although incomprehensible) naming scheme.[7]

The ring spiral algorithm shows that the C_{60} molecule has 1812 different possible isomeric structures; however, experimentally only the I_h-C_{60} isomer is observed. The observation that unsaturated organic molecules containing edge-sharing pentagons tend to be unstable is the basis of the Isolated Pentagonal Rule (IPR) for fullerene stability.[2,8,9] This rule is elegantly confirmed by I_h-C_{60} being the only isomer of C_{60} for which all the pentagonal rings are indeed isolated from one another. Using this principle the fullerene D_{5h}-C_{50} is (correctly) predicted to display enhanced stability since it is the smallest system to exclude triplets of edge-sharing pentagons, although stability is also dependent on several other factors, including electronic structure and molecular strain (Section 2.3). The lowest energy structures of all the smaller fullerenes (C_n, $20 \leq n \leq 70$) have been calculated, and this study confirms that those isomers with the fewest edge-sharing pentagons are indeed the most stable.[10] Under the appropriate experimental conditions (single photon ionization), the enhanced stability of the smaller fullerene cations C_{28}^+, C_{32}^+, and C_{50}^+ is apparent (Figure 5).[11]

To date, all isolable nonderivatized fullerenes satisfy the IPR, although this rule does not necessarily predict that a fullerene will be stable or isolable (Section 2.3). After I_h-C_{60} the next possible IPR fullerene structure is D_{5h}-C_{70}, and historically the observation that C_{60} and C_{70} displayed special stability provided strong evidence for both the cage structures of these molecules and the IPR.[2] Other fullerenes which have been characterized to date are D_2-C_{76}, C_{2v}-C_{78}, C'_{2v}-C_{78}, D_3-C_{78}, C_2-C_{82} (maybe more than one isomer), C_{2v}-C_{82}, C_{3v}-C_{82}, D_2-C_{84}, and D_{2d}-C_{84} (Section 5.3).[12–15] D_2-C_{76} has the interesting feature of being the smallest, chiral fullerene so far isolated (Figure 6). For C_{78} and the larger fullerenes there are many possible IPR isomers, although only a few have been isolated to date. Mixtures containing fullerenes larger than

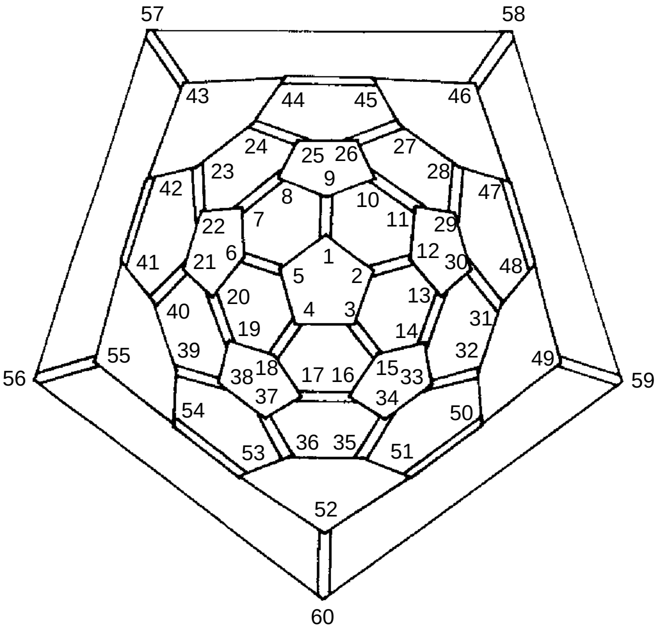

Figure 7 Schlegel diagram of C_{60} showing the accepted carbon atom numbering scheme

C_{84} are known, but their structures and isomeric compositions have yet to be determined.[16]

The isolable fullerenes C_{60} and C_{70} have been chemically functionalized and an unambiguous atom numbering scheme is required for the systematic naming of their derivatives. Although no generally applicable numbering scheme for all fullerenes has been developed, the accepted procedure for the C_{60} cage is to start with a pentagonal ring and spiral clockwise round the molecule (Figure 7), e.g. 1,6,9,12,15,18-hexabromofullerene-60 (Section 6.2.2, Figure 24(b)). Unfortunately this method is not readily adaptable to C_{70} and the other fullerenes.

Very large (giant) fullerenes can be envisaged. In the family of fullerenes having the same symmetry as I_h-C_{60}, the next two members are C_{240} and C_{540} (Figure 8).[2] In addition, there is a second I_h family based on I_h-C_{80}, and many other fullerenes of lower I symmetry.[17] With increasing size these ideal structures become more icosahedral rather than spherical, although the 20 triangular faces actually form a single, smoothly curved 'graphitic' surface with strain largely localized around the pentagonal defects. Such molecules can be nested inside one another to produce idealized onion-like structures. For the $C_{60}/C_{240}/C_{540}$ family the distance between

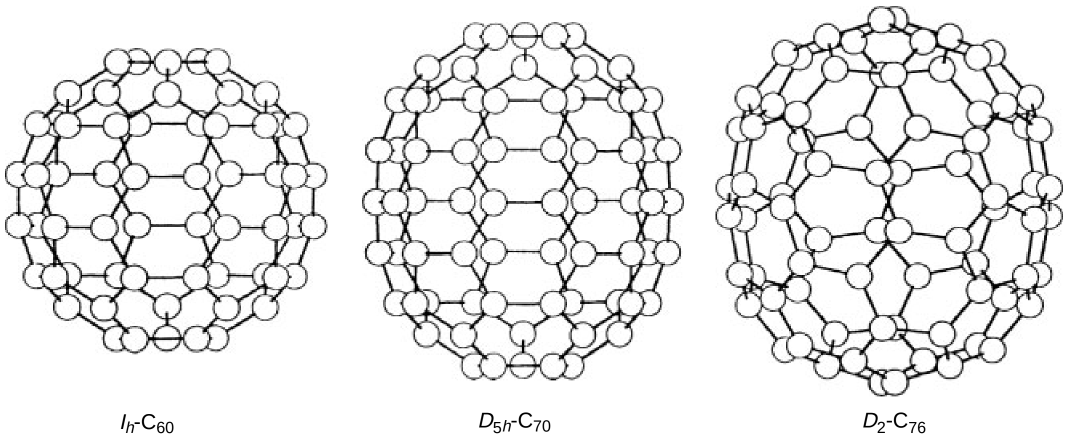

Figure 6 The spectroscopically confirmed cage structures of the first three fullerenes to be isolated in macroscopic amounts; I_h-C_{60}, D_{5h}-C_{70}, and the chiral fullerene D_2-C_{76}

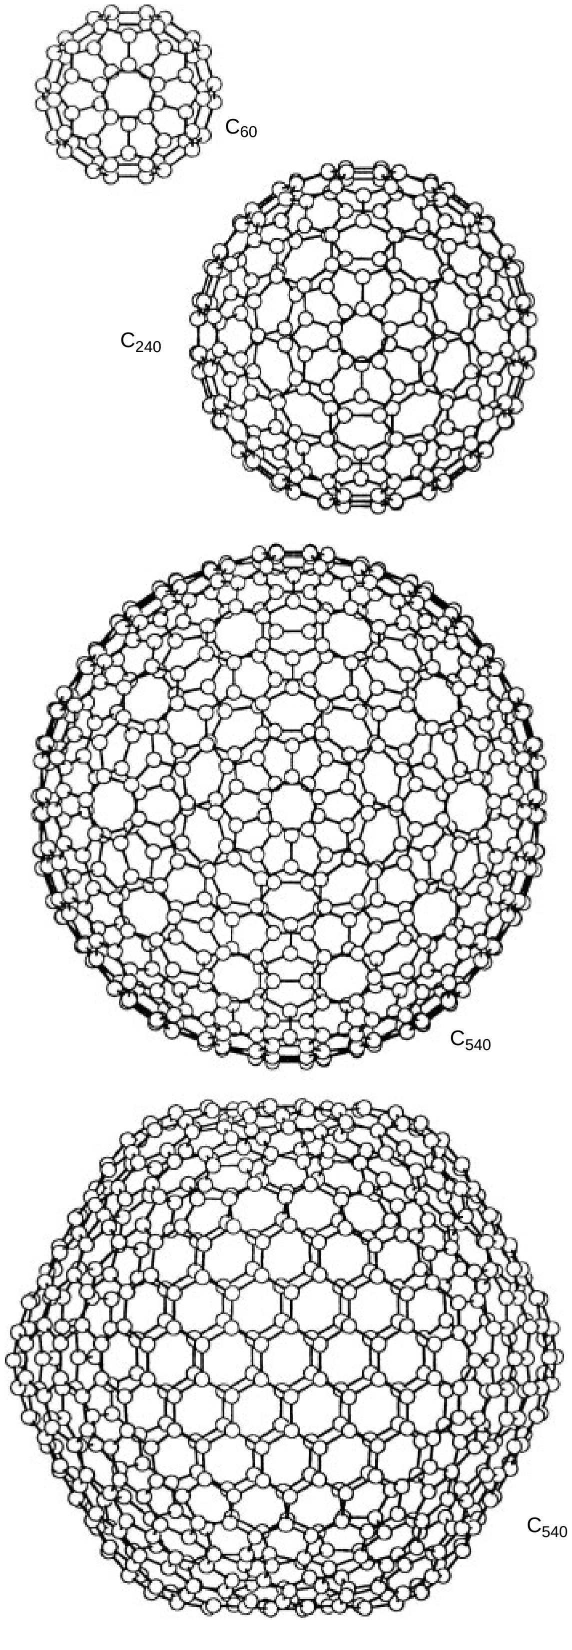

Figure 8 Computer-generated cage structures of the I_h-fullerenes C_{60}, C_{240}, and C_{540} (viewed along C_5-axes). The icosahedral shape of C_{540} is emphasized by viewing along a C_3-axis

concentric shells is always ~3.5 Å, which corresponds well to the *inter*-plane distance reported for graphite. Real, albeit imperfect, structures of this type, comprising up to 70 shells, have been observed in transmission electron micrographs of carbon soot that had been annealed by strong electron beam irradiation (Figure 9(a)).[18]

Nanofiber structures, which appear to grow spontaneously from carbon vapor under the appropriate experimental conditions, have also been identified (Figure 9(b)).[19] They consist of concentric cylinders which are closed at the ends by capping groups similar in structure to one half of the onion structures described previously. Under specific experimental conditions (O_2/molten Pb) some endcaps appear to open, and the lead atoms flow inside the tubes.[20]

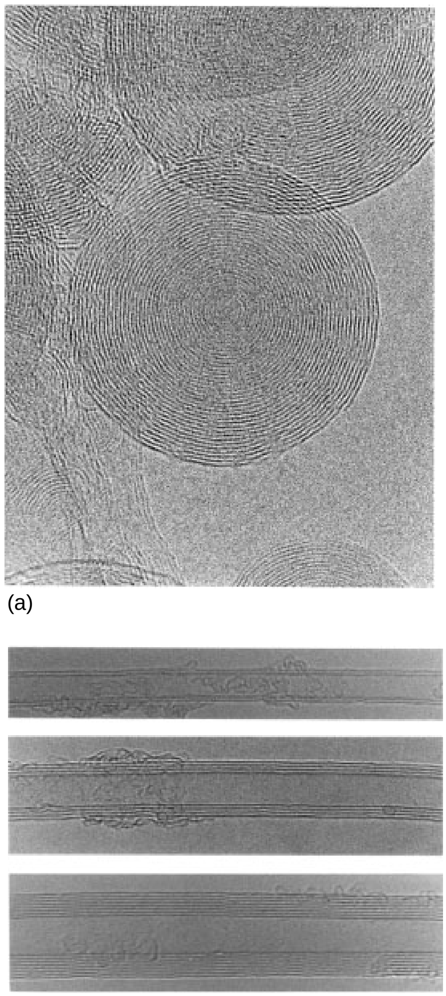

Figure 9 Transmission electron micrographs of nonplanar, carbon structures in which the *inter*-layer distances correspond to graphitic spacing (~3.4 Å). (a) Multishell carbon onions. (Reprinted with permission of Macmillan from D. Ugarte.[18]) (b) Carbon nanotubes. (Reprinted with permission of Macmillan from T.W. Ebbesen and P.M. Ajayan.[19])

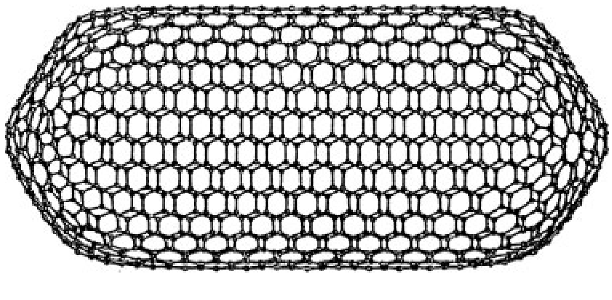

Figure 10 Computer-generated structure of a closed cylindrical fullerene cage (zeppelene). (Reprinted with permission from Ref. 21. © 1992 American Chemical Society)

The term zeppelene (Figure 10) has been coined to describe the discrete molecules formed by closing single cylinders at both ends (or alternatively by elongating a fullerene).[21] The nonplanar nature of all these materials has opened a debate on the relative stabilities of carbon structures on the microscopic and macroscopic scale, and has consequences for the generally accepted planar 2D description of graphite.[22]

In the transmission electron micrographs of these carbon structures, the carbon sheets are sometimes found to have regions of negative curvature. This is only possible with the incorporation of heptagonal or larger ring defects; positive curvature is defined by pentagonal defects and results in closure (fullerenes), whereas negative curvature produces open structures.[23] From equation (2) the theoretical possibility arises that a graphitic sheet can be deformed to enclose a macroscopic volume of any shape or size simply by the incorporation of $12 + n$ pentagonal and n heptagonal defects.

2.3 Stability and Electronic Structure

Stability within the IPR fullerene family is dependent on a balance of electronic and molecular strain factors. The carbon atoms in the fullerenes are approximately sp^2 hybridized (although curvature of the cage causes a small admixture of sp^3), with the remaining p-orbitals (mixed with a small s-orbital contribution) on each carbon forming a π-system which covers both the outside (*exo*) and inside (*endo*) surfaces of the cage. The electronic structure of these extended π-systems are readily modeled with basic Hückel molecular orbital theory (*see Hückel Theory*). These simple calculations show that C_{60} is a closed-shell molecule with a large *HOMO–LUMO Gap* (Figure 11),[24] and is a rare example of an organic molecule with a threefold degenerate t_{1u} LUMO, not to mention a fivefold degenerate h_u HOMO.[2] Theoretical calculations also show that of all the possible resonance (Kekulé) structures for C_{60}, the one in which the 30 six–six ring fusions correspond to the double bonds is the dominant contribution to the π-electronic structure (Figure 7). Thus the π-bonding in C_{60} is best described as localized rather than 'superaromatic', and this localized polyalkene description is in good agreement with the observed chemical reactivity of C_{60} to date (Section 6.2).

The only closed-shell fullerenes predicted by simple Hückel theory fall into two types; the leapfrog fullerenes C_{60+6n} ($n \neq 1$), and the cylinders C_{70+30m} and C_{84+36m} ($m \geq 0$) formed by stretching D_{5h}-C_{70} and D_{6h}-C_{84} along their respective C_5 and C_6 axes.[25] The simplicity of the theory unfortunately prevents these rules having any general utility. Neither of the two IPR-isomers of C_{76} is predicted to be stable but D_2-C_{76} has been isolated, whereas the expected fullerene D_{6d}-C_{72} has not, although its apparent low stability may be

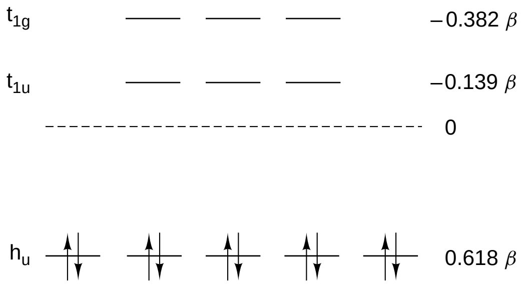

Figure 11 Energy level diagram for the HOMO and first two LUMOs of the 60π-electron system of C_{60}, calculated by simple Hückel molecular orbital theory

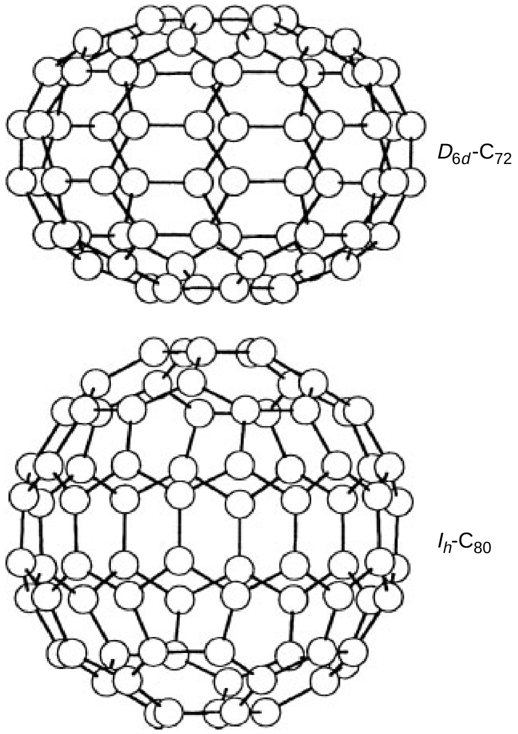

Figure 12 Computer-generated cage structures of the nonisolable IPR fullerenes D_{6d}-C_{72} and I_h-C_{80}. The experimentally elusive nature of these molecules is believed to be due to molecular strain and electronic factors, respectively

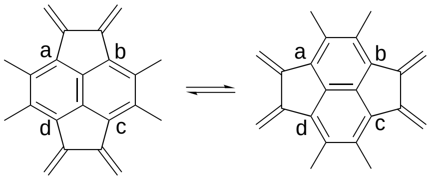

Figure 13 The interconversion of pairs of pentagonal and hexagonal rings through the thermally forbidden Stone–Wales transformation

due to its flattened shape and the consequent concentration of strain around its waist. Hückel theory, however, does predict the high instability of all isomers of C_{80}. In particular, I_h-C_{80} is a spherical molecule which has less strain per carbon atom than C_{60} but has not been isolated as the free fullerene (Figure 12). However, metal encapsulation appears to be able to stabilize formally open-shell fullerenes by the transfer of electrons from the metal to the cage, e.g. $C_{80}{}^{n-}$ in the endohedral fullerenes $M@C_{80}$ (Section 6.3).

The Stone–Wales (pyracyclene) transformation has been proposed as a mechanism for the interconversion of fullerene isomers through the interchange of pairs of pentagons and hexagons (Figure 13).[26] The rearrangement is a high-energy process which is thermally forbidden but photochemically allowed, and may therefore occur within the vicinity of a carbon arc.[27]

Restricted Stone–Wales isomerization (i.e. between IPR structures only) has been invoked to explain why relatively few isomers of the higher IPR fullerenes have been found:[13] three of the possible five for C_{78} have been reported, at least three out of nine for C_{82}, and two out of 24 for C_{84}. It is postulated that near the carbon arc those isomers which are interconvertable are annealed to the thermodynamically most stable one. At first sight the experimental facts appear to contradict this proposal since all nine of the C_{82} isomers can interconvert, yet at least three isomers have been shown to coexist.[28] It is possible, however, that if these three isomers are of similar energy then a statistical distribution of products would be expected, and this distribution would naturally be dependent upon the temperature at which the Stone–Wales interconversion ceases. As a consequence, whenever a particular fullerene is isolated the isomer distribution should be reproducible. Results consistent with this idea have indeed been reported for mixtures of the two Stone–Wales interconvertable C_{84} isomers prepared in different laboratories.[29]

3 SYNTHESIS AND PURIFICATION

Since the synthesis of macroscopic amounts of C_{60} was achieved in late 1990, several strategies for each stage of fullerene synthesis and purification have been developed.

3.1 Soot Generation

Fullerene-containing ‘soot’ can be prepared either directly from graphite (resistive heating/carbon arc, inductive heating, laser vaporization) or from hydrocarbons by controlled incomplete combustion. The latter two techniques are unsuitable for the bulk generation of soot: laser vaporization results in high fullerene yields but is not easily scaled up, whilst combustion methods are inefficient and the soot produced is contaminated with organic byproducts. The most widespread technique employed is graphite vaporization by resistive heating in an arc, and the yield of extractable fullerenes is typically 3–11%, though up to 44% has been reported.[30] This method produces ‘pure’ soot that contains C_{60} and C_{70} in the approximate ratio 85:15 along with traces (<1%) of the higher fullerenes, although optimization of the conditions for C_{70} production yields a ratio close to 50:50.[31] Vaporization by inductive heating (2700 °C) gives soot containing 8–12% extractable fullerenes and is reported to give slightly greater yields of the higher fullerenes.[32]

Soot containing small quantities of the endohedral metallofullerenes can be simply prepared by vaporizing graphite doped with a source of the appropriate metal, typically the metal oxide. The characterization of these materials is discussed in Section 6.3.

3.2 Fullerene Extraction and Purification

Soxhlet extraction of the soot with a suitable solvent yields crude fullerene mixtures. The nature of the solvent influences the rate of extraction and the efficiency with which the less soluble, higher fullerenes are extracted. For C_{60} and C_{70} the commonly used solvents are hexane, CH_2Cl_2, and $CHCl_3$, whereas for the larger fullerenes, CS_2, toluene, pyridine, and quinoline are used.[30]

Simple recrystallization of the crude fullerene extract can yield C_{60} of greater than 98% purity.[33] In order to remove all detectable traces of C_{70}, however, chromatographic techniques must be used and several efficient methods for the preparation of pure C_{60} and C_{70} have been published.[34–36] Small amounts of the higher fullerenes (C_{76}, C_{78}, C_{82}, C_{84}, C_{90}, etc.) must be separated and purified by time-consuming preparative HPLC.[12–15] Chromatographically purified fullerenes always contain traces of solvent impurities, although very high purity, solvent-free C_{60} and C_{70} can be obtained by repeated sublimation under high vacuum.

Although the fullerenes are very stable molecules in isolation, over time some degradation is observed both in the solid state and in solution. It is probable that light, combined with the presence of air, moisture, or trace impurities, is responsible (Section 6.2.3).

3.3 Toxicity

The short and long term toxicities of the fullerenes and related materials are unknown, and they should therefore be

handled with all suitable precautions. The soot generated from graphite vaporization is very light and fluffy, and contains varying amounts of nanofiber structures. Such materials should not be inhaled because fine particulates are known to be responsible for the crippling and ultimately fatal conditions of asbestosis, silicosis, and emphysema. Although no studies on the toxicity of C_{60} have been reported, it is known to be a potent sensitizer for singlet oxygen and should therefore be handled with caution.[37]

4 BEAM STUDIES

4.1 Fullerene Formation and Fragmentation

The fullerenes were first observed by mass spectrometric techniques: a carbon plasma produced by laser vaporization of graphite aggregating to large carbon clusters C_n upon cooling.[2] The relative gas phase mobilities of these carbon clusters have been rationalized in terms of their structure; the smaller clusters are believed to have chain or ring structures, whereas the larger clusters adopt the closed fullerene structure.[38] This latter assignment is consistent with previous observations that for the larger clusters ($n > 30$) only those with an even number of carbon atoms (a requirement of the closed fullerene structure) are long lived, of which C_{60} and C_{70} exhibit particular stability (Figure 2).[2] Under similar conditions, endohedral fullerenes are formed by the vaporization of graphite doped with a source of the chosen element.

Mass spectrometric study of the gas phase oligomerization of the polyalkyne cyclocarbons (annulynes or cyclocumulenes) C_{18}, C_{24}, and C_{30} shows the preferential formation of the fullerene ions $C_{60}{}^{+}$ and $C_{70}{}^{+}$; in particular, C_{30} dimerizes almost exclusively to produce $C_{60}{}^{+}$.[2] Interestingly, inspection of the C_{60} cage reveals that this dimerization can be achieved by multiple cycloadditions without the need for any C–C bond breaking in the original C_{30} rings.

Multiphoton fragmentation of the fullerenes proceeds with elimination of even carbon fragments C_n ($n = 2, 4, 6$, etc.).[2] $C_{60}{}^{+}$ and $C_{70}{}^{+}$ are the preferred fragmentation products of the larger fullerenes C_{2n} ($2n > 70$), which further indicates the special stability of these clusters. For the $C_{32}{}^{+}$ ion, fragmentation results in the formation of a range of smaller species and the cage structure is lost. The corresponding fragmentation of the endohedral fullerenes (Section 6.3) also proceeds by multiples of C_2 elimination, but now the radius of the encapsulated element sets a lower limit on the size of the cage, e.g. $[K@C_{44}]^{+}$ and $[Cs@C_{48}]^{+}$ are the smallest endohedral fullerene ions observed for these elements. This sudden cut-off in stability at a particular cage size correlates well with the size of the encapsulated element, and provides strong evidence for the endohedral structure of these species.

Fullerene coalescence has been observed in the hot dense vapors produced by laser desorption of a fullerene sample into an inert carrier gas.[39] A broad distribution of products is seen, with distinct maxima corresponding to multiples of the starting fullerene: $C_{118}{}^{+}$ and $C_{178}{}^{+}$ for pure C_{60}, and $C_{138}{}^{+}$ for pure C_{70}. Coalescence is not observed in the absence of the carrier gas, indicating that the hot vapor must be constrained in order for reaction to take place. Under these conditions, not only do the initially formed $C_{120}{}^{+}$ and $C_{180}{}^{+}$ molecules fragment by loss of multiples of C_2, but aggregation to $C_{120+2n}{}^{+}$ and $C_{180+2n}{}^{+}$ also occurs.

4.2 Beam Reactions

C_{60} reacts with electrophiles E^{+} (E = H, Me, Et, *t*-Bu) in the gas phase to give $[C_{60}E]^{+}$.[37] Proton transfer experiments have shown that the proton affinity of the C_{60} molecule lies in the range 204–207 kcal mol^{-1}, and the relatively high stability of the $[C_{60}H]^{+}$ species is demonstrated by the observation that in single collision experiments of the *t*-Bu^{+} adduct $[C_{60}\cdots H\cdots C_4H_8]^{+}$ with Xe, fragmentation predominantly gives $[C_{60}H]^{+}$ and C_4H_8. Collision of C_{60} with C^{+} ions in the gas phase over the energy range 2–78 eV results in the formation of $C_{61}{}^{+}$, which decays to $C_{60}{}^{+}$ and carbon atoms.[40] Reaction with $^{13}C^{+}$ produces ^{13}C enrichment of the $C_{60}{}^{+}$, clearly demonstrating that atom scrambling occurs in $[^{12}C_{60}{}^{13}C]^{+}$. Fragmentation to $C_{58}{}^{+}$, $C_{56}{}^{+}$, etc. is only observed for collision energies greater than 20 eV.

Adduct formation has been observed for the reaction of the fullerene dications $C_{60}{}^{2+}$ and $C_{70}{}^{2+}$ with neutral unsaturated hydrocarbons and amines, e.g. C_2H_2 and NH_3 produce $[C_{60}\cdot C_2H_2]^{2+}$ and $[C_{60}\cdot NH_3]^{2+}$ respectively, although for many systems charge transfer is a significant competing reaction.[41] Under different conditions the reaction of $C_{60}{}^{2+}$ with NH_3 is reported to give the adduct $[C_{60}NH_2]^{+}$,[42] in which the NH_2 fragment is thought to have added across a six–six ring fusion, giving the protonated aziridine analog of the C_{60} epoxide $C_{60}O$ (Section 6.2.3). Depending upon the NH_3 pressure, different amounts of the adducts $[C_{60}NH_2(NH_3)_n]^{+}$ ($n = 1$–3) are also observed. The NH_3 moieties are more weakly associated than the NH_2 group and are believed to be bound to the NH_2 group through hydrogen bonding.

Exohedral metal complexes $[C_{60}M]^{+}$ are formed by the reaction of C_{60} with naked M^{+} ions (M = Fe, Co, Ni, Cu, Rh, La).[37] For Ni^{+} the bis-fullerene complex $[(C_{60})_2Ni]^{+}$ was also observed. In contrast to the endohedral fullerenes, excitation of these complexes results in facile metal elimination with no associated cage fragmentation.

Collision-induced fragmentation of $C_{60}{}^{n+}$ ($n = 1$–3) with the noble gases helium and neon at high energy (typically 6 keV) results in the formation of encapsulated products, e.g. $[He@C_{60}]^{n+}$.[37,43] The retention of the gas atoms in the fragmentation products $[He@C_{2m}]^{n+}$ ($2m = 58, 56, 54$, etc.) is consistent with endohedral complex formulation. Furthermore, $[He@C_{60}]^{+}$ has been neutralized in the gas phase to produce $He@C_{60}$ (lifetime >90 μs), which was then successfully

re-ionized. The observed stability of neutral He@C_{60} is compelling evidence for its proposed endohedral structure.

5 PHYSICAL AND SPECTROSCOPIC PROPERTIES

The fullerenes have been extensively studied by mass spectrometric techniques (Sections 2 and 4) and stable peaks for the cluster ions C_{2n}^+ ($2n \geq 32$), as well as evidence for species down to C_{20}^+, have been observed. Those fullerenes which are sufficiently stable and/or abundant to be isolated in macroscopic amounts have been investigated further using a range of physical and spectroscopic techniques.

5.1 General Properties

As C_{60} is the most readily produced fullerene, it has been the most intensively investigated. It is an approximately spherical molecule with a center-to-carbon distance of ~3.5 Å and a van der Waals radius of ~5.0 Å.[44,45] The cage contains two types of C–C bond: 30 short six–six ring fusions (~1.39 Å) and 60 long five–six ring fusions (~1.45 Å), and this bond length alternation is consistent with the localized polyalkene description of C_{60} (Section 2.3). The structure of the C_{70} molecule is more complex with eight different bond types, ranging in length from 1.37 to 1.48 Å.[46] Some general physical properties of C_{60} are listed in Table 1.

5.2 X-ray and Neutron Diffraction

Diffraction studies (*see* ***Diffraction Methods in Inorganic Chemistry***) show pure, sublimed C_{60} to be crystalline with the near spherical molecules arranged in a face-centered cubic (fcc) array, with a center-to-center *inter*-C_{60} distance of 10.02 Å.[47,49] The presence of traces of solvent impurities appears to stabilize an hexagonal close-packed (hcp) arrangement (*see Close Packing*). In the fcc phase at room temperature, each C_{60} molecule rotates essentially isotropically and has a very short rotational correlation time ($\tau \approx 9$ ps), faster even than in tetrachloroethane solution ($\tau \approx 15$ ps). A phase transition from fcc ($Fm\bar{3}m$) to a simple cubic structure ($Pa\bar{3}$) occurs at 260 K. Neutron diffraction and ^{13}C NMR studies of this phase reveal that the C_{60} molecules appear to be jumping between symmetry-equivalent orientations. Below 90 K this motion is frozen, yielding a partly disordered structure in which the main *inter*-C_{60} interaction is between a relatively electron rich six–six ring fusion (double bond) of one molecule and an electron deficient five-membered ring of an adjacent one (Figure 14).[50]

Table 1 General physical properties of C_{60}

Density[47]	1.65 g cm^{-3}

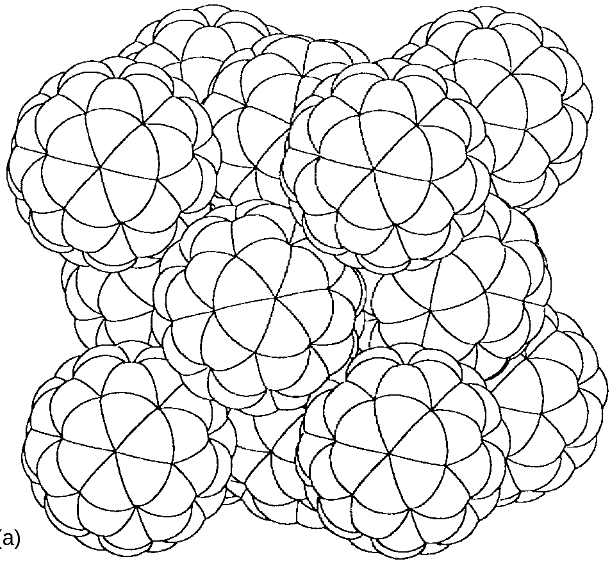
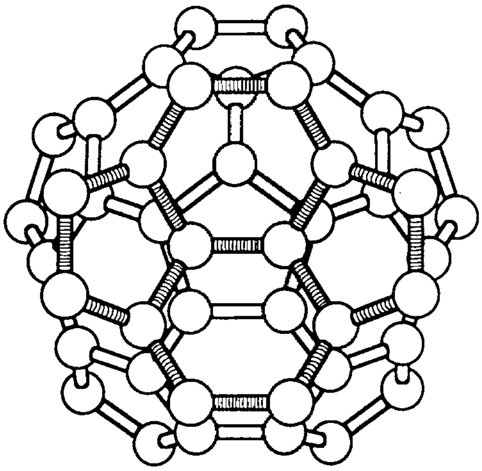
Benzene	1.44 g L^{-1}
CCl_4	0.45 g L^{-1}
Hexane	0.04 g L^{-1}



(a)



(b)

Figure 14 Face-centered cubic (fcc) packing of crystalline C_{60}. (a) At room temperature the C_{60} molecules rotate essentially isotropically, but below 260 K a phase transition occurs from fcc to simple cubic, in which the C_{60} molecules jump between symmetry equivalent positions. (b) At 5 K all rotation is frozen and the resulting *inter*-C_{60} contact is between a six–six ring fusion and a pentagonal face. (Reprinted with permission of Macmillan from W.I.F. David *et al.*[50])

Localized fcc packing is also found in the insoluble C_{60} films formed on a water surface by controlled evaporation of C_{60} solutions.[51,52] These films consist of rigid close-packed layers of fullerene molecules with a reported thickness of 4–8 molecules.

For pure C_{70} a fcc phase and two different hcp phases have been identified and upon annealing at 300 °C in vacuo the two hcp phases are progressively transformed to the pure fcc phase.[53]

5.3 ^{13}C NMR Spectroscopy

For each of the first two isolable fullerenes (C_{60} and C_{70}), only one IPR isomer is possible; however, the next fullerene (C_{76}) has two possible IPR structures, but only one has been observed. For C_{78} and higher fullerenes, several isomers are found to coexist. In the cases where sufficient material has been isolated, the composition of these isomer mixtures and the molecular symmetries of their components have been investigated by ^{13}C NMR spectroscopy.

The study of the fullerenes by ^{13}C NMR spectroscopy is not straightforward. ^{13}C has a low natural isotopic abundance (1.11%) and a low relative receptivity. In addition, the carbon atoms in fullerenes have relatively long relaxation times and spectra for the higher, less symmetric fullerenes can only be obtained within a reasonable time by using paramagnetic relaxation reagents, typically $Cr(acac)_3$.

The carbon atoms in C_{60} are equivalent, and as expected only a single line is observed: δ142.7 ppm (C_6D_6). C_{70} has D_{5h} symmetry and as there are five distinct carbon atom environments, a five-line spectrum is observed: δ150.1, 147.5, 146.8, 144.8, and 130.3 ppm (C_6D_6) of intensity ratio 10:20:10:20:10 (Figure 15).[5] The initial assignments based on chemical intuition have been subsequently confirmed by 2D ^{13}C NMR.[2] The upfield line (δ130.9 ppm) corresponds to the 10 'graphitic' atoms around the waist (type e), that lie at the intersection of three six-membered rings.

A similar atom type partition is found for C_{76}.[12] This molecule has D_2 symmetry and the expected 19-line spectrum is observed. The four upfield lines ($\delta < 137.1$ ppm) are assigned to the 16 (4 × 4 atoms) 'graphitic' carbons, whereas the remaining 60 carbons (15 × 4 atoms, $\delta > 141.3$ ppm) make up the 12 five-membered rings. Some other higher fullerenes have been successfully characterized as mixtures of isomers. Thus for C_{78}, five isomers are possible, but only three have been characterized by ^{13}C NMR: C_{2v} (21 lines), C'_{2v} (21 lines), and D_3 (13 lines). For C_{82}, nine isomers are possible and three (possibly with traces of a fourth) have been seen, at least one C_2 (41 lines), C_{2v} (17 lines), and C_{3v} (12 lines). For C_{84}, 24 isomers are possible, but only two have been seen, D_2 (21 lines) and D_{2d} (10 lines).[13–15]

5.4 Vibrational Spectroscopy

For pure C_{60} all four allowed IR transitions are observed as characteristic, sharp bands: 1429, 1183, 577, and 528 cm^{-1}

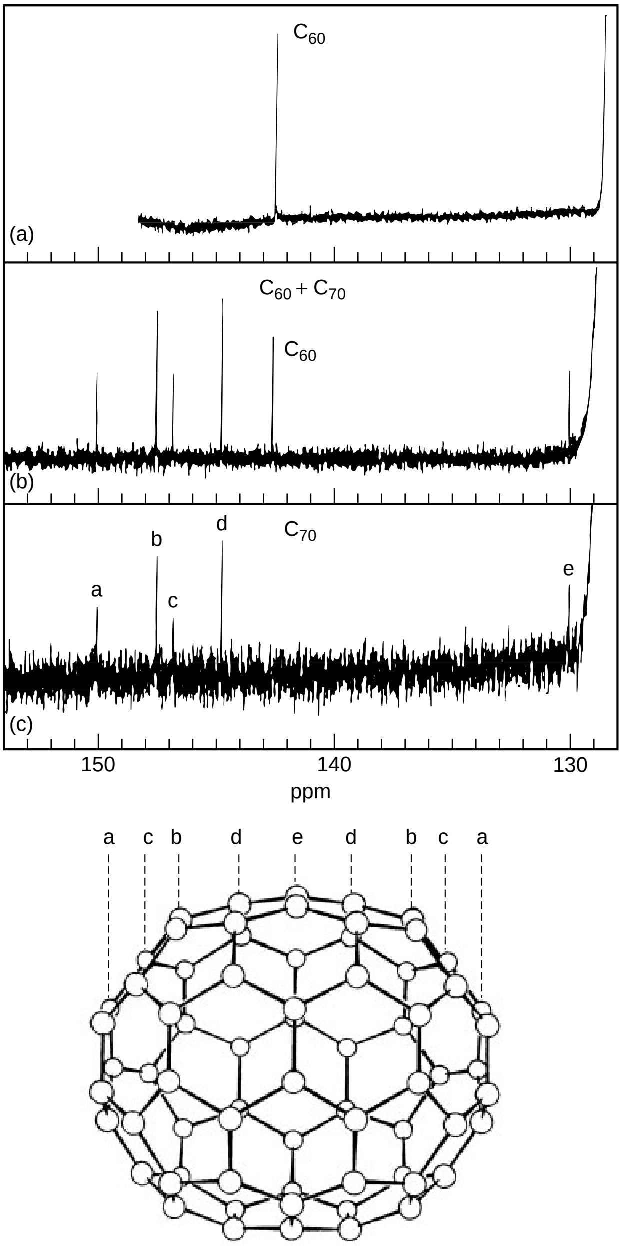


Figure 15 ^{13}C NMR spectra and assignments of C_{60} and C_{70}. (Ref. 5. Reproduced by permission of The Royal Society of Chemistry)

(Figure 16).[54] Four similar IR bands are also observed in an emission spectrum from hot C_{60} vapor.[2] Furthermore, all 10 allowed bands are seen in the Raman spectrum: 1573, 1467, 1422, 1250, 1099, 772, 711, 495, 429, and 272 cm^{-1}. Pure $^{13}C_{60}$ has also been prepared and the IR bands are shifted by the predicted amount to 1375, 1138, 554, and 506 cm^{-1}.[55]

The IR (Figure 16) and Raman spectra of pure C_{70},[2,54] and the 1450–500 cm^{-1} region of the solution IR spectrum (CS_2) of C_{76} have also been reported.[12] They are more

complex than the C_{60} spectra due to the lower symmetry of these molecules.

5.5 UV/Visible Spectroscopy and Photophysical Properties

A characteristic feature of the fullerenes is that they form highly colored solutions: C_{60} (magenta), C_{70} (red), C_{76} (yellow/green), C_{2v}-C_{78} (chestnut brown), and D_3-C_{78} (golden yellow). The optical spectra in solution are complex (Figure 17),[56] and the higher fullerenes give spectra that are particularly rich in structure, with many overlapping bands between 400 and 1000 nm.[12,13]

The photophysical properties of C_{60} and C_{70} have been reported.[57] C_{60} does not display any detectable fluorescence or phosphorescence, but is an efficient producer of singlet oxygen ($^1O_2$) with a quantum yield of unity (532 nm). The properties of C_{70} are similar, except that a weak fluorescence is now apparent and the quantum yield of $^1O_2$ is slightly less than unity. These differences are explained by the lower symmetry of the C_{70} molecule relaxing the forbidden nature of some of the absorption and emission processes. In addition, the fluorescence, phosphorescence, and nonlinear optical properties of C_{60} and C_{70} solutions containing the charge-transfer donor *N*,*N*-diethylaniline have been reported.[58,59]

Solutions of C_{60} and C_{70} display optical limiting properties of comparable efficiency with materials used at present.[60] For pulsed light (532 nm) of low intensity these solutions obey Beer's law, but as the intensity increases the transmitted fluence becomes fixed at a maximum value. This behavior is a consequence of the long lifetimes (~40 µs) and greater absorption cross-sections of the photoexcited triplet states of C_{60} and C_{70}.

Table 2 Values for the redox potentials (V) of the fullerenes C_{60}, C_{70}, C_{76}, and C_{84} in solution

5.6 Electrochemistry

The electrochemical properties of C_{60}, C_{70}, C_{76}, and C_{84} in solution have been studied (Table 2), and all show some dependence on the nature of the solvent (*see* ***Electrochemistry: Applications in Inorganic Chemistry*** and *Redox Properties & Processes*). C_{60} and C_{70} display very similar behavior: to date, six separate, reversible, one-electron reductions to $C_{60}{}^{6-}$ and $C_{70}{}^{6-}$ respectively have been observed (Figure 18), whereas oxidation is irreversible.[61,62] For both molecules the first reduction occurs at only ~ -1.0 V (versus Fc/Fc^+), highlighting their electron-accepting nature. C_{76} is especially interesting as it displays both donor and acceptor behavior; in THF a single reversible oxidation is observed at -0.57 V (versus Fc/Fc^+) along with four reversible reduction waves.[63] C_{84} has been studied as a mixture of isomers and at least four reversible one-electron reductions, but no oxidations, are observed.[64]

The UV/visible/NIR spectra of the electrochemically generated anions $C_{60}{}^{-}$, $C_{60}{}^{2-}$, and $C_{60}{}^{3-}$ have been reported and the transitions assigned on the basis of theoretical calculations.[65] The ESR spectra of these ions (frozen solution) suggest singlet, triplet, and singlet magnetic ground states, respectively. There was no evidence for the quartet ($S = 3/2$) state of $C_{60}{}^{3-}$.[66] Pure C_{60} and C_{60}/C_{70} mixtures have also been chemically reduced by lithium metal in THF to yield red/brown diamagnetic solutions, postulated to contain predominantly $C_{60}{}^{6-}$ and $C_{70}{}^{6-}$.[37] The ^{13}C NMR spectra (approximate shifts relative to the neutral molecules in parentheses) consist of a single line at δ156.7 (+14.0) ppm for $C_{60}{}^{6-}$, and five lines at δ158.3 (+8.2), 152.3 (+4.8), 149.6 (+2.8), 137.9 (−6.9), and 133.7 (+3.4) ppm for $C_{70}{}^{6-}$. The strong deshielding of the carbon atoms in $C_{60}{}^{6-}$ is remarkable, as carbanions generally exhibit shielding relative to the neutral molecule. This phenomenon is explained by the particular balance of the diamagnetic and paramagnetic contributions to the ^{13}C chemical shifts found in fullerenes and their anions. A small overall deshielding effect is also found for $C_{70}{}^{6-}$; however, one of the carbon atom environments is strongly shielded (type d, Figure 15).

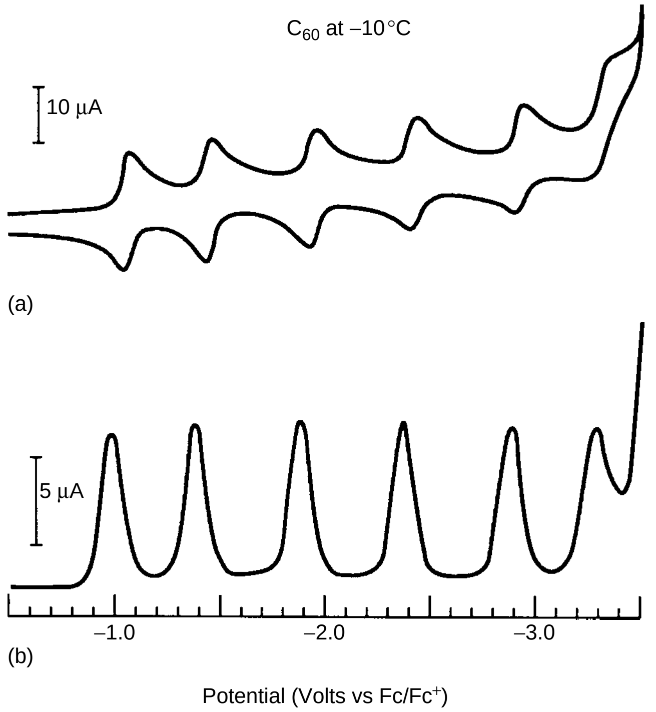

Figure 18 Under the appropriate experimental conditions (PhMe/MeCN, −10 °C), C_{60} undergoes six reversible one-electron reductions: (a) cyclic voltammetry, (b) differential pulse voltammetry. C_{70} displays similar properties. (Reprinted with permission from Ref. 61. © 1992 American Chemical Society)

6 CHEMISTRY

Although macroscopic quantities of the fullerenes have only been available since late 1990, huge advances have been made in their chemistry. Fullerene chemistry may be constructively divided into three broad areas: materials containing discrete fullerene molecules, chemical functionalization of the fullerene cage, and endohedral fullerenes.

6.1 Fullerene Materials

6.1.1 Charge Transfer Salts

Due to its electron acceptor properties (Section 5.6), C_{60} reacts with strong reducing agents (D) to yield salts of general formula $[D]_n{}^+[C_{60}]^{n-}$.[67] With the alkali metals (Group 1), a broad range of compounds has been reported, e.g. $Li_{12}C_{60}$, $Na_{11}C_{60}$, A_6C_{60} (A = K, Rb, Cs), K_4C_{60}, and A_3C_{60} ($A_3 = K_3$, Rb_3, $RbCs_2$).

The compound $Li_{12}C_{60}$ is prepared by the electrochemical intercalation of lithium into solid C_{60} (*see* ***Intercalation Chemistry***).[68] Both the t_{1u} and t_{1g} levels of the C_{60} molecule are completely filled (Figure 11) and theoretical studies indicate that this anion would be stable in the solid state with one Li^+ ion located above each pentagonal face.[69] During the course of its preparation the discrete phases Li_nC_{60} ($n = 0.5$, 2, 3, 4) are also apparent, although their structures are unknown. Intercalation of sodium atoms into C_{60} gives the range of compounds Na_nC_{60} ($2 \le n \le 11$), for which the fcc structure of pure C_{60} is maintained throughout.[70] The highest doping level is proposed to correspond to $Na_{11}C_{60}$, in which each tetrahedral interstice contains a single Na^+ ion and each octahedral interstice contains a body-centered cluster of nine Na^+ ions.

With the heavier alkali metals (K, Rb, and Cs), direct intercalation stops at A_6C_{60} in which only the t_{1u} level is filled.[47,71] The structure of K_6C_{60} at room temperature has

been shown to be body-centered cubic (bcc) with the $C_{60}{}^{6-}$ molecules frozen in one orientation and the K^+ ions filling distorted tetrahedral interstices. The A_3C_{60} compounds are especially interesting as they become superconducting at low temperature, with transition temperatures (T_c) of 19 K for K_3C_{60}, 28 K for Rb_3C_{60}, and 33 K for $RbCs_2C_{60}$. The fcc structure of C_{60} is retained (Figure 14), with the A^+ ions filling all the tetrahedral and octahedral interstices.[72] These compounds belong to the third of the three known groups of superconductors (metal alloys, metal oxides/cuprates, ‘organic’ superconductors). They have by far the highest T_c values reported for ‘organic’ superconductors to date, and are only surpassed overall by the cuprate systems (*see* ***Superconductivity***). For the heavier alkali metals the compounds A_nC_{60} with lower doping levels ($n < 3$) have not been observed, and are believed to disproportionate to C_{60} and A_3C_{60}.

C_{60} has also been doped with the alkaline earth metals calcium, strontium, and barium (Group 2).[73] Two discrete phases have been characterized: Ca_5C_{60} is simple cubic with the same cell parameters as pure C_{60}, and Ba_6C_{60} is bcc. These compounds are reported to have superconducting transition temperatures (T_c) of 8.4 and 7 K, respectively.[74,75]

Salts of $C_{60}{}^{n-}$ with large cations have also been prepared.[37] Electroreduction of C_{60} in the presence of $[Ph_4P^+][Cl^-]$ produces crystals of the mixed salt $[Ph_4P^+]_3[C_{60}{}^-][Cl^-]_2$.[76] Direct reaction of C_{60} with the neutral, one-electron reductants (**1**), (**2**), and (**3**) yields the salts $[(\mathbf{1})^+][C_{60}{}^-][THF]_3$, $[(\mathbf{2})]_n[C_{60}]$ ($n \approx 0.87$), and $[(\mathbf{3})^+]_n[C_{60}{}^{n-}]$ ($n = 1$–3).[37,77] In the first compound the electron transfer is reversible in solution and depends upon the solvent used: toluene favors the neutral molecules, whereas in THF the oxidized chromium(III) porphyrin is stabilized through solvation and the compound is ionic.

(**3**)

6.1.2 Fullerene Complexation

C_{60} forms complexes with a variety of molecules. In the solid state the intermolecular interactions in these materials stabilize lattice structures which, because they are novel, are of potentially great interest. This is particularly the case if the resulting systems exhibit the properties associated with partial or complete electron transfer (Section 6.1.1).

Classical charge transfer complexes are formed with weak electron donors. In these cases an electron is not formally transferred from the donor to the C_{60}; however, a charge transfer band is often observed in the solid state UV/visible spectrum. Several compounds with the sulfur- or tellurium-based organic donors (**4**), (**5**), and (**6**) have been prepared.[44,78,79] In $[C_{60}][(\mathbf{4})]_2$ the normally planar molecule (**4**) has curled around the C_{60} molecule to maximize the intermolecular interaction (Figure 20) and a charge transfer band is observed at ~750 nm (KBr pellet). The C_{60} molecules are arranged in parallel double-columnar stacks (Figure 19(b)) separated from one another by the molecules of (**4**), and the center–center *inter*-C_{60} distances in these stacks are 9.92 Å. In $[C_{60}]$[ferrocene]$_2$ the C_{60} molecules are arranged in close-packed layers (Figure 19(c)) separated by layers of *Ferrocene* (**7**) molecules (Figure 21).[45] The three different, in-plane, center–center, *inter*-C_{60} distances are 9.90, 10.37, and 10.39 Å, with a closest *inter*-C_{60} distance between parallel layers of 11.34 Å. The 1D structure of $[C_{60}][(\mathbf{4})]_2$ and the 2D sandwich structure of $[C_{60}]$[ferrocene]$_2$ may confer interesting anisotropic properties on these and related materials, e.g. electrical conduction and/or photophysical properties.

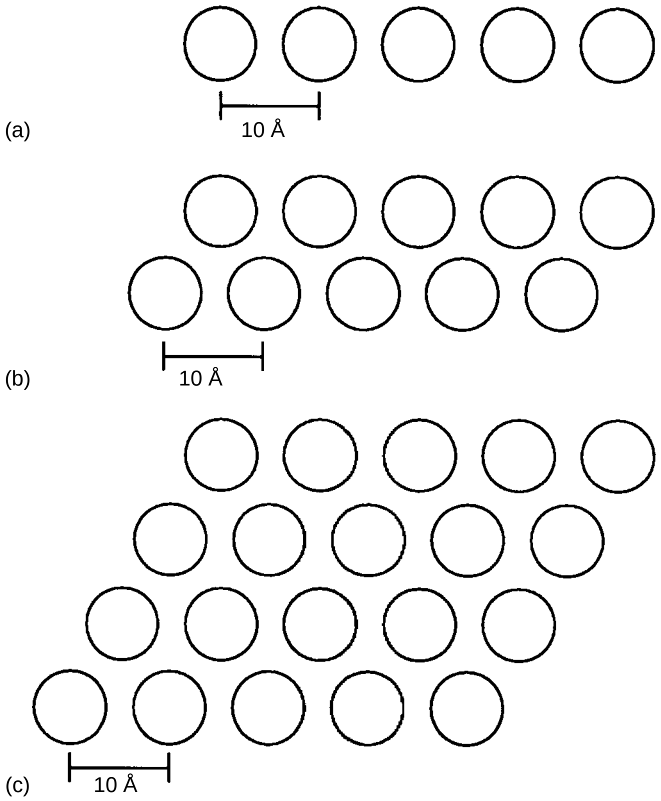

Figure 19 Packing arrangements of C_{60} molecules in composite materials in which the *inter*-C_{60} contacts are restricted to 1- or 2-dimensions: (a) single columnar stacks, (b) double columnar stacks, (c) close-packed layers

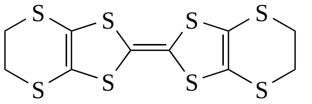
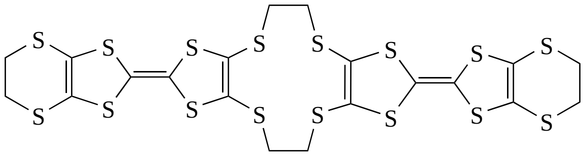
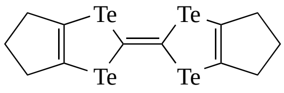
In $[C_{60}]$[1,4-dihydroquinone]$_3$ the C_{60} molecules are trapped in a hydrogen-bonded super-polonium network of 1,4-dihydroquinone molecules.[37] Unlike the (**4**) and



(**4**)



(**5**)



(**6**)

$(\eta^5\text{-}C_5H_5)_2Fe^{II}$

(**7**)

ferrocene complexes, the C_{60} molecules in this material are orientationally disordered. Each C_{60} has six nearest neighbors at 10.44 Å and these *inter*-C_{60} contacts form a 3D network. The solvated C_{60} compounds $[C_{60}][C_6H_6]_4$ and $[C_{60}][CH_2I_2][C_6H_6]$,[80–82] and the intercalate $[C_{60}][I_2]_2$, have also been structurally characterized.[83]

The structure of one C_{70}-containing material has been determined. In $[C_{70}][S_8]_6$ the orientationally ordered C_{70} molecules are arranged in close-packed layers separated by the S_8 molecules.[46]

C_{60} complexes with γ-cyclodextrin to form the encapsulated water soluble system $[C_{60}][\gamma\text{-cyclodextrin}]_2$ (*see Cyclodextrins*).[37] In this compound the C_{60} is weakly bound and readily extracted by shaking the complex with a good solvent for C_{60}, e.g. toluene. C_{70} does not form an analogous compound, presumably because it is larger and nonspherical.

6.2 Fullerene Derivatives

Although the IPR fullerenes are really quite stable molecules, they are reactive and display a rich chemistry, and research in this field is proving to be an endeavor with many inherent challenges.[37,67] To date only C_{60}, and to a lesser extent C_{70}, can be prepared in sufficient quantities for their chemistry to be thoroughly studied. Since the fullerenes are closed unsaturated cages there are no functional groups which can be substituted by others, and therefore the chemistry is limited to addition to the cage by the removal of unsaturation (perhaps followed by subsequent substitution), and/or to the breaking of bonds within the cage. With formally 30 double bonds and 60 carbon atoms available for addition, C_{60} may potentially yield a huge number of products of different composition and/or structure upon reaction with any particular reagent, e.g. $C_{60}X_2$ has 23 possible isomers! It is therefore of great importance

to understand the principles through which the synthesis of fullerene derivatives may be controlled in order to maximize the probability of forming a single major product. A less favorable alternative is the development of techniques for the efficient separation of these complex product mixtures.

Several general features of C_{60} chemistry have emerged. Firstly, the cage is susceptible to nucleophilic attack, with the degree of addition often difficult to control. Secondly, reactivity tends to be associated with the six–six ring fusions (formal double bonds). Both observations are consistent with the accepted description of C_{60} as a localized, electron-deficient polyalkene (Section 2.3). Furthermore, it is generally observed that addition at only one or two carbon atoms of the C_{60} cage does not greatly perturb its redox and spectroscopic (IR, UV/vis) properties. With multiple additions, however, these characteristic spectroscopic fingerprints are rapidly lost.

6.2.1 *Hydrogenation*

The smallest perhydrogenated fullerene known is dodecahedrane ($C_{20}H_{20}$), formally derived from the smallest possible (but unknown) fullerene C_{20} (Figure 4), which comprises just 12 pentagonal faces. The $C_{20}H_{20}$ molecule was first prepared in 1983 by an elegant multistep synthesis and has an interesting organic chemistry, but will not be discussed further here.

The Birch reduction (Li metal, liquid NH_3) of C_{60} yields a material that appears to contain hydrogenated C_{60} (perhaps mixed with aminated derivatives).[37] Chemical oxidation results in reconversion into C_{60}, indicating that the cage structure had remained intact. The mass spectrum shows signals for $C_{60}H_{18}$ and $C_{60}H_{36}$, although it is not known whether these species are present in the reaction mixture or are formed during mass spectrometric sampling. The quenching of $C_{60}{}^{6-}$ solutions with water yields hydrogenated products of unknown composition which are sensitive to reoxidation, and in this case regenerated C_{60} is the sole product observed by mass spectrometric techniques.[37] The reaction of C_{60} with $Li[BHEt_3]$ is reported to give the weak base $[HC_{60}]^-$, isolated as the solvated salt $Li[HC_{60}][H_2O]_{6-9}$.[84]

The relative stabilities of selected isomers of $C_{60}H_n$ ($n = 2$, 36, 60) have been calculated; in particular, the hypothetical molecule $C_{60}H_{60}$, in which all the hydrogen atoms are *exo* to the cage, is expected to be highly strained.[37,85]

6.2.2 *Halogenation*

The preferred pattern for addition of X_2 (X = H, F, Cl, Br, I) to C_{60} has been calculated to be 1,9- for small groups and 1,7- for bulky groups (Figure 22).[85] Fluorine atoms are small enough for 1,9-addition to be favored and C_{60} does indeed yield highly fluorinated derivatives upon careful reaction with F_2 gas.[86] Exhaustive fluorination of C_{60} yields a product which exhibits a single ^{19}F NMR line.[87] This result indicates the production of a highly fluorinated species in which all the fluorines appear equivalent. $C_{60}F_{60}$ is a possible structure for this species but is expected to be highly strained, and the formation of another symmetric, less highly substituted (or fluxional) derivative is also consistent with the experimental observations. The potential use of highly fluorinated fullerenes as lubricants is unfortunately prevented because, although they are thermally very stable molecules, they are reactive towards even weakly nucleophilic reagents.[88]

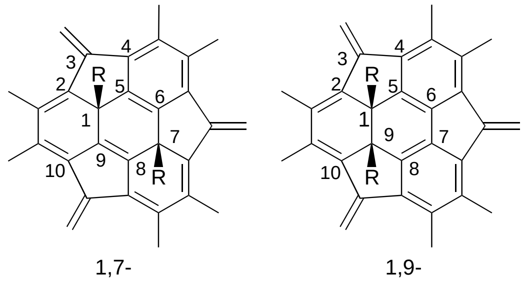

Figure 22 Of the 23 possible isomers of $C_{60}R_2$, the 1,7- and 1,9-addition products are calculated to be of lowest energy. Usually only one of these isomers is observed experimentally, depending upon the size of R

C_{60} reacts with Cl_2 gas at 250 °C to yield a material of average composition $C_{60}Cl_{24}$, although only C_{60} can be detected by mass spectrometry.[37] However, the chlorinated product can be converted into $C_{60}(OMe)_n$ by refluxing with methanol/KOH, and this material gives mass peaks corresponding to the more robust polymethoxylated species ($n \leq 26$). C_{60} also reacts with liquid Cl_2 at its boiling point (−35 °C) to yield a compound of average composition $C_{60}Cl_{12}$.[89] C_{60} can be recovered in >50% yield from this material by dechlorination with PPh_3 at room temperature. Alternatively, any of the chlorinated derivatives can be reconverted into C_{60} upon heating to 300–400 °C in vacuo.

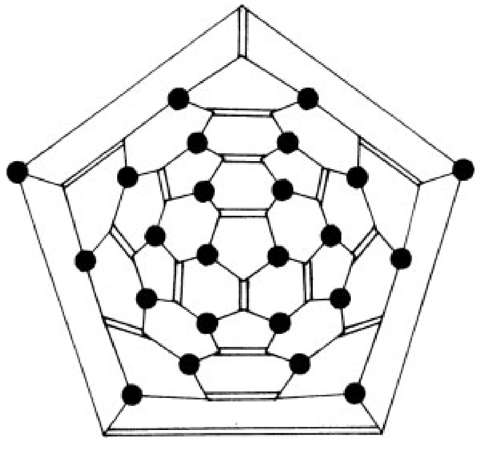

Figure 23 Schlegel diagram of the bromine (filled circles) addition pattern for $C_{60}Br_{24}$

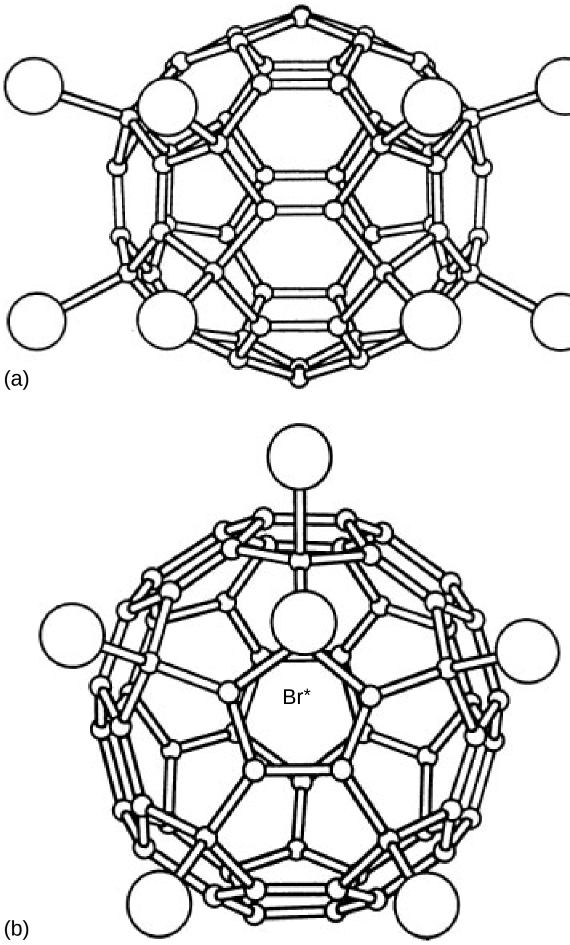

Figure 24 Molecular structures of partly brominated C_{60} derivatives: (a) $C_{60}Br_8$ and (b) $C_{60}Br_6$. (Reprinted with permission of Macmillan from P.R. Birkett *et al*.[91])

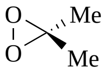
C_{60} reacts with liquid Br_2 to yield $C_{60}Br_{24}$ (Figure 23), in which all 24 bromine atoms are equivalent.[90] It is noteworthy that 24 is the maximum number of groups that can be arranged on C_{60} without resorting to the sterically unfavored 1,9-addition (Figure 22). The use of a cosolvent for the bromination results in the formation of partly brominated products: $C_{60}Br_8$ from CS_2, and $C_{60}Br_6$ from C_6H_6 or CCl_4 (Figure 24).[91] In both cases the bromine atoms are gregarious, forming localized aggregates on the cage, rather than being dispersed. In $C_{60}Br_8$ the structure corresponds to a portion of the $C_{60}Br_{24}$ molecule, whereas $C_{60}Br_6$ contains one unfavorable eclipsing interaction. This latter structure may arise by successive 1,7-additions to form the stable cyclopentadienyl radical $[C_{60}Br_5]^\bullet$, which is trapped by addition of the central bromine atom (Br*). All the brominated derivatives may be reconverted into C_{60} by heating to 100–150 °C in vacuo.

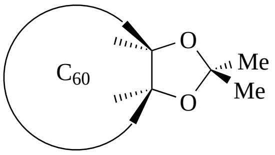
The trend to weaker C_{60}–halogen bonds continues with I_2, and indeed no derivative of C_{60} with iodine atoms covalently bound to the cage has been reported to date. The only characterized iodine-containing compounds are the intercalates $[C_{60}][CH_2I_2][C_6H_6]$ and $[C_{60}][I_2]_2$ (Section 6.1.2).

6.2.3 Heteroatom Derivatives

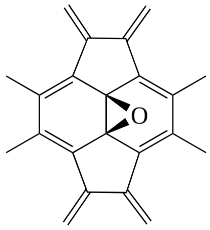
The fullerene oxides $C_{60}O$ and $C_{70}O$ are observed as minor components in fullerene-containing soot, although it is reported that $C_{60}O$ decomposes to C_{60} during the separation process.[92] Other higher oxides $C_{60}O_n$ ($n = 2$–5) and $C_{70}O_2$ have been prepared by electrochemical or photolytic oxidation and characterized by mass spectrometry. The reaction of thin C_{60} films with singlet oxygen ($^1O_2$) to yield $C_{60}O_2$ and $C_{60}O_4$ has been studied by IR spectroscopy.[93] The observation of bands assignable to ketonic C=O groups indicates that some C–C bond cleavage (cage opening) has occurred in these species. Of these fullerene oxides, only $C_{60}O$ has been isolated as a pure compound in macroscopic amounts. It can be prepared from C_{60} either by photooxygenation, or by reaction with dimethyldioxirane (**8**).[92,94] In the latter reaction, unreacted C_{60} is the major product but the dioxolane derivative (**9**), in which (**8**) has added across a six–six ring fusion, is a significant byproduct and has been shown not to be an intermediate in the formation of $C_{60}O$. The spectroscopic properties of $C_{60}O$ indicate that the oxygen atom has added at a six–six ring junction to give the epoxide structure (**10**), and not the isomeric opened 1,9-oxido[10]annulene structure (**11**).



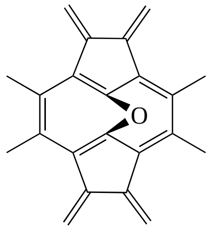
(**8**)



(**9**)



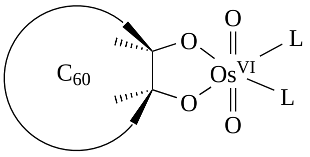
(**10**)



(**11**)

Osmylation of C_{60} with OsO_4, in the presence of 4-*t*-butylpyridine (L), yields the osmyl ester $C_{60}[OsO_4L_2]$ (**12**), the first structurally characterized C_{60} derivative.[67,95] The OsO_4 adds across a six–six ring junction, in a similar manner to the dioxolane derivative (**9**), and the two sp^3 hybridized carbon atoms are moved away from the center of the cage: center-to-C(sp^3) distances, 3.80 Å; average center-to-C(sp^2) distance,

3.55 Å. The bis-osmyl ester $C_{60}[OsO_4L_2]_2$ has been prepared as a mixture of five isomers and probable structures for all five compounds have been deduced from ^1H and ^{13}C NMR studies of the separated components.[96]



(**12**)

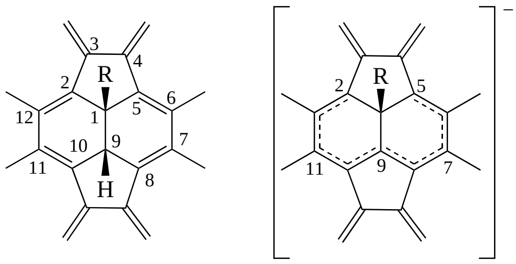
Reaction of C_{60} with $[NO][BF_4]$ in the presence of aryl carboxylic acids ($ArCO_2H$) in H_2O yields a mixture of $C_{60}(O_2CAr)_x(OH)_y$ isomers,[97] which were warmed with aqueous NaOH to yield the water-soluble polyhydroxylated derivatives $C_{60}(OH)_n$ ($n \leq 20$). Similar products ($n \leq 15$) have been prepared by the direct reaction of C_{60} with a mixture of concentrated nitric and sulfuric acids.[98] The polymethoxylated derivatives $C_{60}(OMe)_n$ ($n \leq 26$) have been prepared from polychlorinated C_{60} (Section 6.2.2).

C_{60} is attacked by primary and secondary amines to yield derivatives with the general formula $C_{60}H_n(NR^1R^2)_n$ where n depends on the nature of the amine, e.g. $n \leq 12$ for n-propylamine and $n \leq 6$ for morpholine.[37,84] ESR spectroscopy shows that the reaction proceeds by single-electron transfer (SET), followed by covalent bond formation and hydrogen transfer. The hydrogens have been shown to exchange rapidly with a source of D^+ (MeOD) and comparison of the IR spectra of the deuterated and nondeuterated secondary amine derivatives indicates that the hydrogens are bound to carbon atoms of the C_{60} cage rather than to the amine nitrogens.

6.2.4 *Alkyl and Aryl Derivatives*

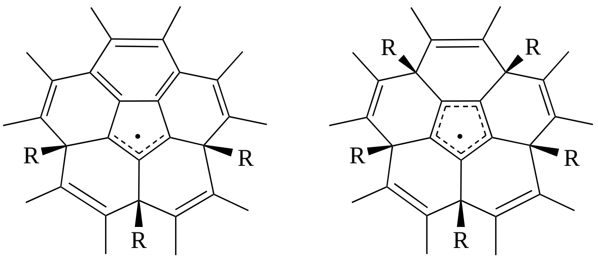
Functionalization of C_{60} through C–C bond formation has been achieved by a variety of methods: nucleophilic addition of carbanions, quenching of C_{60} anions with alkyl halides, Friedel–Crafts arylation, radical addition, and cycloadditions.

C_{60} reacts with an excess of Grignard (RMgBr) (*see Grignard Reagents*) or organolithium (RLi) reagents to produce solutions thought to contain anions of general formula $[C_{60}R_n]^{m-}$.[84] These anions may be quenched with an excess of MeI to yield product mixtures of average composition $C_{60}R_nMe_m$, where n and m depend upon the nature of R and the conditions used. The mass spectrum of $C_{60}Me_n$, prepared by quenching $C_{60}{}^{6-}$ with MeI, indicates the presence of species up to $C_{60}Me_{24}$ with the dominant products corresponding to $C_{60}Me_6$ and $C_{60}Me_8$,[37] an interesting observation in the light of the known stability of $C_{60}Br_6$ and $C_{60}Br_8$ (Section 6.2.2). The mechanism for the formation of such highly alkylated derivatives is not known, but may indicate rapid electron transfer from unreacted $C_{60}{}^{6-}$ to partially methylated C_{60}. All these derivatives appear to be mixtures of isomers of unknown structure; however, reaction of C_{60} with one equivalent of t-BuLi or EtMgBr followed by quenching with water yields the 1,9-disubstituted products $C_{60}RH$ (**13**) (R = t-Bu, Et) in up to 50% yield.[99] The intermediate mono-substituted anion $[C_{60}\text{-}t\text{-Bu}]^-$ (**14**) has been isolated as the green microcrystalline salt $[Li(THF)_4][C_{60}\text{-}t\text{-Bu}]$,[100] and is a very weak base (cf. $[C_{60}H]^-$, Section 6.2.1). Protonation yields $C_{60}(t\text{-Bu})H$ ($pK_a \approx 5.7$, *see Acids & Acidity*) as either the 1,7- or 1,9-isomer (Figure 22), depending the source of H^+. The 1,7-isomer is a kinetic product and slowly converts into the thermodynamically more stable 1,9-isomer.



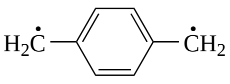
(**13**) (**14**)

Friedel–Crafts arylation of C_{60} with ArH (PhH and PhMe) catalyzed by $AlCl_3$ yields materials of composition $C_{60}H_nAr_n$.[37] Mass spectra show strong peaks for species up to $C_{60}H_{12}Ar_{12}$, and some evidence for $C_{60}H_{16}Ar_{16}$. Reaction of $C_{60}Cl_n$ ($n \approx 24$) with PhH under similar conditions gives the simple phenylated derivatives $C_{60}Ph_n$ ($n \leq 22$). Arylation with $PhH/FeCl_3/Br_2$ yields $C_{60}Ph_{5-12}$, with relative mass spectral intensities of 2:11:2:11:1:3:1:2, and again the predominant species appear to be the hexa- and octafunctionalized species.[101] The repeated appearance of these two 'magic numbers' for addition to C_{60} is a strong indication of the stability of these species; however, it does not necessarily follow that they are the favored products of the chemical reaction under investigation. It may be that the particular mass spectrometric sampling methods used are either biased towards these species, or in some way anneal the product mixtures to these islands of stability.



(**15**) (**16**)

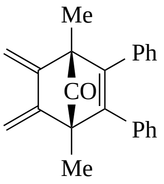
C_{60} reacts with benzyl radicals to give addition products $C_{60}(CH_2Ph)_n$ ($n \leq 15$), as determined by mass spectrometry.[102] The formation of allyl (**15**) and cyclopentadienyl (**16**) radical sites on the cage has been revealed by ESR spectroscopy and these sites are thought to arise from multiple 1,7-additions (cf. $[C_{60}Br_5]$•, Section 6.2.2). The corresponding reaction of C_{60} with the *p*-xylylene diradical (**17**) gives an interesting polymeric material.[103]



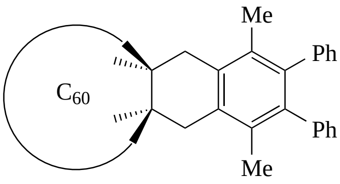
(**17**)

Under appropriate conditions the addition of a single radical (R•) to C_{60} is observed. In $[C_{60}R]$• the radical is not delocalized over the cage but spin density is almost exclusively restricted to the 2, 5, 7, 9, and 11 positions (see **14**). Variable temperature ESR studies of the bulky group derivatives (R = *t*-Bu, CCl_3, CBr_3) indicate that the radical is in equilibrium with its dimer, which is believed to be linked through the 7 or 11 positions as these are the most sterically accessible.[104,105] For the addition of a single radical to C_{70}, the formation of three of the five possible different isomers has been established by ESR.[106]

The reaction of C_{60} with benzyne yields the adducts $C_{60}(C_6H_4)_{1-4}$, of which the monoadduct has been isolated and characterized by ^{1}H and ^{13}C NMR.[107] The benzyne adds across a six–six ring fusion with the formation of a four-membered ring. C_{60} also forms Diels–Alder adducts with dienes, although the products are difficult to characterize and the reaction is often reversible.[84] The diene (**18**), however, cycloadds at a six–six ring fusion of C_{60}, and subsequent loss of CO ensures the irreversible formation of the stable product (**19**), which has been structurally characterized.[108]

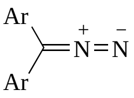


(**18**)

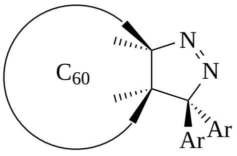


(**19**)

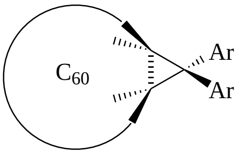
C_{60} undergoes cycloadditions with diaryldiazomethanes (**20**) to form pyrazolines (**21**) which spontaneously lose N_2 to yield diarylhomofullerenes (**22**), in which the 60π electronic structure of the cage is largely preserved (cf. **11**).[67] Addition occurs across a six–six ring fusion and species up to $C_{60}(CAr_2)_6$ have been observed, though the monoadducts are the most readily prepared. This strategy has been extended to the preparation of protected *C*-glycoside derivatives of C_{60}.[109] Polymers have also been prepared from functionalized diarylhomofullerenes,[110] and bis-diazo reagents have been used to prepare soluble bis-homofullerenes as models for the corresponding polymer systems.[111] The electrochemical and spectroscopic properties of the bis- and polyhomofullerenes are not significantly perturbed compared to the monomers.



(**20**)

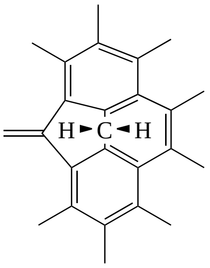


(**21**)



(**22**)

The parent dihydrohomofullerene $C_{60}(CH_2)$ (**23**) is prepared by reaction of C_{60} with CH_2N_2. In this case the intermediate pyrazoline is isolable at room temperature, but loses N_2 upon heating (110 °C).[112] Interestingly ^{1}H and ^{13}C NMR studies show that the CH_2N_2 molecule has added across a six–six ring fusion in the pyrazoline, whereas upon loss of N_2 the CH_2 group migrates to a five–six ring fusion. The two previously equivalent protons are now in distinct chemical environments: ^{1}H NMR, δ2.87 (H_a) and 6.35 (H_b) ppm, and $J_{ab} = 9.7$ Hz.



(**23**)

6.2.5 Organometallic Derivatives

The organometallic chemistry of C_{60} is dictated by its spherical geometry and localized polyalkene π-electronic structure. All the derivatives reported to date are η^2 complexes (*see Hapticity*) in which the metal coordinates at a six–six ring fusion (formal double bond); no analogous η^4-diene or η^6-triene complexes have been prepared to date (*see Alkene Complexes*). The instability of these polyene complexes is postulated to be due to the curvature of the C_{60} molecule and the corresponding divergence of the surface p-orbitals, which results in poor overlap with the metal orbitals.[113]

The representative complex $C_{60}Pt(PPh_3)_2$ (**24**) displays the salient features of all the η^2 compounds.[67,113] The coordinated 'alkene' carbon atoms are distorted towards a tetrahedral geometry and the corresponding relief of strain in the cage probably makes a significant contribution to the stability of these complexes. The reaction with excess organometallic reagent yields the hexaadducts $C_{60}[M(PEt_3)_2]_6$ (M = Ni, Pd,

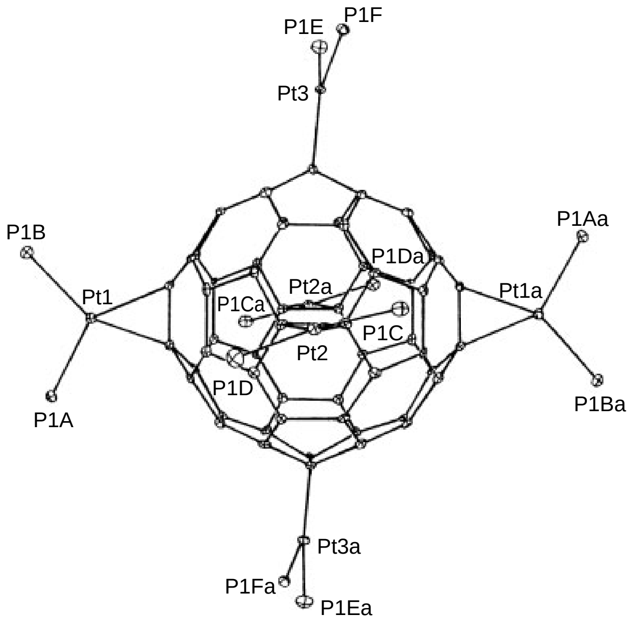


Figure 25 Molecular structure of $C_{60}[Pt(PEt_3)_2]_6$. The phosphine ethyl groups have been omitted for clarity. (Reprinted with permission of the American Chemical Society from P.J. Fagan *et al.*[114])

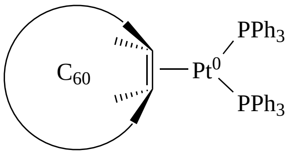


(**24**)

Pt) in which the metals lie at the vertices of an octahedron (Figure 25).[114]

The π*-Back Bonding* from the metal to the C_{60} molecule in these complexes is responsible for band shifts in the C_{60} Raman spectra,[115] and for rendering the cage more resistant to electrochemical reduction;[67] the mono- and hexaadducts being respectively $\sim$0.34 V and >2.7 V harder to reduce than C_{60}.[116] Similar observations have been made for the mono- and bis-iridium complexes $C_{60}Ir(\eta^5\text{-}C_9H_7)(CO)$,[117] $C_{60}Ir(CO)Cl(PPh_3)_2$,[118] and $C_{60}[Ir(CO)Cl(PMe_2Ph)_2]_2$ (*see Vaska's Complex*).[119] The position of the ν_{CO} band for these complexes show that C_{60} is a relatively poor π-acceptor ligand compared to other electron-deficient alkenes, e.g. $F_2C{=}CF_2$ and $(NC)_2C{=}C(CN)_2$. The structures of mono- and bis-iridium complexes of C_{70}, $C_{70}Ir(CO)Cl(PPh_3)_2$ and $C_{70}[Ir(CO)Cl(PPhMe_2)_2]_2$, have also been reported.[37,120]

Reaction of C_{60} with $Pd_2(dba)_3$ yields the organometallic polymer $C_{60}Pd_n$.[121] Material of varying composition may be prepared, but those with $n > 3$ are active for the catalytic hydrogenation of alkenes and alkynes.[122] This material is proposed to consist of catalytically active palladium atoms distributed on an inert 3D polymer $C_{60}Pd_3$.

6.3 Endohedral Fullerenes

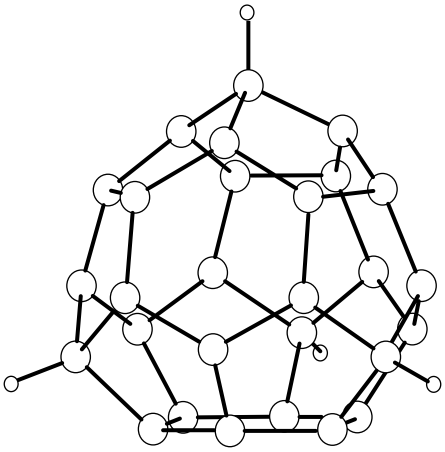
The formation and study of endohedral fullerenes in molecular beams has been discussed in Section 4. These molecules are expected to have interesting and potentially very useful bulk properties as well as a fascinating chemistry. Therefore their synthesis in macroscopic amounts is an important goal in fullerene chemistry. Mixtures of normal and endohedral fullerenes can be isolated from the soot generated by vaporizing a mixture of graphite and a source of the desired element (Section 3.1). Present methods allow only very small amounts of the endohedral materials to be synthesized, and their characterization is generally restricted to highly sensitive techniques, e.g. mass spectrometry and ESR.[37]

To date, all the confirmed isolable endohedral fullerenes contain metals; either scandium, yttrium, or one of the f-block elements may be encapsulated, and compounds containing up to three metals have been reported.[123] The proportions of the endohedral fullerenes observed depends upon the manner by which they are extracted from the soot.[124] For lanthanum, predominantly $La@C_{82}$ and $La_2@C_{80}$ are isolated by solvent extraction techniques, whereas direct sublimation from the soot yields $La@C_{60}$, $La@C_{70}$, $La@C_{74}$, and $La@C_{82}$. An explanation for this behavior is that most of the endohedral fullerenes are present as insoluble salts, e.g. $[La@C_{60}]^+[C_{60}]^-$, and only $La@C_{82}$ and $La_2@C_{80}$ are sufficiently redox stable to be extracted as the neutral molecules.

The monometallic endohedral fullerenes are typified by $M@C_{82}$ (M = Sc, Y, La), and ESR studies of these molecules indicate that they are best described as the charge-separated species $M^{3+}@C_{82}{}^{3-}$.[125] For all three species, two distinct signals are seen, indicating the presence of two isomers of $M@C_{82}$, although it is not known whether these correspond to any of the observed isomers of the parent fullerene C_{82}. EXAFS studies of $Y@C_{82}$ indicate that each yttrium atom has seven nearest neighbor carbon atoms at 2.35 Å as well as another yttrium atom at 4.05 Å.[126] These data are not consistent with a simple endohedral structure and further studies are required to clarify this apparent contradiction.

The endohedral fullerenes $U@C_{28}$ and $U@C_{60}$ have been reported to be sufficiently stable to allow chemical isolation.[127] Endohedral complexes of the smaller fullerenes (C_{2n}, $2n < 60$) are commonly observed in molecular beam experiments (Section 4.1), but this stabilization of C_{28} by uranium atom encapsulation is remarkable. A theoretical study of $[T_d\text{-}C_{28}]^{4-}$ and $T_d\text{-}C_{28}H_4$ (**25**) indicate that they are stable molecules, and that the laboratory preparation of their derivatives may be viable.[9,128]

The formation of multimetallic endohedral fullerenes is strongly dependent on the metal to carbon ratio of the vaporized graphite. For the lanthanides the dimetallic fullerenes $M_2@C_{80}$ and/or $M_2@C_{82}$ are often the most abundant, but small amounts of higher species are also seen. In addition, the existence of the mixed metal system $YLa@C_{80}$ has been reported.[124] No ESR spectra have been observed



(**25**)

for any of these dimetallic compounds to date, indicating that they may not be paramagnetic. However, the existence of the trimetallic species $Sc_3@C_{82}$ has been demonstrated by its mass spectrum peak and its characteristic ESR signal.[129,130] The scandium atoms are thought to be encapsulated as the triply charged, equilateral triangle cluster Sc_3^{3+}.

1 INTRODUCTION

Carbon is the basis of organic chemistry; there are more compounds of carbon than of any other element except hydrogen and possibly fluorine. However, most of the chemistry of carbon is the province of organic chemistry and thus not covered in this encyclopedia. The 'inorganic' chemistry of carbon discussed in this article, which is an update of an excellent article written previously by professor R. Bruce King (University of Georgia, Athens), includes the allotropic forms of elemental carbon, simple molecular carbon halides and oxides, carbon oxyacids and oxyanions, carbon−sulfur derivatives, simple cyano derivatives, and carbon-based molecular ladders.

Carbon chemistry has the following features:

1. Carbon normally forms a total of four bonds including both σ- and π-bonds. The coordination number of a carbon atom forming four bonds can be two (≡C–, as in alkynes, or =C=, as in allene), three (=C<, as in alkenes), or four (as in alkanes) with linear, planar triangular, and tetrahedral geometries, respectively. The carbon atoms in carbon monoxide ($:\bar{\mathrm{C}}{\equiv}\overset{+}{\mathrm{O}}:$) and the isocyanide carbon atom in isocyanides ($:\mathrm{C}{\equiv}\overset{+}{\mathrm{N}}\text{–}\mathrm{R}:$) have coordination numbers of only one. Stable trivalent carbon 'free radicals,' $R_3C\cdot$, can be isolated if R is an aryl group; tris(pentachlorophenyl)methyl, $(C_6Cl_5)_3C\cdot$, is particularly stable.[1]
2. Exceptional examples of carbon atoms with apparent coordination numbers greater than four include five-coordinate carbon atoms in bridging alkyl groups in metal alkyls (e.g. $Al_2(CH_3)_6$), five- and six-coordinate carbon atoms in deltahedral carboranes of the general formula $C_2B_{n-2}H_n$ ($6 \le n \le 12$), and five-, six-, and eight-coordinate carbon atoms in transition metal carbide clusters such as a five-coordinate carbon in the center of an Fe_5 square pyramid in $Fe_5(CO)_{15}C$, a six-coordinate carbon in the center of an Ru_6 octahedron in $Ru_6(CO)_{17}C$, and an eight-coordinate carbon in the center of a Co_8 square antiprism in the anion $Co_8C(CO)_{18}{}^{2-}$.
3. The high carbon−carbon bond strength leads to the unusual stability of catenated carbon compounds: the basis of organic chemistry. Thus the C–C bond strength of $\approx$356 kJ mol^{-1} is comparable to the C–O bond strength of $\approx$336 kJ mol^{-1}. This contrasts with the heavier congener of carbon, silicon, as well as with sulfur: Si–O bonds ($\approx$368 kJ mol^{-1}) and S–O bonds ($\approx$330 kJ mol^{-1}) are much stronger than Si–Si bonds ($\approx$226 kJ mol^{-1}) and S–S bonds ($\approx$226 kJ mol^{-1}).

2 CARBON ISOTOPES AND ELEMENTAL CARBON

2.1 Isotopes of Carbon

Table 1 summarizes some of the important properties of the carbon isotopes. Note that only the rare ($\approx$1%), naturally occurring, stable carbon isotope, namely, ^{13}C, has a nuclear spin and is observable by NMR.[2] The organic chemist is fortunate that $\approx$99% of natural carbon is the isotope ^{12}C with no nuclear spin, so that proton and carbon-13 NMR spectra of organic compounds are not complicated by spin−spin splitting arising from adjacent carbon atoms. The radioisotope[3] ^{14}C is made by thermal neutron irradiation of lithium or aluminum nitride (equation 1). It decays back to stable $^{14}_{7}N$ by β^- emission, with a half-life of 5570 years (equation 2). Cosmic rays generate thermal neutrons, which leads to the formation of $^{14}CO_2$ in the atmosphere (equation 1). Metabolism of

Table 1 Properties of the Carbon Isotopes

Isotope	Natural abundance (%)	Half-life	Spin	NMR sensitivity[a]
^{12}C	98.89	Stable	0	0
^{13}C	1.11	Stable	1/2	0.0159
^{14}C	1.2×10^{-10}	5570 years, β^-	0	0

[a]Relative to the proton for equal numbers of nuclei.

this $^{14}CO_2$ by living organisms is the basis of radiocarbon dating.

$$^{14}_{7}N + ^{1}_{0}n \longrightarrow ^{14}_{6}C + ^{1}_{1}H \quad (1)$$

$$^{14}_{6}C \longrightarrow ^{14}_{7}N + \beta^- \quad (2)$$

2.2 Allotropes of Carbon

Carbon forms three types of allotropes: diamond, graphite, and the recently discovered fullerenes. The properties of these allotropes are compared in Table 2.

2.2.1 Diamond[4]

Diamonds are found naturally in Kimberly, South Africa, in ancient volcanic pipes embedded in a relatively soft, dark colored basic rock in low concentrations (≈1 part per 1.5×10^7). The structure of diamond consists of an infinite three-dimensional lattice of sp^3 carbon atoms in which there are interlocking six-membered C_6 rings, similar to those in cyclohexane or adamantane, and C–C distances of 1.514 Å. Diamond is normally found in the cubic form, but a hexagonal form (lonsdaleite) is found in certain meteorites and is available synthetically. Diamond is the hardest solid known and has the highest melting point (≈4000 °C) and thermal conductivity, as well as the lowest molar entropy (2.4 J mol^{-1} K^{-1}) of any element. Diamond is an insulator. The density of diamond (3.51 g cm^{-3}) is much greater than that of graphite (2.22 g cm^{-3}) so that high pressures (e.g. >125 kbar) can be used to convert graphite to diamond even though graphite is thermodynamically more stable than diamond by 2.9 kJ mol^{-1}. In order to attain useful rates for the high-pressure conversion of graphite to diamond, a transition metal catalyst such as Cr, Fe, or Pt is used. Diamond burns in air at elevated temperatures (600–800 °C).

2.2.2 Graphite[5,6]

Graphite consists of planar layers of hexagons of sp^2 hybridized carbon atoms with a separation of 3.35 Å between layers. The relatively slight forces between graphite layers are consistent with its softness and lubricity. The infinite delocalization of π-electrons in the graphite structure leads to electrical conductivity. The average C–C bond order in graphite is 1.33, corresponding to a C–C distance of 1.415 Å. By contrast, the average C–C bond order in benzene is 1.5, corresponding to the expected shorter C–C distance of 1.39 Å. The most stable and common form of graphite is hexagonal α-graphite with an ABABAB... stacking of the graphite layers. However, rhombohedral β-graphite with an ABCABC... stacking of the layers is also known. Strong oriented graphite fibers can be obtained by pyrolysis of fibers of organic polymers such as poly(acrylonitrile). Amorphous carbons (carbon black, soot, charcoal, etc.) are microcrystalline forms of graphite; their physical properties depend upon their surface area and the nature of their surface (e.g. the presence and type of oxygenated groups).

Molecules and ions can penetrate between the layers of graphite to form interstitial or lamellar compounds. These so-called intercalation compounds are of two types, namely, nonconducting compounds, in which the planarity of the graphite layers is destroyed, and conducting compounds, in which the planarity of the graphite layers is preserved (*see* ***Intercalation Chemistry***).[7,8]

Table 2 Properties of the carbon allotropes

Allotrope	C Hybridization	Structure
Diamond	sp^3	Infinite 3D-lattice
Graphite	sp^2	Infinite 2D-planar layers of hexagons
Fullerenes	sp^2	Finite C_n cages with 12 pentagons and $n - 12$ hexagons

2.2.3 Fullerenes[9,10]

Fullerenes are large molecular carbon cages that are isolated by extraction of specially prepared soot with organic solvents such as benzene. A rich source of fullerene is soot made by arcing graphite rods in a helium atmosphere at 200 Torr pressure.[11] The most common fullerene is C_{60}, which has a truncated icosahedral 'soccer ball' structure with icosahedral (I_h) symmetry. Less symmetrical fullerenes with larger numbers of carbon atoms are known. C_{70} is the next most abundant after C_{60}; C_{76} and C_{84} are also known (*see* ***Carbon: Fullerenes***).

3 CARBON HALIDES

Carbon tetrafluoride, CF_4, mp −185 °C, bp −128 °C, which is the end product of the fluorination of carbon compounds, is a very stable gas. It can also be made by the fluorination of silicon carbide (equation 3). The SiF_4 is removed from the CF_4 by passing the product gases through 20% aqueous NaOH, which removes the SiF_4 as soluble sodium silicate but leaves the CF_4 unaffected. This major difference in hydrolytic reactivity of CF_4 and SiF_4 is a consequence of accessible d orbitals on silicon but not on carbon.

$$SiC + 4F_2 \longrightarrow SiF_4 + CF_4 \quad (3)$$

Organic compounds containing only carbon and fluorine are called fluorocarbons; the chemistry of fluorocarbons is a vast area far beyond the scope of this encyclopedia.[12–15]

General routes to saturated fluorocarbons include the fluorination of hydrocarbons with higher valent fluorides such as CoF_3 or the fluorination of chlorocarbons with SbF_3, often in the presence of catalytic amounts of Sb^V. Since such fluorination procedures usually add fluorine to all carbon–carbon double and triple bonds giving products with exclusively carbon–carbon single bonds, unsaturated fluorocarbons normally require indirect methods of synthesis, generally using dehalogenation reactions by metals such as zinc or dehydrohalogenation reactions with bases. Fluorocarbons have diverse chemical and physiological properties. Thus poly(tetrafluoroethylene), $(–CF_2CF_2–)_n$, commonly known as 'Teflon,' is very chemically inert and has a low coefficient of friction. Octafluoroisobutene, $(CF_3)_2C{=}CF_2$, is highly toxic, but other fluorocarbons, such as perfluorodecahydronaphthalene, $C_{10}F_{18}$, are so physiologically inactive that they are the active components of blood substitute, because of the relatively high solubility of oxygen in fluorocarbons.[16]

Carbon tetrachloride, a liquid with mp −23 °C and bp 76 °C, is a common solvent and is useful for converting metal oxides to metal chlorides at elevated temperatures (300–500 °C). It is thermodynamically unstable with respect to hydrolysis, but is kinetically very inert to hydrolysis because of the absence of empty acceptor orbitals (e.g. d orbitals) for nucleophilic attack. However, heating carbon tetrachloride with free alkali metals or other strong reducing agents can lead to dangerous explosions.

Organic compounds containing only carbon and chlorine are called chlorocarbons. The presence of relatively large chlorine atoms on a carbon network makes the properties of chlorocarbons very different than those of corresponding hydrocarbons. In general, chlorocarbons with trigonal sp^2 carbon atoms are more stable than chlorocarbons with tetrahedral sp^3 carbon atoms. As a result, certain chlorocarbons having only sp^2 carbon atoms, for example, perchlorofulvene and perchlorofulvalene, are very stable under normal conditions, whereas their hydrocarbon analogs polymerize rapidly. Chlorocarbon free radicals[1] with trivalent carbon atoms are among the most stable carbon free radicals. For example, the trivalent carbon atom in $(C_6Cl_5)_3C\bullet$ is stable not only to air but even to permanganate oxidation.

Carbon tetrabromide is a pale yellow water-insoluble solid, mp 90.1 °C, bp 189.5 °C. Carbon tetraiodide is a bright red solid which decomposes readily to I_2 and $I_2C{=}CI_2$, again indicating the stability of sp^2 carbon atoms relative to sp^3 carbon atoms in halocarbons (other than fluorocarbons). Carbon tetraiodide is made by an electrophilic halogen exchange reaction (equation 4).[17] The increasing instability of the carbon tetrahalides with increasing atomic weight of the halogen relates to the steady decrease in C–X bond energies from 485 kJ mol^{-1} for the C–F bond to 213 kJ mol^{-1} for the C–I bond.

$$CCl_4 + 4EtI \xrightarrow{AlCl_3} CI_4 + 4EtCl \qquad (4)$$

Carbonyl halides, $O{=}CX_2$ (X = F, Cl, Br, I), are all known, although the existence of COI_2 has recently been questioned.[18] The fluoride and chloride are made by reaction of carbon monoxide with the corresponding halogen; the bromide is made by the partial hydrolysis of CBr_4 with concentrated sulfuric acid. Carbonyl chloride, $O{=}CCl_2$, bp +7.6 °C, also known as phosgene (from $\phi\omega\zeta$ = *phōs* for *light* and -$\gamma\varepsilon\nu\eta\zeta$ = -*genēs* for *form*, relating to its formation from CO + Cl_2 in sunlight), is a toxic gas smelling like 'new-mown hay,' which was used as a war gas in World War I. Thiocarbonyl chloride or 'thiophosgene,' $S{=}CCl_2$, is an evil-smelling orange toxic liquid, bp 73 °C.[19]

4 CARBON OXIDES

The oxides of carbon include the very stable and abundant CO and CO_2, the unstable but isolable C_3O_2, and more complicated carbon oxides derived from organic backbones by removal of all hydrogen, for example, $C_{12}O_9$, from the complete dehydration of mellitic acid (benzenehexacarboxylic acid). Oxocarbon anions, $C_nO_n{}^{2-}$, with apparent 'aromatic' properties are also known.[20,21] The properties of these carbon–oxygen compounds are summarized below.

4.1 Carbon Monoxide

Carbon monoxide, mp −205 °C, bp −190 °C, $:\bar{C}{\equiv}\overset{+}{O}:$, is a colorless, odorless, but very toxic gas that is sparingly soluble in water. Carbon monoxide is formed by burning carbon in a deficiency of oxygen. It therefore is a dangerous product of many combustion processes. Carbon monoxide is also made by the 'water gas reaction' from steam and coal as 'synthesis gas,' a 1:1 CO/H_2 mixture arising from equation (5) at elevated temperatures. On the laboratory scale, pure carbon monoxide may be generated by the acid dehydration of formic acid, HCO_2H, using concentrated sulfuric acid. Transition metals combine with carbon monoxide to form metal carbonyls, which play a key role in vast areas of organometallic and coordination chemistry (*see Metal Carbonyls*; ***Carbonyl Complexes of the Transition Metals***, and ***Carbonylation Processes by Homogeneous Catalysis***). The toxicity of carbon monoxide is a consequence of its binding to the iron in blood hemoglobin, thereby inhibiting the essential function of hemoglobin as an oxygen carrier. Carbon monoxide can bond to transition metals as a terminal or a bridging ligand (Figure 1). Simple, neutral binary-metal carbonyls are volatile covalent compounds, which readily decompose on heating to carbon monoxide and the free metal, and thus are often useful sources of finely divided and/or pure metals such as chromium, molybdenum, iron, and nickel. Carbon monoxide reacts with alkali metals to give the so-called alkali metal carbonyls, which contain salts of the acetylenediolate ion, $^-O–C{\equiv}C–O^-$; on

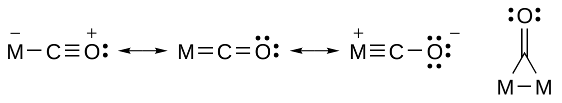

Figure 1 The bonding of CO to transition metals in metal carbonyls as terminal and bridging ligands

hydrolysis, these can give hexahydroxybenzene derivatives.

$$C + H_2O \xrightarrow{\Delta} CO + H_2 \quad (5)$$

4.2 Carbon Dioxide

Carbon dioxide, :Ö=C=Ö:, mp −57 °C (5.2 atm), bp −79 °C (sublimes), is obtained from the combustion of carbon and hydrocarbons in excess air or oxygen or by the pyrolysis (‘calcination’) of $CaCO_3$ (limestone). The photosynthesis in plants reduces CO_2 to organic matter, but the similar reduction of CO_2 in a nonliving system (‘in vitro’) appears to be very difficult. However, CO_2 can be reduced electrochemically to methanol, formate, oxalate, methane, and/or CO depending upon the conditions. Numerous transition metal complexes of CO_2 are known,[22–28] which exhibit the modes of metal–CO_2 bonding depicted in Figure 2.

4.3 Carbon Suboxide

Carbon suboxide, C_3O_2, :Ö=C=C=C=Ö:, also called 1,2-propadiene-1,3-dione, is an evil-smelling unstable gas, bp +6.8 °C, which is obtained by the dehydration of malonic acid with P_4O_{10} in vacuum at 140–150 °C (equation 6). Carbon suboxide polymerizes readily at room temperature to a yellow solid, and above 100 °C to a ruby-red water-soluble solid. Photolysis of C_3O_2 gives C_2O (:C=C=Ö:) as a reactive intermediate, which reacts with alkenes by carbon atom insertion (equation 7).

$$HO_2C\text{–}CH_2\text{–}CO_2H \xrightarrow{P_4O_{10}} :\ddot{O}=C=C=C=\ddot{O}: + 2H_2O \quad (6)$$

$$H_2C=CH_2 + :C=C=\ddot{O}: \xrightarrow{h\nu} H_2C=C=CH_2 + CO \quad (7)$$

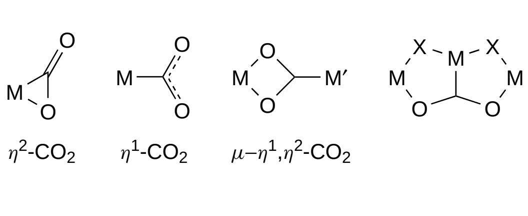

Figure 2 Some bonding modes of carbon dioxide to one or two transition metals (M and M′), illustrating the η^n method for indicating number of attachment points

4.4 More Complicated Carbon Oxides

Some more complicated carbon oxides are known with carbon backbones familiar in organic chemistry. An example is benzenehexacarboxylic acid (mellitic acid) trianhydride, $C_{12}O_9 = C_6[(CO)_2O]_3$ (**1**), a white sublimable solid obtained by dehydration of the corresponding acid with acetyl chloride in a sealed tube at 160 °C.

5 CARBON OXYACIDS AND OXYANIONS

5.1 Carbonic Acid

Carbon dioxide is the anhydride of carbonic acid but hydrolyzes only slowly at pH 7 to H_2CO_3. In aqueous solution, CO_2 is physically dissolved and only loosely solvated so that only ≈0.2% is present as $H_2CO_3/HCO_3^-/CO_3^{2-}$. This relates to the stability of the :Ö=C=Ö: structure for CO_2 and the reluctance of water to add to one of the C=O double bonds of CO_2. Carbonic acid is a weak acid with the true dissociation constants $K_1 = 1.6 \times 10^{-4}$ and $K_2 = 4.7 \times 10^{-11}$; determination of K_1 without allowing for the fact that ≈99.8% of an aqueous solution of CO_2 is undissociated CO_2 gives the fictitious dissociation constant of 4.16×10^{-7} for ‘K_1’ of H_2CO_3. Pure carbonic acid, H_2CO_3, cannot be isolated because of its ready dehydration to CO_2. However, colorless crystals of a white crystalline etherate $H_2CO_3{\cdot}Me_2O$, mp −47 °C, can be isolated by treatment of Na_2CO_3 at −35 °C with hydrogen chloride in dimethyl ether; this etherate decomposes above −26 °C into CO_2, H_2O, and Me_2O.

5.2 Oxocarbon Anions[21,29]

Oxocarbon anions, $C_nO_n^{2-}$ ($3 \le n \le 6$), are derived from the cyclic dihydroxy compounds depicted in Figure 3. Deltic and squaric acids are made by hydrolysis of suitable cyclopropene and cyclobutene derivatives (Figure 4). Much milder conditions (e.g. *n*-butanol in diethyl ether) are

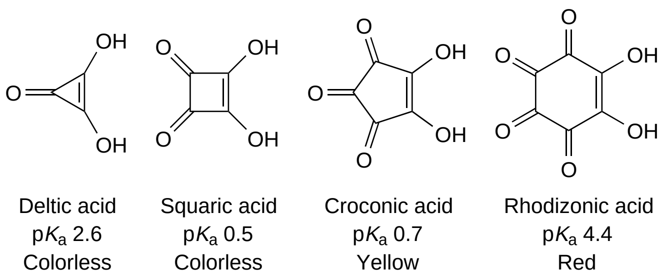

Figure 3 The acids giving the oxocarbon anions $C_nO_n^{2-}$ ($3 \le n \le 6$)

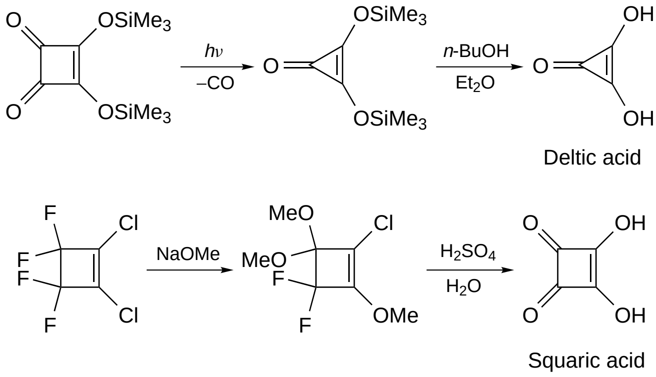

Figure 4 Syntheses of squaric acid and deltic acid

used for the preparation of deltic acid than for squaric acid, in order to avoid cleavage of the three-membered ring in deltic acid. Squaric acid can also be made by the electrolytic reduction of carbon monoxide in DMF at 18 °C/230 atmospheres with tetrabutylammonium bromide as the supporting electrolyte, using the stainless steel pressure vessel as the cathode and an aluminum anode. Rhodizonic acid is obtained from the microbiological oxidation of myoinositol or by the chemical oxidation (HNO_3 followed by O_2/Me_3CO_2K) of hexahydroxycyclohexane. Alternatively, carbon monoxide can be reduced with potassium metal under mild conditions to give potassium ethynediolate, $K_2C_2O_2$, which under heating undergoes cyclotrimerization to the potassium derivative of hexahydroxybenzene, $K_6C_6O_6$, which in turn can be oxidized to potassium rhodizonate, $K_2C_6O_6$. Further oxidation of rhodizonate in basic solution results in ring contraction to give potassium croconate. The preparation of rhodizonic and croconic acids from elemental carbon was already known in the early nineteenth century, long before their structures were known; therefore, the trivial names of these acids are based on the characteristic colors of their salts, that is, *ρωδιζειν* (*rhōdizein*) = rose red and *κρωκσ* (*krōkos*) = yellow. Rhodizonates are used as spot test reagents for alkaline earth and other divalent ions such as Pb^{2+}.

6 CARBON–SULFUR DERIVATIVES

6.1 Carbon Disulfide, Thiocarbonates, and Thiocarbamates

The raw material for much of carbon–sulfur chemistry is carbon disulfide, CS_2 ($:\ddot{S}{=}C{=}\ddot{S}:$), a very flammable and reactive liquid, mp −109 °C, bp +46 °C, which can be synthesized from elemental carbon or methane and sulfur at high temperatures.[30] Chlorination of carbon disulfide (equation 8) provides a source of carbon tetrachloride on an industrial scale. The carbon in carbon disulfide is susceptible toward nucleophilic attack by HS^-, RO^-, RNH_2, R_2 NH, and so on. Nucleophilic attack of carbon disulfide with SH^- in basic solution gives the yellow trithiocarbonate ion, CS_3^{2-}. Further reaction of the trithiocarbonate ion with elemental sulfur gives the ion CS_4^{2-}, shown to have the disulfide structure $[S_2C–S–S]^{2-}$. The free acids H_2CS_3 and H_2CS_4 can be obtained from these anions as red liquids, stable only at low temperatures. Reaction of carbon disulfide with secondary amines in basic solution leads to dithiocarbamates (equation 9; R = methyl, ethyl, etc.).[31]

$$CS_2 + 3Cl_2 \longrightarrow CCl_4 + S_2Cl_2 \quad (8)$$

$$CS_2 + R_2NH + NaOH \longrightarrow R_2NCS_2^-Na^+ + H_2O \quad (9)$$

Zinc, manganese, and iron dithiocarbamates are extensively used as agricultural fungicides and zinc dithiocarbamates are used as accelerators in rubber vulcanization. Oxidation of aqueous dimethyldithiocarbamate with Cl_2, H_2O_2, or $S_2O_8^{2-}$ gives tetramethylthiuram disulfide, $Me_2NC({=}S)–S–S–C({=}S)NMe_2$. The lability of its sulfur–sulfur bond makes tetramethylthiuram disulfide a useful free radical source for polymerization initiators and vulcanization accelerators. Tetraethylthiuram disulfide, $Et_2NC({=}S)–S–S–C({=}S)NEt_2$, is the drug ‘Antabuse’, which is used to treat alcoholism by making the body react to ethanol. Carbon disulfide is a very versatile ligand toward transition metals, forming various types of metal complexes including complex types analogous to those found for carbon dioxide (Figure 2).

6.2 Carbon Monosulfide

Carbon monosulfide, CS, unlike carbon monoxide, is not stable (dec. > -160 °C). However, numerous transition metal complexes of carbon monosulfide are known;[32–34] such complexes are generally called metal thiocarbonyls, by analogy to metal carbonyls. Selenocarbonyls containing the CSe group are also known. The inaccessibility of free CS restricts the variety of metal thiocarbonyls that can be prepared, and relatively few complexes with more than one CS ligand are known. For example, $M(CS)_6$ (M = Cr, Mo, W) and $Fe(CS)_5$, analogous to $M(CO)_6$ and $Fe(CO)_5$ respectively, remain unknown. Sources of CS ligands in metal complexes include CS_2 and $CSCl_2$ (equations 10 and 11).

$$(Ph_3P)_3RhCl + CS_2 \longrightarrow (Ph_3P)_2Rh(CS)Cl + Ph_3PS \quad (10)$$

$$Na_2W(CO)_5 + S{=}CCl_2 \longrightarrow W(CO)_5CS + 2NaCl \quad (11)$$

A problem with equation (11) is the separation of $W(CO)_5CS$ from $W(CO)_6$ formed in side reactions, since these compounds have very similar properties. Coordinated CS is reactive toward an electrophilic attack at sulfur and a nucleophilic attack at carbon (equations 12 and 13). The

greater reactivity of metal thiocarbonyl derivatives relative to corresponding metal-carbonyl derivatives provides the best method for separating $W(CO)_5CS$ from $W(CO)_6$. Thus, $W(CO)_5CS$ reacts with iodide ion to give ionic *trans*-$W(CO)_4(CS)I^-$ under conditions where $W(CO)_6$ is unaffected; this reaction coupled with regeneration of $W(CO)_5CS$ from *trans*-$W(CO)_4(CS)I^-$ by treatment with $AgSO_3CF_3$ in a CO atmosphere provides a useful method for separating $W(CO)_6/W(CO)_5CS$ mixtures.

$$L_nM(CS) + RI \longrightarrow [L_nM(CSR)]^+I^- \quad (12)$$

R = Me, etc.

$$L_nM(CS) + R_2N^- \longrightarrow [L_nM\text{–}C(=S)MR_2]^- \quad (13)$$

6.3 More Complicated Carbon Sulfides

Besides carbon sulfides CS and CS_2, described in previous sections, some other binary compounds of sulfur and carbon have been known for a long time, such as C_3S_2 and the two isomers of C_4S_6 and C_9S_9. In the latter, extensive delocalization leads to the formation of disulfide bonds within linear three-sulfur sequences, and the molecule is sometimes considered to be a carbon–sulfur analogue of coronene (Figure 5).[35]

In addition, potential application of materials containing carbon–sulfur bonds in electronic industries has recently provided an impetus for the synthesis of further binary carbon sulfides, leading to the discovery and characterization of C_3S_7, C_3S_8, C_5S_7, C_6S_8, C_6S_{10}, and C_6S_{12}.[36] The syntheses of the sulfides involve the dithiolate complex of a transition metal ion as a precursor and are based on the oxidative coupling and electrophilic sulfiding (e.g. via S_2Cl_2) of either the α- or β-$C_3S_5^{2-}$ anion (Figure 6) and, consequently, molecular structures of such compounds are based on either the α- or β-C_3S_5 subunit, respectively (Figure 6). Specifically, C_3S_7, C_3S_8, C_6S_{10}, and C_6S_{12} are based on the α-C_3S_5 subunit, while C_5S_7 contains the β-C_3S_5 subunit. In case of C_6S_8, two isomers have been obtained, one of which is based on the β-C_3S_5 subunit.

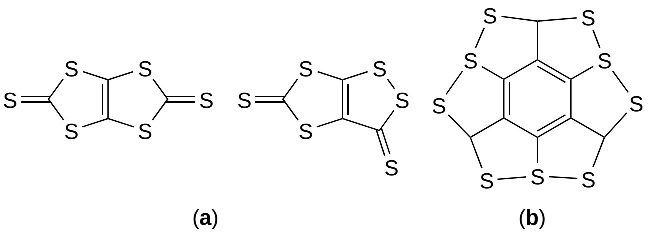

Figure 5 Schematic representation of (a) two isomers of C_4S_6, and (b) C_9S_9

7 CYANIDES AND RELATED COMPOUNDS

7.1 Cyanogen

Cyanogen, :N≡C–C≡N:, is a flammable and toxic gas, mp −28 °C, bp −21 °C, which is kinetically stable but endothermic (297 kJ mol^{-1}). It has a linear structure with a sufficiently weak C–C bond to allow dissociation into •CN radicals. Cyanogen can be prepared by various oxidation reactions of cyano derivatives. Thus, cyanogen is obtained from the oxidation of hydrogen cyanide (see below) with oxygen over a silver catalyst, with chlorine over activated carbon or silica, or with nitrogen dioxide over CaO/glass. Cyanogen is also obtained by oxidation of an aqueous

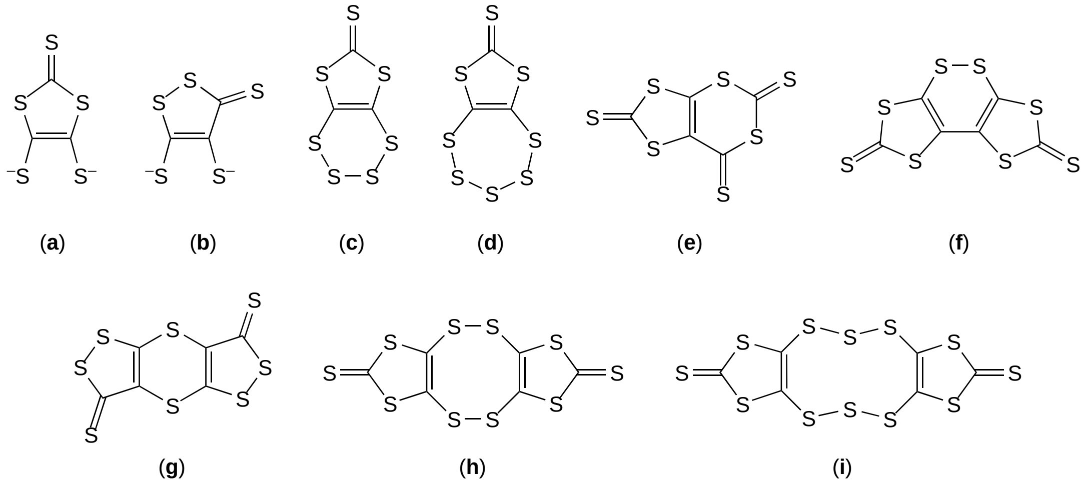

Figure 6 Schematic representation of (a) α-C_3S_5 anion, (b) β-C_3S_5 anion, (c) C_3S_7, (d) C_3S_8, (e) C_5S_7, (f) one of two isomers of C_6S_8, (g) the isomer of C_6S_8 based on the β-C_3S_5 unit, (h) C_6S_{10}, and (i) C_6S_{12}

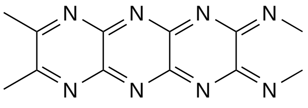

Figure 7 Structure of paracyanogen

cyanide ion with copper(II) or persulfate ($S_2O_8^{2-}$) in acid solution or by a solid-state reaction between $Hg(CN)_2$ and $HgCl_2$ (equation 14). Cyanogen disproportionates in basic solution (equation 15). Because of its endothermic nature, cyanogen burns in a stoichiometric amount of pure oxygen with one of the hottest known flames from a chemical reaction (5050 K). Cyanogen polymerizes readily on heating to give paracyanogen (Figure 7) as an infinite chain polymer.

$$Hg(CN)_2 + HgCl_2 \longrightarrow Hg_2Cl_2 + :N{\equiv}C{-}C{\equiv}N: \quad (14)$$

$$:N{\equiv}C{-}C{\equiv}N: + 2OH^- \longrightarrow CN^- + OCN^- + H_2O \quad (15)$$

7.2 Hydrogen Cyanide

Hydrogen cyanide, H–C≡N:, is a colorless, extremely toxic, volatile liquid, mp −13.4 °C, bp +25.6 °C, with a high dielectric constant (107 at 25 °C). It functions as a weak acid ($K_a = 4.9 \times 10^{-10}$). It is made by acidifying aqueous solutions of cyanides or industrially by the exothermic reaction of methane with ammonia in a fast flow/rapid quench system (equation 16). Hydrogen cyanide polymerizes readily under a variety of conditions; hydrogen cyanide oligomers include the trimer aminomalononitrile and the tetramer diaminomaleonitrile (Figure 8).

$$CH_4 + NH_3 \xrightarrow[1200\,^\circ C]{\text{Pt catalyst}} HCN + 3H_2 \quad (16)$$
$$\Delta H = -247\ \text{kJ mol}^{-1}$$

7.3 Cyanide Ion

Cyanide ion, $:\bar{C}{\equiv}N:$, is made by treatment of hydrogen cyanide with base (e.g. NaOH or Na_2CO_3 for the preparation of sodium cyanide) or from sodium, ammonia, and carbon (equation 17).

$$2Na + 2NH_3 \longrightarrow H_2 + NaNH_2 \quad (17a)$$

Figure 8 Some oligomers of hydrogen cyanide

Sodium amide or 'sodamide'

$$2NaNH_2 + C \longrightarrow 2H_2 + Na_2NCN \quad (17b)$$

Disodium cyanamide

$$Na_2NCN + C \longrightarrow 2NaCN \quad (17c)$$

The cyanide ion in crystalline alkali metal cyanides is rotationally disordered and thus is effectively spherical with a radius of 1.92 Å. Cyanide ion forms strong complexes (e.g. $Fe(CN)_6^{4-}$: hexacyanoferrate(II) or ferrocyanide) in aqueous solution with transition metals;[35] the transition metal always bonds to the carbon atom of the cyano group in these complexes (*see* ***Cyanide Complexes of the Transition Metals***). The cyanide ion occupies a high position in the spectrochemical series, giving rise to a large nephelauxetic effect and producing a large trans effect. A unidentate cyanide ion always bonds to the metal through its carbon atom but M–C≡N–M links are present in many solid cyanides, such as AuCN, $Zn(CN)_2$, and the Prussian blues, which are highly colored mixed oxidation state $Fe^{II/III}$ derivatives. Anhydrous acids corresponding to the more stable complex transition metal cyanides can be isolated, for example, $H_3Rh(CN)_6$ and $H_4Fe(CN)_6$; such acids have hydrogen-bonded M–C≡N–H···N≡C–M units. Related species are the hydrogen isocyanide complexes, such as $HNCW(CO)_5$, obtained by protonation of the coordinated cyano group in $W(CO)_5CN^-$; such protonation reactions indicate the basicity of the nitrogen atoms in coordinated cyano groups. Sodium cyanide is used in the extraction of gold and silver from their ores since it forms very stable linear cyano complexes $[:N{\equiv}C{-}M{-}C{\equiv}N:]^-$ (M = Ag, Au) with these metals. Organic isocyanides, $R{-}\overset{+}{N}{\equiv}\overset{-}{C}:$ (R = alkyl or aryl group), also form an extensive series of transition metal complexes, including zerovalent derivatives such as $(PhNC)_6Cr$; as in the case of metal cyano complexes, the transition metal always bonds to the carbon rather than the nitrogen atom of isocyanides.[37]

7.4 Cyanamide

Cyanamide, $H_2\ddot{N}{-}C{\equiv}N:$, is a crystalline solid, mp 45 °C, prepared by hydrolysis of its calcium salt, CaNCN, under mild conditions (e.g. aqueous CO_2) in order to avoid further hydrolysis of cyanamide. Calcium cyanamide is made on a large industrial scale by a high-temperature reaction of calcium carbide with molecular nitrogen (equation 18). The cyanamide dianion in CaNCN, namely, $CN_2^{2-} = :\ddot{N}^- {=}C{=}\ddot{N}^-:$, is isoelectronic and isostructural with carbon dioxide ($CO_2 = :\ddot{O}{=}C{=}\ddot{O}:$). Cyanamide dimerizes in an aqueous alkaline solution at 80 °C to form dicyandiamide, $(H_2N)_2C{=}NCN$, mp 209 °C (dec.), which undergoes further conversion to a trimer, 1,3,5-triamino-1,3,5-triazine, or melamine, by heating in ammonia (Figure 9). Melamine, which is a useful ingredient in polymers and plastics, can also be made by heating urea under

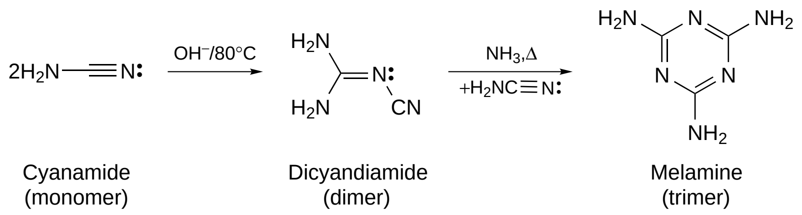

Figure 9 Oligomerization of cyanamide to give dicyandiamide and melamine

pressure (equation 19). The NH_3 and CO_2 produced in this reaction can be recycled to make more urea starting material.

$$CaC_2 + N_2 \xrightarrow{\sim 1000\,^\circ C} CaNCN + C \qquad \Delta H = -297\,\text{kJ mol}^{-1} \quad (18)$$

$$6H_2NC(=O)NH_2 \xrightarrow[100\,\text{atm}]{300\,^\circ C} 6NH_3 + 3CO_2 + C_3N_3(NH_2)_3 \quad (19)$$

7.5 Cyanogen Halides

Cyanogen chloride, Cl–C≡N:, a toxic gas, bp +13 °C, is obtained by reaction of HCN with Cl_2 or by electrolysis of an aqueous solution containing HCN and NH_4Cl. It readily undergoes trimerization to give cyanuric chloride, $C_3N_3Cl_3$, which has a similar 1,3,5-triazine structure to melamine (Figure 9). The chlorine atoms in cyanuric chloride are reactive toward nucleophilic substitution. Fluorination of cyanuric chloride gives cyanuric fluoride, $C_3N_3F_3$, which can be cracked thermally to give cyanogen fluoride, F–C≡N:, bp −46 °C, which polymerizes at room temperature. Cyanogen bromide, mp 52 °C, bp 61.4 °C, and cyanogen iodide, mp 147 °C, are volatile solids that can be made by treatment of cyanide ion with the free halogen in aqueous solution. Cyanogen iodide can also be obtained from $Hg(CN)_2$ and I_2.

7.6 Cyanic Acid and Cyanates

The cyanate ion, $:\ddot{O}=C=\ddot{N}^{-}$, like the cyanamide dianion, is isoelectronic and isostructural with carbon dioxide, and is made by the mild oxidation of aqueous cyanide ion (equation 20). Sodium cyanate can also be made by heating sodium carbonate with urea in the absence of a solvent (equation 21). Unstable free cyanic acid (HOCN, bp 23.5 °C, $K_a = 1.2 \times 10^{-4}$) can be obtained by hydrolysis of cyanuric chloride (see above) to 'cyanuric acid,' 1,3,5-trihydroxy-1,3,5-triazine, $C_3N_3(OH)_3$, followed by pyrolysis. Cyanic acid undergoes facile hydrolysis in aqueous solution to give carbon dioxide and ammonia (equation 22). In covalent derivatives or metal complexes, cyanate can bond either through oxygen (cyanates) or nitrogen (isocyanates), thereby providing examples of linkage isomerism.[38] The facile isomerization of ammonium cyanate (NH_4^+ OCN^-) to urea ($O=C(NH_2)_2$), which was first found in the early nineteenth century, is regarded as the first link between inorganic and organic chemistry.

$$KCN\,(aq) + PbO\,(aq) \longrightarrow Pb\,(s) + KOCN\,(aq) \quad (20)$$

$$Na_2CO_3 + 2O=C(NH_2)_2 \xrightarrow[\text{dry}]{\text{heat}} 2NaOCN + CO_2 + 2NH_3 + H_2O \quad (21)$$

$$HOCN + H_2O \longrightarrow NH_3 + CO_2 \quad (22)$$

7.7 Thiocyanates and Selenocyanates

The thiocyanate ion,[36] $:\ddot{S}=C=\ddot{N}^{-}:$, also called the 'rhodanid' ion in the early German literature because of the intense red color of its Fe^{III} derivative, is obtained by the fusion of alkali metal cyanides with sulfur. It is also the product of the detoxification of the cyanide ion in living systems. Most thiocyanate salts are very soluble in both water and liquid ammonia and are useful soluble sources of metal ions in liquid ammonia. Thiocyanogen, :N≡C–S–S–C≡N:, is the prototypical example of a pseudohalogen, that is, a group of atoms that behaves like a halogen, X_2 (X = Cl, Br, I). Thiocyanogen is made by bromination of a metal thiocyanate in an inert (nonprotonic) solvent (equation 23). Thiocyanogen is rapidly hydrolyzed by water and rapidly and irreversibly polymerized in the pure state. However, it can be handled in solutions in inert solvents including glacial acetic acid, as well as carbon tetrachloride or carbon disulfide.

$$2AgSCN + Br_2 \longrightarrow 2AgBr + :N{\equiv}C{-}S{-}S{-}C{\equiv}N: \quad (23)$$

Selenocyanates are also known; they are analogous to thiocyanates but are less stable.

7.8 Fulminic Acid

Fulminic acid, $:\bar{C}{\equiv}\overset{+}{N}{-}OH \longleftrightarrow :C{=}\ddot{N}{-}OH$, is a 'divalent' carbon derivative like carbon monoxide; it is formally an 'oxime' of carbon monoxide. Free fulminic acid is unstable, but the explosive mercury salt, which is used as a detonator, is obtained by treatment of elemental mercury with a mixture of ethanol and nitric acid. The fulminate ion, $:\bar{C}{\equiv}\overset{+}{N}{-}\bar{O}$, like carbon monoxide and cyanide ion, functions as a strong-field

ligand toward transition metals to form complexes such as $Fe(CNO)_6^{4-}$ analogous to the ferrocyanide ion, $Fe(CN)_6^{4-}$. However, fulminato metal complexes, like mercury fulminate, are frequently explosive. The likewise explosive silver fulminate (AgCNO) and silver cyanate (AgOCN) are of historical interest in being the first pair of isomers discovered, and they led to the first proposal of the concept of isomerism (Liebig, 1823).[39]

8 CARBON-BASED MOLECULAR LADDERS

Structures resembling a ladder are encountered in the chemistry (e.g. Zintl phases) of many elements, but among group IV elements are found only in the case of carbon.[40] The molecular ladders of carbon chemistry are [n]-ladderanes,[41] small molecules built up of n edge-fused four-membered rings, with $n \geq 1$ (Figure 10). The four-membered rings in [n]-ladderanes generally contain only carbon atoms, although derivatives involving nitrogen are known.[42]

8.1 Strain and Isomerism

The simplest member of the class is the [1]-ladderane, a small and familiar strained molecule known as cyclobutane. The strain in a [n]-ladderane increases with the number of fused rings and the introduction of multiple bonds.[43] The [2]-ladderane derivative, Dewar benzene, is highly unstable and converts readily to the conjugation-stabilized counterpart, benzene. Depending on the stereochemistry of bridgehead atoms in the fused-ring system, [n]ladderanes

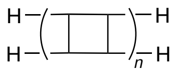

Figure 10 Schematic representation of a [n]-ladderane

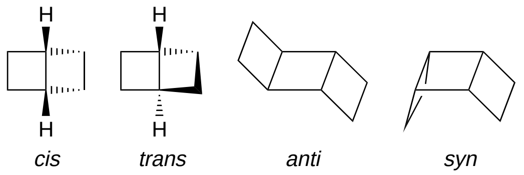

Figure 11 Different types of ladderane isomers

with $n \geq 2$ can exist as different isomers. Specifically, the cis- or trans- positioning of substituents on bridgehead carbon atoms leads to two structurally distinct molecular types, the more strained being the one with substituents in trans-positions. Further possibilities of isomerism in [3]-ladderane and higher members of the family arise from the possibility of a nonterminal cyclobutane ring adopting either the anti or syn configuration (Figure 11).

8.2 Significance

The [n]-ladderane framework has gained additional theoretical interest. The framework has been discovered in biology and has been recognized as a potentially useful building block in materials science. These developments have provided an impetus for synthetic methods to construct [n]-ladderanes to be advanced.

8.3 Theoretical

Most recent quantum chemical calculations involving [n]-ladderanes suggest a defect in the ladderane framework, in the form of an olefin pair, can result in fluxional molecules named sigmatropic shiftamers.[44,45] The fluxional nature would stem from the ability of the olefin pair to travel across the defective ladderane framework via a series of Cope rearrangements (Figure 12). Calculations predict the fluxionality of the molecules depends on the size of the framework. Specifically, [n]-ladderanes with $n > 7$ are expected to be fluxional at and above room temperature.

8.4 Biochemistry and Materials Science

Biomolecules containing [3]- and [5]-ladderanes have been discovered within intracellular lipid membranes of *anammox* bacteria[46] that recycle atmospheric nitrogen. The ladderane lipids are found in the membrane surrounding a unique cytoplasmic organelle, the *anammoxosome*, within which the anaerobic oxidation of ammonia into molecular nitrogen occurs. The oxidation, known as the *anammox* process, follows the reaction (equation 24):

$$NH_4^+ + NO_2^- \longrightarrow N_2 + 2H_2O \qquad (24)$$

The ladderane moieties are thought to rigidify and thereby decrease the permeability of the anammoxosome membrane,

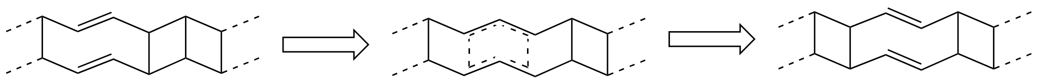

Figure 12 Interconversion of sigmatropic shiftamers via a Cope rearrangement

enabling the containment of small energetic molecules (e.g. hydrazine) within the organelle, making the denitrification process energetically feasible for the bacterium. The ability of [*n*]-ladderanes to increase the rigidity of the lipid bilayer is supported by experiments involving ladderane-enriched membranes, as well as molecular dynamics simulations. The simulations illustrated the ladderane-containing membrane to have a significantly higher density (up to $1.5\,kg\,m^{-3}$) than typically encountered in membrane systems (less than $1.2\,kg\,m^{-3}$). Since approximately up to 50% of Earth's atmospheric nitrogen is believed to be recycled through the bacterial *anammox* process, [*n*]-ladderanes should be regarded as an important class of biomolecules, rather than just an evolutionary curiosity.[46]

The rigidity of the fused cyclobutane rings system has led to the recognition of [*n*]-ladderanes as potential architectural components in molecular electronics.[47] Along with poly(norbornanes) as bent rigid constituents, [*n*]-ladderanes of nanometer length ($n > 7$) have been suggested as molecular beams and rods in nanoscale devices.[48] Fullerene derivatives of [*n*]-ladderanes have been synthesized, as well as ladderane frameworks carrying chromophore groups.[49] Notably, the square-like structure of the [1]-ladderane ring has been used in the construction of supramolecular ladder-like structures in molecular crystals.[50]

8.5 Synthesis

The two most successful strategies to construct molecular ladders are based upon the [2 + 2] cycloaddition of olefins. The first, involving the polymerization of cyclobutadiene derivatives, has served to produce the highest known member of the family, the [13]-ladderane.[51] The second, relying on the dimerization of conjugated polyenes, has provided [*n*]-ladderanes in the highest yields and stereoselectivities. Schematically, the first method corresponds to a rung-by-rung construction of a ladder, while the second strategy is similar to assembling a ladder by welding the two sidepieces together (Figure 13).

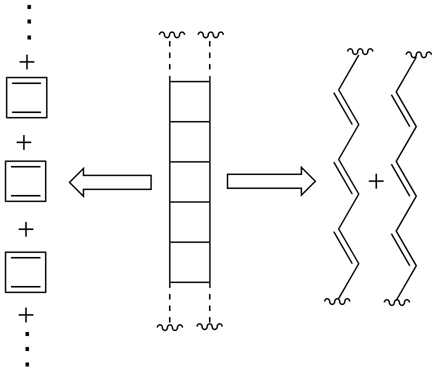

Figure 13 Two retrosynthetic routes to the [*n*]-ladderane framework

8.5.1 *Cyclobutadiene Oligomerization*

The Ce(IV)-oxidation of a tricarbonyliron(0)-cyclobutadiene complex releases the cyclobutadiene (**1a–c**) that subsequently oligomerizes to yield a mixture of [*n*]-ladderanes (Figure 14).[52]

While cyclobutadiene itself yields only a dimer ([3]-ladderane) in such process, some derivatives, such as (**2b**) or (**2c**), provide higher members of the series. The difference in reactivities stems from a difference in the HOMO–LUMO energy gap of the reactants. The energy gap is readily calculated, providing a way to select the most suitable cyclobutadiene derivative to undergo oligomerization to a ladder.[53]

8.5.2 *Dimerization of Conjugated Polyenes*

The construction of molecular ladders from two conjugated polyenes employs UV-induced [2 + 2] photodimerizations. The task is complicated by a requirement to position the sidepieces, in the form of polyenes, in the orientation for the reaction. Such control of positioning may be accomplished using two distinct approaches. The first one is intramolecular, involving a [2 + 2] cycloaddition of

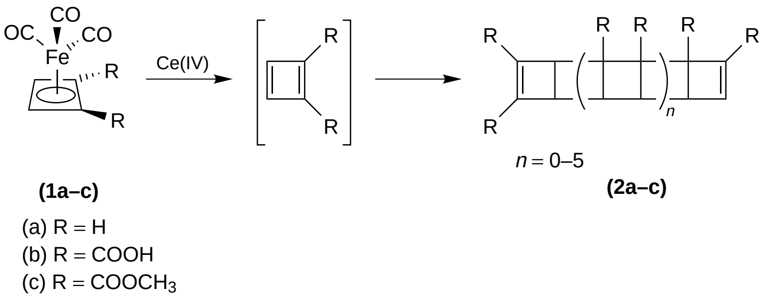

Figure 14 Synthesis of [*n*]-ladderanes through cyclobutadiene oligomerization

conjugated polyenes in the same molecule, while the second one is intermolecular, relying on the reaction between two molecules. The second approach requires the reactants to be highly organized and, so far, has been applied only in the solid state.

The first approach has been pioneered by Hopf and coworkers by covalently attaching polyene chains onto a rigid molecular fragment, a [2.2]-paracyclophane.[54] The paracyclophane scaffold serves as a template to hold the two polyenes in the vicinity for a sequential [2 + 2] photodimerization. The covalent attachment of the polyene chains onto the cyclophane effectively makes the dimerization an intramolecular process (Figure 15). Upon UV-irradiation in solution, single isomers of the [3]- and the [5]-ladderane are obtained in excellent yields (100% and 80%, respectively).[55]

Using the second approach, [3]-ladderane has been synthesized using arene-perfluoroarene interactions to bring reactant polyenes together in the crystal (Figure 16). The reaction yields are low (20–25%) and limited by the breakdown of the crystal as the reaction proceeds.[56]

Most recently, the methods of template-directed solid-state synthesis[57] were employed to construct the [3]- and the [5]-ladderane. The construction involved a resorcinol derivative (5-methoxyresorcinol) as a linear template to organize pyridine-substituted polyenes for the reaction within discrete molecular assemblies in solids. The assemblies are

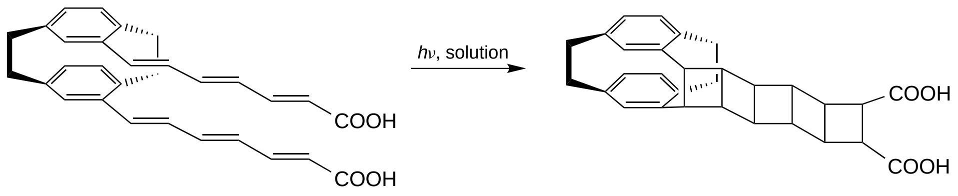

Figure 15 Synthesis of a [5]-ladderane using the paracyclophane scaffolding as a template

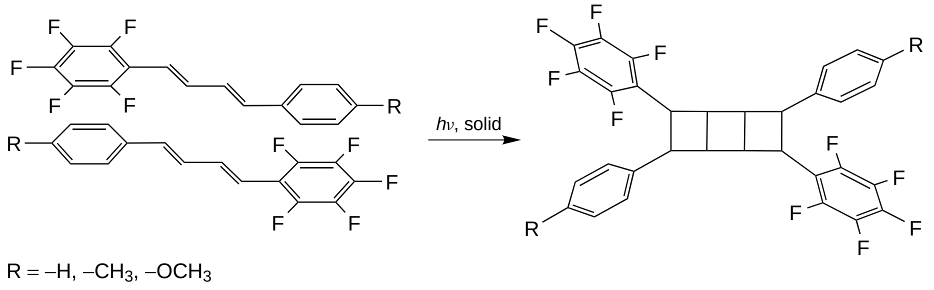

Figure 16 Synthesis of a [3]-ladderane in the solid state

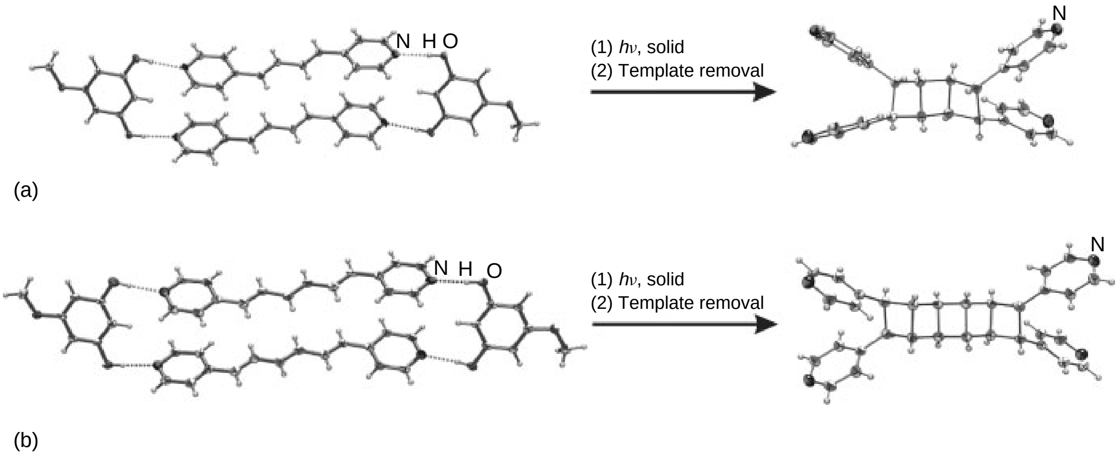

Figure 17 Template-directed solid-state synthesis of the [3]- (a) and the [5]-ladderane (b)

held together via O–H···N hydrogen bonds between hydroxyl groups of the template and pyridine nitrogen atoms of the reactant (Figure 17). While the liaison between the template and the reactant is based on a noncovalent interaction, the intermolecular nature of the photodimerization is retained. Upon UV-irradiation of each assembly in the solid, single isomers of the [3]- and the [5]-ladderane were obtained in 100% yield.[58]

1 INTRODUCTION

Metal carbonyls are compounds containing one or more M–CO bonds, where M is a transition metal, that is, an element possessing an incomplete d shell, of electronic configuration d^n $(0 < n < 10)$. However, there are some examples of compounds of this class containing metals with a completely filled (d^{10}) or an empty (d^0) shell.[1–5] A few carbonyl derivatives are also known for lanthanide[6] and actinide[7] cations, of 4f and 5f electronic configuration, respectively. Outside the d and f transition series, carbonyl derivatives have been reported, the best described examples being those of boron(III), which have been crystallographically established, with ν_{CO}'s at 2176 cm^{-1} for $B(BCl_2)_3(CO)$[8] and at 2251 cm^{-1} for $B(CF_3)_3(CO)$.[9] Moreover, unstable combinations with CO, such as $Be(CO)_n$[10] and $B_4(CO)_2$[11] are known for main group elements, as prepared by the metal vaporization technique, that is, by contacting carbon monoxide with the metal vapor quenched in a solid matrix around 20 K or lower.[10,11]

Carbon monoxide is the product of partial combustion of carbon, the ΔH_f^0 being $-110.4\,kJ\,mol^{-1}$. Its enthalpy of dissociation ($1073\,kJ\,mol^{-1}$) is the highest known for a diatomic molecule. In agreement with the oxidation state +II for carbon, CO can be prepared by a *syn*-proportionation reaction ($\Delta G^0 = +120.1\,kJ\,mol^{-1}$), favored at high temperature (equation 1).

$$C(s) + CO_2(g) \rightleftharpoons 2CO(g) \qquad (1)$$

$$\overset{-}{C}\equiv\overset{+}{O} \longleftrightarrow :C=\ddot{O}:$$

(**1**)

The electronic structure of CO, in valence bond terms, can be visualized as (**1**).

Carbon monoxide can undergo base-catalyzed reactions with, for example, alcohols or secondary amines, yielding formates HCO_2R or formamides $HCONR_2$. Also, acid-catalyzed reactions of CO are known, such as the carbonyl insertion in toluene to give *p*-toluylaldehyde (equation 2) in the presence of HF/BF_3.

$$Me–C_6H_5 + CO \xrightarrow{HF/BF_3} p\text{-}Me–C_6H_4CHO \qquad (2)$$

The formyl cation HCO^+ (ν_{CO} at 2110 cm^{-1}) is generated from CO under pressure in the presence of HF/SbF_5.[12] Concentrated sulfuric acid or the HCl/CuCl system, activates carbon monoxide toward the electrophilic attack on aromatic hydrocarbons to form aromatic aldehydes (Gatterman–Koch reaction). Branched carboxylic acids are obtained from alkenes and CO in the presence of concentrated sulfuric acid (Koch process) (equation 3).[13]

$$Me_2C{=}CH_2 + CO + H_2O \longrightarrow Me_3C–CO_2H \qquad (3)$$

Carbon monoxide forms binary combinations with transition metals. Well-established examples are the metal carbonyls of the 3d series: $V(CO)_6$, $Cr(CO)_6$, $Mn_2(CO)_{10}$, $Fe(CO)_5$, $Co_2(CO)_8$, $Ni(CO)_4$.

When carbon monoxide is bonded to a transition element, in a positively charged or even uncharged compound, the electrophilic capacity of carbon increases compared with the isolated molecule. Examples of nucleophilic attack are in equations (4) and (5). The reaction of methyl–lithium with $W(CO)_6$ giving the anionic acyl complex of equation (4a) is followed by alkylation to the carbene derivative of equation (4b). The formation of a carbamoyl complex with *cis*-$PtCl_2(CO)_2$ is shown in equation (5).

$$W(CO)_6 + LiMe \longrightarrow Li[W(CO)_5C(O)Me] \qquad (4a)$$

$$Li[W(CO)_5C(O)Me] \xrightarrow{Me_3O^+} W(CO)_5C(OMe)Me \qquad (4b)$$

$$cis\text{-}PtCl_2(CO)_2 + 2R_2NH \longrightarrow NH_2R_2[cis\text{-}PtCl_2(CO)C(O)NR_2] \qquad (5)$$

2 SYNTHESIS

2.1 Generalities

Binary metal carbonyls span a wide range of oxidation states from positive,[14] for example, +III in $[Ir(CO)_6]^{3+}$, to

Table 1 Binary metal carbonyls stable at room temperature[a]

Compound	d^n Electronic configuration	Color and properties
$[Ti(CO)_6]^{2-}$	$3d^6$	Dark violet[b]
$[Zr(CO)_6]^{2-}$	$4d^6$	Dark purple[b]
$[Hf(CO)_6]^{2-}$	$5d^6$	Deep red[b]
$[V(CO)_6]^{-}$	$3d^6$	Yellow[c]
$[Nb(CO)_6]^{-}$	$4d^6$	Yellow[c]
$[Ta(CO)_6]^{-}$	$5d^6$	Yellow[c]
$V(CO)_6$	$3d^5$	Black–green, slightly soluble in hydrocarbons, paramag., dec. 70 °C
$[Cr(CO)_5]^{2-}$	$3d^8$	Yellow[c]
$[Mo(CO)_5]^{2-}$	$4d^8$	Yellow[c]
$[W(CO)_5]^{2-}$	$5d^8$	Yellow[c]
$Cr(CO)_6$	$3d^6$	Colorless, slightly soluble in hydrocarbons, dec. 130 °C
$Mo(CO)_6$	$4d^6$	Colorless, slightly soluble in hydrocarbons
$W(CO)_6$	$5d^6$	Colorless, slightly soluble in hydrocarbons
$Mn_2(CO)_{10}$	$3d^7$	Golden yellow, moderately soluble in hydrocarbons, mp 154–155 °C
$Tc_2(CO)_{10}$	$4d^7$	Colorless, moderately soluble in hydrocarbons, mp 159–160 °C
$Re_2(CO)_{10}$	$5d^7$	Colorless, moderately soluble in hydrocarbons, mp 177–178 °C
$[Mn(CO)_6]^{+}$	$3d^6$	Colorless[d]
$Fe(CO)_5$	$3d^8$	Yellow, miscible with hydrocarbons, mp −20.5 °C, bp 103–104 °C (extrap.)
$Fe_2(CO)_9$	$3d^8$	Orange, almost insoluble in inert organic solvents, dec. ca. 100 °C
$Fe_3(CO)_{12}$	$3d^8$	Black–green, moderately soluble in hydrocarbons, dec. ca. 140 °C
$Co_2(CO)_8$	$3d^9$	Orange, soluble in hydrocarbons, dec. 51–52 °C
$Co_4(CO)_{12}$	$3d^9$	Black, slightly soluble in hydrocarbons
$Co_6(CO)_{16}$	$3d^9$	Black, dec. ca. 100 °C
$Rh_4(CO)_{12}$	$4d^9$	Dark red, dec. ca. 150 °C
$Rh_6(CO)_{16}$	$4d^9$	Black, dec. ca. 220 °C
$Ir_4(CO)_{12}$	$5d^9$	Canary yellow, dec. ca. 210 °C
$Ni(CO)_4$	$3d^{10}$	Colorless, miscible with hydrocarbons, mp −19.3 °C, bp −42.1 °C

[a]For the mononuclear and dinuclear compounds, except $V(CO)_6$, the number of valence electrons per metal atom is 18. The EAN (effective atomic number) of the metal is the number of electrons of the d^n configuration added to twice the number of CO groups, one electron being further added in the case of metal–metal bonded dinuclear systems. For trinuclear, tetranuclear, and hexanuclear compounds (metal–carbonyl clusters), the cluster valence electron counting is 48, 60, and 86, respectively. [b]As the $[K(cryptand\ 2.2.2)]^+$ derivative. [c]As the tetraalkylammonium derivative. [d]As the tetrachloroaluminate.

negative,[15,16] for example, −IV in $[M(CO)_4]^{4-}$ (M = Cr, Mo, W). Interesting cases of intermediate oxidation states are the hexacarbonyl metalates(−II)[17–19] of the group 4 metals (Ti, Zr, Hf) of formula $[M(CO)_6]^{2-}$. Some relevant examples of anionic, neutral, and cationic binary metal carbonyls are listed in Table 1.

In practice, nickel is the only metal which, when activated and finely divided, can be converted into the corresponding carbonyl $Ni(CO)_4$ under mild conditions of temperature and pressure (equation 6). This compound, discovered[20] by Mond and coworkers, has played an important role in both the development of nickel-catalyzed organic syntheses[13] and in the technical manufacture of nickel.

$$Ni(s) + 4CO(g) \longrightarrow Ni(CO)_4(g) \qquad (6)$$

Important aspects of the synthesis of metal carbonyls by reductive ligation (*see Reductive Ligation*) are (a) the reducing agent; (b) the reaction medium; and (c) the pressure of CO and the temperature.

2.1.1 *The Reducing Agent*

Reduction of a readily available inorganic compound is usually required to prepare the corresponding carbonyl derivative. The choice of the reducing agent is usually the most critical point in the synthesis. Sometimes, no additional reducing agent is necessary, when CO plays this role. The oxidation products are CO_2 ($\Delta G_f^0 = -394\,kJ\,mol^{-1}$) or $COCl_2$ ($\Delta G_f^0 = -206\,kJ\,mol^{-1}$), if the starting material is a metal oxide or a metal chloride, respectively. The reductive carbonylation is mostly used with metal oxides and metal chlorides of a covalent nature, that is, in relatively high oxidation states. Decacarbonylditechnetium(0) and decacarbonyldirhenium(0) can be prepared by heating $NH_4[MO_4]$, M = Tc, Re, with carbon monoxide under pressure at high temperature, the reducing agent being CO, with the possible participation by the ammonium cation, vide infra.

Molecular hydrogen can be used as a reducing agent in the presence of CO; the equimolar CO/H_2 synthesis gas mixture is employed to reduce metal carboxylates (equation 7). Metal alkyls or aryls, such as Grignard reagents (*see Grignard Reagents*), lithium alkyls or aryls, and aluminum alkyls, have

been used for the preparation of metal–carbonyl derivatives. With a metal chloride as the starting material, ligand exchange occurs, followed by reduction due to homolytic cleavage of the metal–carbyl (alkyl or aryl) bond.

$$M(O_2CR)_n + mCO + \frac{n}{2}H_2 \longrightarrow nRCO_2H + M(CO)_m \quad (7)$$

Electropositive metals characterized by low standard reduction potentials (alkali metals, Mg, Zn) have been frequently used for the reduction of transition metal halides in the presence of carbon monoxide. The finely divided reducing metal is previously activated by one of the conventional methods. Ethers are frequently used as reaction media.

The reduction may be accompanied by secondary reactions with formation of carbon–carbon bonds (see equation 8). The products with $n = 2$ contain the acetylenediolate anion $[C_2O_2]^{2-}$, the sodium, potassium, rubidium, and cesium derivatives being isotypical; the reaction of CO with a potassium melt leads to the product with $n = 6$, containing the anion of hexahydroxybenzene, $[C_6O_6]^{6-}$.[21]

$$nCO + ne^- \longrightarrow [(CO)_n]^{n-} \quad (8)$$

2.1.2 The Reaction Medium

In dry methods, no solvent is used. In wet methods, an anhydrous organic solvent is employed, normally hydrocarbons or ethers. Exceptionally, in the case of the carbonyl derivatives of palladium(II), platinum(II), and gold(I), thionyl chloride is used as solvent, as it provides the rigorously anhydrous conditions for the survival of the reaction product. In certain cases, water can also be used as the reaction medium with or without the addition of a specific reducing agent. In the latter case, CO is the reducing agent and carbonate is the corresponding oxidation product. Reducing agents such as $Na_2S_2O_4$ or formamidinesulfinic acid have also been used.

2.1.3 Temperature and Pressure of CO

The preparative procedures reported in the literature usually require high temperature (50–200 °C) and pressure (50–300 atm). On a laboratory scale, attention has been paid to design new preparative methods operating at ambient or slightly higher temperature and atmospheric pressure for safety reasons and for avoiding the use of expensive stainless steel autoclaves. The solubility of CO in the reaction medium increases with pressure; in organic solvents, the concentration of CO in solution is about 7×10^{-3} M at atmospheric pressure. The rate of reduction of the metal species must match the rate of transfer of CO from the gas phase to the solution, and efficient stirring is therefore essential. Methods of preparation that use mild reaction conditions will be specifically noted in the following subsections.

Reviews have appeared on preparative and structural aspects of metal carbonyls.[22–25]

2.2 Group 6

The neutral mononuclear carbonyls of this group have the formula $M(CO)_6$ (M = Cr, Mo, W) (see Table 1). Hexacarbonylchromium(0) can be prepared by treating anhydrous $CrCl_3$ with the phenyl Grignard reagent PhMgBr in THF with CO under pressure at temperatures between −4 and +10 °C. The intermediacy of the chromium(III) derivative $CrPh_3(THF)_3$ in this process has been claimed. A hydrolytic step is required to obtain $Cr(CO)_6$, which suggests that chromium under the reaction conditions is possibly converted to $MgPh^+[Cr(CO)_5C(O)Ph]^-$. Another preparation of $Cr(CO)_6$ involves the reductive carbonylation of several chromium(III) salts under CO pressure (100–300 atm) at 130–180 °C in pyridine as the medium; both magnesium and zinc are used as reductants. Pyridine is essential for this reaction, and zinc and magnesium have a synergic effect; presumably, the formation of the pyridine radical anion is important for the reduction.[23]

The hexacarbonyls of chromium, molybdenum, and tungsten can be prepared by reacting a metal salt with AlR_3 in the presence of CO; yields as high as 92% (Cr), 76% (Mo), and 92% (W) are obtained. Anhydrous $CrCl_3$ can be reduced by $Al/AlCl_3$ in benzene at 140–150 °C under a CO pressure. The intermediacy of the $[Cr(C_6H_6)_2]^+$ cation, which is the primary product of the reaction in the $CrCl_3/Al/AlCl_3$/benzene system in the absence of CO, has been suggested in the carbonylation process.[23]

2.3 Group 7

Decacarbonyldimanganese(0), $Mn_2(CO)_{10}$, was originally prepared from MnI_2, Mg, Cu, and CuI in Et_2O under CO pressure (200 atm) at room temperature. The best method available for the preparation of $Mn_2(CO)_{10}$ is the alkylation of anhydrous manganese(II) acetate with AlR_3 in i-Pr_2O under CO pressure at 60–140 °C. A synthesis operating at atmospheric pressure of CO uses the methylcyclopentadienyl derivative of manganese(I), $Mn(MeC_5H_4)(CO)_3$, which is reduced by sodium in diglyme (16–20% yield).[23]

Decacarbonylditechnetium, $Tc_2(CO)_{10}$, requires some special precautions since technetium is a β-emitter. $Tc_2(CO)_{10}$ has been proposed as the starting material for the preparation of technetium compounds with potential radiopharmaceutical properties.[26] The original method of preparing $Tc_2(CO)_{10}$ consists of treating the heptoxide, Tc_2O_7, with CO under pressure (250–350 atm) at 220–275 °C (equation 9; M = Tc).[23]

$$M_2O_7 + 17CO \longrightarrow 7CO_2 + M_2(CO)_{10} \quad (9)$$
$$M = \text{Tc, Re}$$

The rhenium analog, $Re_2(CO)_{10}$, can be prepared similarly. The heptoxides of technetium(VII) and rhenium(VII) are difficult to handle. The primary products of technetium and rhenium manufacturing are the tetraoxo anions $[MO_4]^-$. Some synthetic procedures for preparing $M_2(CO)_{10}$ from the potassium or ammonium tetraoxometalates(VII) have been reported.[23] $K[ReO_4]$ can be reductively carbonylated to form $Re_2(CO)_{10}$ under CO pressure (300 atm) at 300 °C with copper as reducing agent. The carbonylation of $NH_4[ReO_4]$ under CO pressure (100 atm) at about 190 °C is reported to give a 69% yield of $Re_2(CO)_{10}$ with the reduction being carried out by CO. Evidence exists that the ammonium cation also participates in the reduction process: a by-product of the reaction is the cyano derivative $Re_3(CN)_3(CO)_{12}$, whose molecular structure has been established crystallographically to consist of a triangular arrangement of $Re(CO)_4$ units connected by CN bridges (*see* ***Cyanide Complexes of the Transition Metals***).[27] Application of this method to $NH_4[TcO_4]$ gave a 90% yield of $Tc_2(CO)_{10}$ under less drastic conditions than those required for $NH_4[ReO_4]$. The use of $Al(i\text{-}Bu)_2H$ as a reducing agent allows the carbonylation of $NH_4[ReO_4]$ to be carried out at atmospheric pressure of CO at 70–80 °C, the yield of $Re_2(CO)_{10}$ being about 60%.[28]

2.4 Group 8

Pentacarbonyliron(0) is obtained by carbonylation of anhydrous FeI_2 under drastic conditions (200 °C, 200 atm of CO pressure) in the presence of copper as halogen acceptor.[23] This is consistent with the observation that iodo-carbonyls of group 11 metals (Cu, Ag, Au) are unstable with respect to the corresponding metal iodides, and no contamination from other carbonyl products can occur from the use of copper. The yields of $Fe(CO)_5$ are essentially quantitative; considerably lower yields are obtained with $FeCl_2$ (1%) or $FeBr_2$ (20%). Pentacarbonyliron(0) can also be obtained from finely divided iron at 200 °C under pressure (200 atm) of CO, especially in the presence of chalcogens (sulfur or selenium) as promoters. In the presence of sulfur (0.3 at.%), an excellent yield of $Fe(CO)_5$ (94%) is obtained; selenium (0.3 at.%; 93% yield) and tellurium (1 at.%; 89% yield) are equally good under comparable conditions. Probably iron-carbonyl chalcogenides are formed as intermediates.[23] Some compounds of this type have been reported by independent syntheses and have also been structurally characterized.[29–31]

Enneacarbonyldiiron(0), $Fe_2(CO)_9$, is best prepared[23] by visible-light irradiation of solutions of $Fe(CO)_5$ in glacial acetic acid at 10–15 °C (equation 10). The pentacarbonyl is completely miscible in $MeCO_2H$, and the substantially insoluble enneacarbonyl is recovered by filtration. With the quantum yield being 2, this reaction probably occurs by the mechanism shown in equations (11a) and (11b), through the intermediate tetracarbonyl species. Irradiation of $Fe(CO)_5$ in $CF_3COOH/(CF_3CO)_2$ under exclusion of air yields $Fe(CF_3COO)_2$ as the main product, no $Fe_2(CO)_9$ being observed.[32]

$$2Fe(CO)_5 \xrightarrow{h\nu} Fe_2(CO)_9 + CO \quad (10)$$

$$Fe(CO)_5 \xrightarrow{h\nu} {}^*Fe(CO)_4 + CO \quad (11a)$$

$${}^*Fe(CO)_4 + Fe(CO)_5 \longrightarrow Fe_2(CO)_9 \quad (11b)$$

The trinuclear $Fe_3(CO)_{12}$ is best prepared in aqueous solution by oxidation of $[FeH(CO)_4]^-$, the latter being obtained from $Fe(CO)_5$ in alkaline solution (see equations 12 and 13). As the oxidizing agent for $[FeH(CO)_4]^-$, dioxygen, copper(II), or MnO_2 can be used.[23]

$$Fe(CO)_5 + 2NaOH \longrightarrow Na[FeH(CO)_4] + NaHCO_3 \quad (12)$$

$$3[FeH(CO)_4]^- \longrightarrow Fe_3(CO)_{12} + 6e^- + 3H^+ \quad (13)$$

Pentacarbonylruthenium(0), $Ru(CO)_5$, a colorless liquid decomposed by light to $Ru_3(CO)_{12}$, can be prepared by reacting RuI_3 with CO (450 atm) at 170 °C in the presence of a large excess of silver as iodine acceptor. The volatile pentacarbonyl is recovered by gas-phase transfer into a cold trap under CO and then converted into $Ru_3(CO)_{12}$ at room temperature by reducing the partial pressure of CO.[23] The vapor pressure of $Ru(CO)_5$, a colorless liquid at room temperature, is 112 mbar at 19.3 °C with the equation $\ln p = -5072/(T + 21.95)$ being obeyed between 258 and 323 K, with a ΔH_{ev}[33] of $(42.2 \pm 0.6)\,\text{kJ mol}^{-1}$. Trisacetylacetonatoruthenium(III) is converted to $Ru(CO)_5$ or $Ru_3(CO)_{12}$ by CO and H_2 under pressure at high temperature in methanol or heptane as solvent. Bis(acetylacetonato)dicarbonylruthenium(II), *cis*-$Ru(acac)_2(CO)_2$, is probably an intermediate in this reaction.[34] Preparations of $Ru_3(CO)_{12}$ at atmospheric pressure of CO have been reported using the hydrated ruthenium(III) chloride $RuCl_3{\cdot}xH_2O$ or $[Ru_3O(MeCO_2)_6(H_2O)_3]MeCO_2$ in 2-ethoxyethanol or *iso*-propanol, respectively.

Pentacarbonylosmium(0) can be prepared by reacting OsO_4 with CO at high temperature and pressure in a hydrocarbon solvent.[35] Precautions should however be taken to avoid the spontaneous decarbonylation of the pentacarbonyl to the trinuclear cluster (see equations 14 and 15). If CO/H_2 mixtures are used, the product of the carbonylation under these conditions is the dihydrido compound *cis*-$OsH_2(CO)_4$ (see equation 16), spectroscopically established.

$$OsO_4 + 9CO \longrightarrow 4CO_2 + Os(CO)_5 \quad (14)$$

$$3Os(CO)_5 \longrightarrow Os_3(CO)_{12} + 3CO \quad (15)$$

$$OsO_4 + 8CO + H_2 \longrightarrow 4CO + cis\text{-}OsH_2(CO)_4 \quad (16)$$

2.5 Group 9

Octacarbonyldicobalt(0), $Co_2(CO)_8$, is usually prepared by carbonylation of cobalt(II) salts of organic or inorganic acids

with syngas (1:1, CO/H_2) at high temperature and pressure in a hydrocarbon solvent (see equation 17 for the carboxylate). When a Lewis base is used as solvent and preformed $Co_2(CO)_8$ is introduced, excellent yields of $Co_2(CO)_8$ are obtained at 30 °C and 180 atm of H_2 (100 atm) and CO (80 atm).[23]

In the synthesis of octacarbonyldicobalt(0), an important by-product is the hydride $CoH(CO)_4$, which is promptly decomposed to $Co_2(CO)_8$ by adventitious oxygen or spontaneously (equation 18) (*see* ***Hydride Complexes of the Transition Metals***).

$$Co(O_2CR)_2 + 8CO + 2H_2 \longrightarrow Co_2(CO)_8 + 4RCO_2H \quad (17)$$

$$2CoH(CO)_4 \rightleftharpoons H_2 + Co_2(CO)_8 \quad (18)$$

The reverse of equilibrium (equation 18), that is, the formation of $CoH(CO)_4$ from $Co_2(CO)_8$ and dihydrogen has been the subject of several investigations:[36] the hydrido species is formed in an endothermic process, higher concentrations of the product being therefore present at higher temperatures.

The tetracarbonylcobaltate(−I) anion, $[Co(CO)_4]^-$, from which $Co_2(CO)_8$ can be obtained by controlled oxidation, is prepared by carbonylation of an aqueous alkaline solution of cobalt(II) (equation 19). Carbon monoxide is the reducing agent, and the reaction is carried out at atmospheric pressure at room temperature.[23]

$$2Co^{2+} + 12OH^- + 11CO \longrightarrow 2[Co(CO)_4]^- + 3CO_3{}^{2-} + 6H_2O \quad (19)$$

Finely divided cobalt, as obtained from anydrous cobalt halides with Li/naphthalene in glyme, is converted to $Co_2(CO)_8$ in good yields at 100 °C and 95 atm of pressure.

Dodecacarbonyltetracobalt(0), $Co_4(CO)_{12}$, is the product of thermal decarbonylation of $Co_2(CO)_8$ (equation 20). This equilibrium was the first metal–cluster forming reaction to be studied from a thermodynamic viewpoint, as a function of temperature, in 1954.[37] The thermodynamic parameters were estimated: $\Delta H^0 = (123.3 \pm 2)\,\mathrm{kJ\,mol^{-1}}$, $\Delta S^0 = (564.3 \pm 12.5)\,\mathrm{J\,mol^{-1}\,K^{-1}}$.[38]

$$2Co_2(CO)_8 \rightleftharpoons Co_4(CO)_{12} + 4CO \quad (20)$$

Dodecacarbonyltetracobalt(0) can be directly prepared by reducing cobalt(II) salts (2-ethylhexanoate or acetylacetonate) with dihydrogen in the presence of the stoichiometric amount of $Co_2(CO)_8$ (equation 21). Yields are 90% or better.[23]

$$3Co_2(CO)_8 + 2Co(O_2CR)_2 + 2H_2 \longrightarrow 2Co_4(CO)_{12} + 4RCO_2H \quad (21)$$

Dodecacarbonyltetrarhodium(0), $Rh_4(CO)_{12}$, is prepared from $RhCl_3$ and CO at 200 atm in the presence of a halogen acceptor, such as copper, silver, cadmium, or zinc. The nature of the products depends on the temperature: at 50–80 °C the tetranuclear compound is mainly formed, whereas at 80–230 °C the product is $Rh_6(CO)_{16}$. This is consistent with an endothermic equilibrium from the tetramer to the hexamer (equation 22). A two-step synthesis of $Rh_4(CO)_{12}$ at room temperature and atmospheric pressure involves the reduction of the $[RhCl_6]^{3-}$ anion to $[RhCl_2(CO)_2]^-$ with copper, followed by reduction with water and CO in the presence of a sodium citrate buffer. The yields are nearly quantitative.[23]

$$\frac{3}{2}Rh_4(CO)_{12} \rightleftharpoons Rh_6(CO)_{16} + 2CO \quad (22)$$

Dodecacarbonyltetrarhodium (0) and $Rh_2(CO)_8$ are related by a temperature-dependent equilibrium (see equation 23), similar to the equilibrium (equation 20) involving the corresponding cobalt species. On the other hand, $Rh_2(CO)_8$, characterized by carbonyl stretching vibrations at 2084, 2060, 1862, and 1847 cm^{-1} (hexane) can only be observed at relatively low temperatures (between 19.5 and −15.2 °C) and at elevated pressure of CO (198 atm).[39] The thermodynamic parameters for the formation of the tetranuclear species from $Rh_2(CO)_8$ are: $\Delta H^0 = (58.6 \pm 10)\,\mathrm{kJ\,mol^{-1}}$; $\Delta S^0 = (305 \pm 25)\,\mathrm{J\,mol^{-1}\,K^{-1}}$.

$$2Rh_2(CO)_8 \rightleftharpoons Rh_4(CO)_{12} + 4CO \quad (23)$$

The $Rh_4(CO)_{12}/H_2/CO$ system was studied[40] under pressure by IR spectroscopy and shown to produce $RhH(CO)_4$ with carbonyl stretching bands at 2124, 2072, and 2042 cm^{-1}. The formation of the hydride from the tetranuclear species was associated with a $\Delta H_r = -(82.4 \pm 16.2)\,\mathrm{kJ\,mol^{-1}}$ and $\Delta S_r = -(0.44 \pm 0.06)\,\mathrm{kJ\,mol^{-1}\,K^{-1}}$.

Decacarbonyltetrairidium(0), $Ir_4(CO)_{12}$, is prepared normally by carbonylation of iridium halides in the presence of a halogen acceptor (copper or silver), usually at high temperature and pressure. A method of preparation operating at atmospheric pressure requires the carbonylation of $Na_2[IrCl_6]$ or $Na_3[IrCl_6]$ in the presence of NaI in methanol, followed by treatment with a base (74–78% yield). A nearly quantitative yield of $Ir_4(CO)_{12}$ is reported by treating $IrCl_3{\cdot}3H_2O$ or $(NH_4)_2[IrCl_6]$ with 98% HCO_2H, which acts as both the reagent and the reaction medium (see equation 24) at 100 °C in a sealed vessel.[23]

$$4IrCl_3 + 18HCO_2H \longrightarrow Ir_4(CO)_{12} + 12H_2O + 6CO_2 + 12HCl \quad (24)$$

2.6 Group 10

In a systematic study of the carbonylation of nickel halides, NiX_2, in the presence of copper or silver as halogen acceptors (10 h, 250 °C, 200 atm of CO pressure), conversion to $Ni(CO)_4$ decreases from X = I (quantitative) to Br (1%) and Cl (2%). Carbonylation at atmospheric pressure of an aqueous solution of a nickel(II) salt in the presence of a reducing agent such as $[S_2O_4]^{2-}$ gives $Ni(CO)_4$.[23]

Table 2 Carbonyl stretching vibrations of the tetracarbonyls of group 10

Compound	$\tilde{\nu}_{CO}(cm^{-1})$	k_{CO}(mdyn Å^{-1})
$Ni(CO)_4$	2052	17.23
$Pd(CO)_4$[a]	2070	17.55
$Pt(CO)_4$[a]	2053	17.28

[a]Prepared from the metal vapor in a CO matrix at about 20 K.

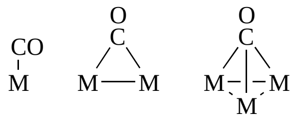
At variance with the easy accessibility of $Ni(CO)_4$, the corresponding tetracarbonyls of palladium(0) and platinum(0), $Pd(CO)_4$ and $Pt(CO)_4$, have been identified only spectroscopically (IR) at low temperature, both being prepared by vaporization of the metal followed by reaction with CO in a solid matrix at about 20 K. These compounds decompose at higher temperature. Table 2 shows the IR spectroscopic properties of the tetracarbonyls of nickel, palladium, and platinum, as obtained by vaporization of the corresponding metal, measured under the same experimental conditions. The compounds show one carbonyl stretching vibration, as expected for the tetrahedral geometry. The values of $\tilde{\nu}_{CO}$ and the C–O force constant of $Pd(CO)_4$ are higher than those of both $Ni(CO)_4$ and $Pt(CO)_4$ (see Section 7).[41–43] Attempts have been made[44] to isolate the tetracarbonyl of platinum(0) by carbonylation of some olefin complexes of platinum(0), in particular, the norbornene derivative $Pt(C_7H_{10})_3$. The reaction, carried out in toluene as solvent and at room temperature or lower, was monitored gasvolumetrically and shown to lead to an amorphous, insoluble, and unstable carbonyl derivative of platinum with a CO:Pt molar ratio of 2 under the best conditions. By using catalytic amounts of CO, the starting olefin complex of platinum is converted to platinum metal at room temperature. These experiments show conclusively that platinum(0)-carbonyl derivatives of low nuclearity are not stable even under the mild conditions used for the carbonylation experiments.

3 MOLECULAR STRUCTURES

Uncharged mononuclear and polynuclear metal carbonyls are known for the group 5 to group 10 metals. The EAN rule (*see Effective Atomic Number Rule*) is normally obeyed, so elements with an even atomic number form mononuclear compounds, for example, $Cr(CO)_6$, $Fe(CO)_5$, and $Ni(CO)_4$, while elements with an odd atomic number form dinuclear compounds, for example, $Mn_2(CO)_{10}$ and $Co_2(CO)_8$, containing metal–metal bonds.

Especially with 4d and 5d elements, polynuclear compounds with metal–metal bonds (metal–carbonyl clusters;[45–49] *see Cluster*) are formed under reduced carbon monoxide pressure and/or high temperature. Heteronuclear metal–carbonyl clusters are also known (*see* ***Polynuclear Organometallic Cluster Complexes***).[50]

The principal bonding arrangements of carbon monoxide are (a) terminal (**2**); (b) doubly bridging (**3**), and (c) triply bridging (**4**) (*see Bridging Ligand*). In polynuclear metal–carbonyl clusters where the metal atoms define a polyhedron, doubly bridging carbonyl groups are also called *edge-bridging*, whereas face-bridging is synonymous with triply bridging ligands. The terminal M–CO bond is nearly linear. Table 3 contains the structural features of some relevant metal carbonyls.



(**2**) (**3**) μ_2-CO (**4**) μ_3-CO

3.1 Group 6

The hexacarbonyls of chromium, molybdenum, and tungsten are mononuclear; the internal bonding parameters are presented in Table 3. The coordination geometry is that of a regular octahedron of idealized O_h symmetry. The crystal packing is due to weak van der Waals interactions (*see van der Waals Forces*), which explains the volatility of these compounds (the vapor pressures of $Cr(CO)_6$, $Mo(CO)_6$, and $W(CO)_6$ at 30 °C are 0.28, 0.27, and 0.06 mmHg, respectively), and their solubility in organic solvents.[23]

3.2 Group 7

The decacarbonyls of manganese, technetium, and rhenium, of formula $M_2(CO)_{10}$, have terminal carbonyl groups and a metal–metal bond. The molecular symmetry is D_{4d} with the two $M(CO)_5$ fragments in a staggered conformation. The heterodinuclear decacarbonyl $MnRe(CO)_{10}$ is also known as obtained by the redox reaction of a rhenium pentacarbonyl halide with the pentacarbonylmanganate(−I) anion at room temperature (at 160 °C or higher, the heterodinuclear carbonyl tends to form the homodinuclear compounds with an equilibrium constant close to the statistical value[51]). The X-ray diffraction study of $MnRe(CO)_{10}$ has shown the Mn–Re distance of 2.909 Å to be shorter than the sum of the covalent radii obtained from the homodinuclear compounds (Table 3).

3.3 Group 8

The molecular structure of $Fe(CO)_5$, determined on the solid compound below its freezing point (−20.5 °C) by X-ray diffraction, is trigonal bipyramidal (D_{3h} symmetry). An

[a]XR = X-ray diffraction; ED = electron diffraction. [b]CO_t = terminal CO. [c]CO_b = bridging CO. Number in parentheses refers to the estimated standard deviation in the least significant digit. [d]Disordered structure.

electron-diffraction study showed a significant difference in the Fe–CO bond distance between the axial and the equatorial carbonyl groups (see Table 3).

$Fe_2(CO)_9$ is a sparingly soluble molecule in most organic inert solvents; the molecule contains three bridging carbonyl groups connecting the two $Fe(CO)_3$ units, and it can be described as $(OC)_3Fe(\mu_2\text{-}CO)_3Fe(CO)_3$. The iron–iron distance is 2.523 Å, according to an X-ray diffraction study.[24]

$Fe_3(CO)_{12}$ is a trinuclear compound that contains two sets of nonequivalent iron atoms: one iron atom is hexacoordinated to four terminal carbonyl groups and to the other two iron atoms, the rest of the molecule being $(OC)_3Fe(\mu_2\text{-}CO)_2Fe(CO)_3$ with terminal and bridging carbonyl groups. The carbonyl bridges are not symmetrical.

The pentacarbonyls of ruthenium(0) and osmium(0), $M(CO)_5$ (M = Ru, Os), show two carbonyl stretching vibrations in the IR spectrum (heptane) at 2035s, 1999vs (Ru) and 2034s, 1991vs (Os) cm^{-1}. On the basis of the number of IR-active bands observed, a trigonal bipyramidal structure of D_{3h} symmetry is suggested.

The isomorphous $Ru_3(CO)_{12}$ and $Os_3(CO)_{12}$ have a highly symmetrical structure of D_{3h} symmetry with equivalent metal atoms at a bond distance of 2.848 Å (Ru) or 2.88 Å (Os). All carbonyl groups are terminal.

3.4 Group 9

The dinuclear $Co_2(CO)_8$[52,53] has a solid-state structure with two doubly bridging carbonyl groups; each cobalt atom is hexacoordinated to three terminal carbonyl groups, to the other cobalt atom, and to two bridging carbon atoms, that is, $(OC)_3Co(\mu_2\text{-}CO)_2Co(CO)_3$. The cobalt–cobalt distance is 2.530 Å (or 2.528 Å in the independent molecule). Within the terminal carbonyl groups, the M–CO bond distances differ significantly between axial and equatorial groups, as for an X-ray diffraction study at low temperature. A cobalt–cobalt interaction through the bridging carbonyl groups has been suggested on the basis of a charge-density study.[53] In solution, this molecule has been suggested to be in equilibrium with a form not containing bridging carbonyl groups (see equation 25), and further with a third isomer. The ΔG^0 of the reaction is about zero at room temperature, the equilibrium

constant being about 1.[54]

$$(OC)_3Co(\mu^2\text{-}CO)_2Co(CO)_3 \rightleftharpoons (OC)_4Co\text{–}Co(CO)_4 \quad (25)$$

This group of elements forms numerous cluster systems.[48,49] Dodecacarbonyltetracobalt, $Co_4(CO)_{12}$, has a tetrahedral arrangement of the four cobalt atoms. An apical $Co(CO)_3$ group is symmetrically coordinated by Co–Co bonds to a basal $Co_3(CO)_9$ fragment consisting of three $Co(CO)_2$ groups joined by doubly bridging carbonyl groups and by a cobalt–cobalt bond, that is, $Co_4(CO)_9(\mu_2\text{-}CO)_3$.

In hexadecacarbonylhexacobalt(0), $Co_6(CO)_{16}$, the six cobalt atoms define an octahedron. The compound is isomorphous with $Rh_6(CO)_{16}$, whose structure is described below.

Dodecacarbonyltetrarhodium(0), $Rh_4(CO)_{12}$, has essentially the same structure as $Co_4(CO)_{12}$, that is, its structure can be described as $Rh_4(CO)_9(\mu_2\text{-}CO)_3$.

In hexadecacarbonylhexarhodium(0), $Rh_6(CO)_{16}$, the six rhodium atoms form an octahedron. Each rhodium atom binds two terminal carbonyl groups, the remaining four carbonyl groups being triply (face) bridging on four triangular faces of the octahedron, that is, $Rh_6(CO)_{12}(\mu_3\text{-}CO)_4$.

At variance with the corresponding cobalt and rhodium analogs, dodecacarbonyltetrairidium(0), $Ir_4(CO)_{12}$, consists of a tetrahedron of four iridium atoms, each being bonded to three terminal carbonyl groups, no bridging carbonyl groups being present.

Two isomeric forms of hexadecacarbonylhexairidium(0), $Ir_6(CO)_{16}$, are known: a red isomer, isostructural with $Rh_6(CO)_{16}$, and a black isomer that has four *edge-bridging* carbonyl groups rather than face-bridging. The structure of the black isomer is described as $Ir_6(CO)_{12}(\mu_2\text{-}CO)_4$.

3.5 Group 10

An electron-diffraction experiment in the gas phase and an X-ray diffraction study at low temperature on solid $Ni(CO)_4$ have shown the compound to have a regular tetrahedral geometry. An accurate refinement of the structural data has established the carbonyl ligands to be *C*-bonded to nickel.[23]

4 REACTIONS OF GROUPS 6–10

Metal carbonyls can undergo three main types of reaction: (a) substitution of the carbonyl groups, (b) oxidation, or (c) reduction. No change of the oxidation state of the metal occurs for (a), while an increase or decrease of the oxidation state occurs for (b) and (c), respectively.

A special case of redox reaction commonly encountered with metal carbonyls is disproportionation in the presence of Lewis bases, as exemplified for $Co_2(CO)_8$ (see equation 26). A similar reaction (see equation 27) has been reported for hexacarbonylvanadium(0).[55] By these reactions, the tetracarbonylcobaltate(−I) and the hexacarbonylvanadate(−I) anions are generated. The crystal and molecular structure of the product of the disproportionation reaction of $V(CO)_6$ with tetrahydrofuran of formula $[V(THF)_4][V(CO)_6]_2$ has been shown[56] to consist of vanadium(II) octahedrally surrounded by four thf's in the equatorial positions and by two axial carbonyl oxygens from two hexacarbonylvanadate anions resulting in a linear V–O–C–V sequence (*see Isocarbonyl Complexes*).

$$3Co_2(CO)_8 + 12L \longrightarrow 2CoL_6[Co(CO)_4]_2 + 8CO \quad (26)$$

$$3V(CO)_6 + 6L \longrightarrow VL_6[V(CO)_6]_2 + 6CO \quad (27)$$

$$L = \text{Lewis base}$$

4.1 Substitutions

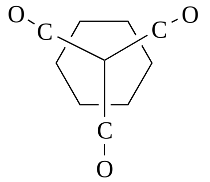
Substitution reactions may be carried out thermally, photochemically, and chemically. In a thermal substitution, heat is used to both increase the kinetics of the process and shift the equilibrium, especially when gaseous carbon monoxide is produced, the ΔS^0 of the reaction being normally positive.

One of the more extensively studied substitution reactions of the hexacarbonyls of group 6 is the formation of the tricarbonylarenemetal(0) complexes (equations 28a), satisfactory conversions being obtained by removing the CO. The tricarbonyl derivatives are converted into the hexacarbonyls with CO at room temperature. For $Mo(CO)_3(\eta^6\text{-arene})$, the carbonylation to $Mo(CO)_6$ is accelerated by catalytic amounts of iodine. This effect is explained by the formation of molybdenum(II) carbonyl complexes (some of which have been isolated and crystallographically established) containing terminal iodide ligands that may act as catalysts in the substitution reaction.[57]

$$M(CO)_6 + \text{arene} \rightleftharpoons M(CO)_3(\eta^6\text{-arene}) + 3CO \quad (28a)$$

$$M = Cr, Mo, W$$

The tricarbonyl-η^6-arene metal complexes of chromium, molybdenum, and tungsten have a pseudooctahedral geometry with the arene occupying the triangular face of the octahedron, the opposite triangular face being defined by the three carbonyl groups, usually in a staggered conformation (**5**).



(**5**)

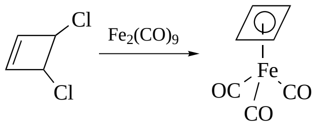
Carbonyl substitution in the hexacarbonyls $M(CO)_6$ (M = Cr, Mo, W) by the cyclopentadienyl anion gives the tricarbonyl Cp derivatives (equation 28b)

$$M(CO)_6 + C_5H_5^- \longrightarrow [M(CO)_3(\eta^5\text{-}C_5H_5)]^- + 3CO \quad (28b)$$

Photochemical substitution of a carbonyl ligand of $M(CO)_6$ in THF as solvent gives the pentacarbonyl derivatives (equation 29). The substitutionally labile THF ligand can be displaced by other ligands; this method has been used extensively to produce pentacarbonyl derivatives of these metals. Photolysis of $Cr(CO)_6$ with UV light in heptane under dihydrogen pressure (100 atm) gives the dihydrogen complex $Cr(CO)_5(H_2)$, a surprisingly stable compound with a $\tau_{1/2}$ of about 25 s at room temperature.[58]

$$M(CO)_6 + THF \xrightarrow{h\nu} M(CO)_5THF + CO \quad (29)$$

Pentacarbonyliron(0) with butadiene gives the tricarbonyl derivative $Fe(CO)_3(C_4H_6)$. Cyclobutadienetricarbonyliron(0), $Fe(CO)_3(C_4H_4)$, is prepared by dehalogenation of *cis*-3,4-dichlorobutene in the presence of $Fe_2(CO)_9$. This was the first cyclobutadiene complex to be reported in the literature (see equation 30).[59]



(30)

Several alkene complexes of iron(0) have been reported, of general formula $Fe(CO)_4$(alkene), where the alkene can be ethylene, acrylonitrile, maleic anhydride, or methyl methacrylate. In these complexes, the original trigonal bipyramidal structure of the pentacarbonyl is retained with one of the equatorial positions now being occupied by the alkene ligand. The tetracarbonyliron(0) complex of fumaric acid has idealized C_2 symmetry and has been resolved into its two enantiomers.[60]

Isocyanides displace carbon monoxide from $Fe(CO)_5$, yielding the tetracarbonyl and the tricarbonyl derivatives, $Fe(CO)_4(RNC)$ and $Fe(CO)_3(RNC)_2$, respectively.

Octacarbonyldicobalt gives substitution reactions with some difficulty because this metal carbonyl frequently undergoes facile disproportionation (*see Disproportionation*) (see equation 26), reduction, or oxidation reactions. With diphenylacetylene, $Co_2(CO)_8$ gives the substitution product $Co_2(CO)_6(C_2Ph_2)$. The molecular structure is directly derived from that of the precursor, with the acetylenic ligand being almost perpendicular to the cobalt–cobalt vector, thereby replacing the two bridging carbonyl groups.[23]

Tetracarbonylnickel(0) is quite reactive and several substitution products are known. For example, with tertiary phosphines and similar pnicogen-containing derivatives, many complexes of formula $Ni(CO)_{4-n}(ER_3)_n$ are known (see equation 31). The tertiary phosphine complexes of nickel(0) are important catalytic precursors, as in the trimerization of substituted acetylenes or in the dimerization of butadiene to *cyclo*-octa-1,5-diene.

$$Ni(CO)_4 + nER_3 \longrightarrow Ni(CO)_{4-n}(ER_3)_n + nCO \quad (31)$$
$$E = P, As, Sb, Bi$$

An example of a chemically induced substitution reaction is represented by the halide removal in $MnCl(CO)_5$ by $AlCl_3$ leading to the hexacarbonylmanganese(I) cation. The driving force of this reaction, carried out at room temperature, is represented by the high affinity of aluminum for chloride. Similarly, the corresponding rhenium(I) derivative $[Re(CO)_6]AlCl_4$ can be prepared. This complex has considerable stability in that it can be dissolved in water without prompt decomposition (equation 32).

$$MX(CO)_5 + AlX_3 + CO \longrightarrow [M(CO)_6]AlX_4 \quad (32)$$
$$M = Mn, Re; X = \text{halide}$$

4.2 Oxidations

Neutral metal carbonyls frequently undergo oxidation by air, and most of these compounds must be handled under an inert atmosphere. The derivatives of groups 6 and 7 are sufficiently inert, and the corresponding solid products can be handled in air for short periods of time. In solution, metal carbonyls may be oxidized by halogens, may be converted by dihydrogen to the corresponding hydrido complexes, may react with alkyl halides and with substances containing active protons. Frequently, oxidation of the central metal atom is followed by partial or complete loss of the carbonyl ligands, since the stability of the M–CO bond generally decreases as the oxidation state of the metal increases. Carbonyl derivatives of metals in oxidation state II or higher are known primarily for the 4d and 5d metals of groups 6–10.

Hexacarbonylchromium(0) is readily attacked by chlorine giving $CrCl_3$, CO, and $COCl_2$. Bromine and iodine do not attack $Cr(CO)_6$ to any substantial extent at room temperature. The chromium tricarbonyl arene complexes, $Cr(CO)_3(\eta^6$-arene), are readily oxidized at room temperature by I_2 to give CrI_3; this is a convenient preparative method for the anhydrous iodide. Although the oxidation of the tricarbonyl arene derivatives of chromium with I_2 does not show evidence of intermediate carbonyl complexes in oxidation states >0, the corresponding molybdenum(0) compounds give a series of carbonyl iodides of molybdenum(II),[57] for example, the ionic $[Mo(CO)_3(\eta^6$-arene)]I.

Hexacarbonylmolybdenum and β-diketones yield the molybdenum(III) chelate complexes as shown in equation (33) for acetylacetone.

$$Mo(CO)_6 + 3C_5H_8O_2 \longrightarrow 6CO + Mo(C_5H_7O_2)_3 + \{3H\} \quad (33)$$

Oxidation of the decacarbonyldimetal(0) compounds of manganese, technetium, and rhenium by halogens gives the corresponding halopentacarbonylmetal(I) complexes (see equation 34).

$$M_2(CO)_{10} + X_2 \longrightarrow 2MX(CO)_5 \qquad M = Mn, Tc, Re \tag{34}$$

Carbonyl derivatives of iron(II) exist. Pentacarbonyliron(0) is oxidized by halogens to give carbonyl halide complexes (equation 35). The stability of these compounds with respect to thermal decomposition and hydrolysis increases in the sequence $Cl < Br < I$.

$$Fe(CO)_5 + X_2 \longrightarrow \textit{cis}\text{-}FeX_2(CO)_4 + CO \tag{35}$$

Ruthenium(II) and osmium(II) form two series of halo carbonyls, $[MX_2(CO)_2]_n$ and $MX_2(CO)_4$ (M = Ru, Os).

The carbonyls of cobalt(0), $Co_2(CO)_8$ and $Co_4(CO)_{12}$, are readily oxidized by air, and halogens normally decompose them to cobalt(II) halides with quantitative evolution of CO.

The rhodium(I) derivative $Rh_2Cl_2(CO)_4$ is a chloride-bridged dimer with terminal carbonyl groups around the square-planar rhodium(I); each dinuclear unit is connected to similar units in the crystal by rhodium–rhodium contacts of 3.31 Å.

Tetracarbonylnickel(0) is readily decomposed by halogens and by several organic halides yielding nickel(II) halides under exhaustive decarbonylation. From a structural viewpoint, all dinuclear halo carbonyls, for example, $Mn_2X_2(CO)_8$ and *trans*-$Pt_2X_4(CO)_2$, have bridging halides and terminal carbonyl groups. An exception to this rule is $[Pd_2Cl_4(CO)_2]^{2-}$, a derivative of d^9 palladium(I), which has bridging carbonyl groups and terminal halides.[61,62]

4.3 Reductions

Neutral metal carbonyls usually undergo one- or two-electron reductions by several reducing agents. The reduced species normally obey the next inert gas rule and the formulas can be easily predicted accordingly. Dinuclear metal carbonyls on reduction give mononuclear anionic species; mononuclear metal carbonyls may become doubly charged with loss of CO or undergo a one-electron reduction with formation of dinuclear anions (equations 36–38).

$$M_2(CO)_n + 2e^- \longrightarrow 2[M(CO)_{n/2}]^- \tag{36}$$

$$M(CO)_n + 2e^- \longrightarrow [M(CO)_{n-1}]^{2-} + CO \tag{37}$$

$$2M(CO)_n + 2e^- \longrightarrow [M_2(CO)_{n-2}]^{2-} + 2CO \tag{38}$$

Reductions are usually carried out in nonaqueous solvents using metals with low standard reduction potentials as electron suppliers. By addition of naphthalene, the system becomes homogeneous due to the formation of the naphthalene radical anion $C_{10}H_8^-$. Soluble reducing agents in hydrocarbons include $CoCp^*_2$, or the corresponding vanadium(II) species.

In basic aqueous solution, coordinated carbon monoxide can act as a reducing agent with carbonate being the oxidation product for the case of a mononuclear compound undergoing a two-electron reduction (equation 39).

$$M(CO)_n + 4OH^- \longrightarrow CO_3^{2-} + [M(CO)_{n-1}]^{2-} + 2H_2O \tag{39}$$

Carbonyl metalates of alkali metals have been studied in solution by IR spectroscopy (see Section 5). Considerable ion pairing occurs with consequent lowering of the anion symmetry, as evidenced by the appearance of more bands than expected in the 1900–1700 cm^{-1} region. The alkali metal cation is assumed to establish an ion–dipole interaction with the carbonyl oxygens.

The hexacarbonyls of chromium, molybdenum, and tungsten are reduced by alkali metals giving the pentacarbonylmetalate(−II) anions. Reduction by $NaBH_4$ gives the dinuclear decacarbonyldimetalates(−I), $[M_2(CO)_{10}]^{2-}$, in liquid ammonia (equation 40).

$$2M(CO)_6 + 2NaBH_4 + 6NH_3 \longrightarrow Na_2[M_2(CO)_{10}] + 2CO + 2B(NH_2)_3 + 7H_2 \tag{40}$$

The dinuclear carbonyls of group 7 are reduced by alkali metals in THF (equation 41). The pentacarbonylmetalate(−I) anions are appropriate entries into the hydrido- or alkyl (aryl) pentacarbonyl derivatives (see equations 42 and 43). These compounds have pseudooctahedral structures of C_{4v} symmetry with the hydrido or alkyl (aryl) ligand occupying one of the positions within the coordination polyhedron.

$$M_2(CO)_{10} + 2Na \longrightarrow 2Na[M(CO)_5] \qquad M = Mn, Tc, Re \tag{41}$$

$$[M(CO)_5]^- + H^+ \longrightarrow MH(CO)_5 \tag{42}$$

$$[M(CO)_5]^- + R^+ \longrightarrow MR(CO)_5 \qquad M = Mn, Tc, Re \tag{43}$$

Iron carbonyls are reduced by sodium metal to the tetracarbonylferrate(−II) anion (see equation 44). The X-ray crystal structure of the sodium derivative, $Na_2(dioxane)_{3/2}[Fe(CO)_4]$, has shown a number of interactions between the sodium cation and the carbonyl oxygens; one of the sodium cations is hexacoordinated to four $Fe(CO)_4$ units with Na···OC distances of 2.32 Å and to two oxygen atoms of the dioxane groups. In oxygenated solvents, such as THF or dialkyl ethers, the sodium is partially solvated. In the presence of a specific complexing agent for the metal cation (e.g. a crown ether, *see Crown Ethers*), the carbonylmetalate anion has its expected idealized geometry {D_{3h} for the pentacarbonyl $[Mn(CO)_5]^-$, trigonal

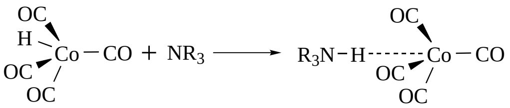
bipyramid; T_d for $[Fe(CO)_4]^{-2}$, tetrahedron}.[63] By forcing the reducing conditions, the tetracarbonylmanganato(−III) and the tetracarbonylchromato(−IV) anions have also been obtained,[15,16] thus expanding the isoelectronic series of the tetracarbonyl compounds: $Ni(CO)_4$, $[Co(CO)_4]^-$, $[Fe(CO)_4]^{2-}$, $[Mn(CO)_4]^{3-}$, $[Cr(CO)_4]^{4-}$.

$$Fe(CO)_5 + 2Na \longrightarrow Na_2[Fe(CO)_4] + CO \qquad (44)$$

The metal carbonyls of group 9 undergo reduction to the tetracarbonylmetalates(−I) (see equation 45 for $Co_2(CO)_8$). Acidification of an aqueous solution of $Na[Co(CO)_4]$ followed by extraction into an organic solvent produces the hydride $CoH(CO)_4$ (see equation 46), which is a sufficiently strong acid to be converted to the trialkylammonium derivative by tertiary amines R_3N (R = Me, Et) (equation 47). The C_{3v} symmetry of $CoH(CO)_4$ in the gas phase is maintained in the trialkylammonium derivatives as shown by X-ray[64] and neutron-diffraction studies.[65,66]

$$Co_2(CO)_8 + 2Na \longrightarrow 2Na[Co(CO)_4] \qquad (45)$$

$$[Co(CO)_4]^- + H^+ \longrightarrow CoH(CO)_4 \qquad (46)$$



Co–H, 1.56 Å Co–H, 2.613(2) Å (47)

5 BONDING AND SPECTRAL DATA

Metal carbonyls have been studied by a number of techniques, vibrational spectroscopy in the IR region and ^{13}C NMR spectrometry being those most frequently used.

Metal carbonyls are characterized by IR-active vibrations associated with the carbonyl groups. Especially studied are the carbonyl stretching vibrations around 2000 cm^{-1}. The vibrational spectra give important information about (a) the electronic distribution within the M−CO bond in terminally bonded carbonyl groups; (b) the molecular structure associated with the number of bands observed; and (c) the type of bonding in dinuclear and polynuclear compounds.

The M–CO bond is usually regarded as a σ-bond from the lone pair on carbon to an empty orbital on the metal, reinforced by π back bonding (*see Back Bonding*) from a metal orbital of appropriate symmetry to an antibonding orbital of CO. The σ and π contributions are viewed as synergic, the result being a mutual reinforcement of the bond. As the π back-bonding contribution increases, the carbonyl stretching vibration is likely to be observed at lower frequencies, in agreement with the resonance hybrid description (**6**). The values of the carbonyl stretching vibrations also depend on the total charge on the complex. This is shown by the IR data for the following compounds with the $\tilde{\nu}_{CO}$ of the main carbonyl stretching vibration being reported in parenthesis (cm^{-1}): $[Fe(CO)_6]^{2+}$ (2204), $[Mn(CO)_6]^+$ (2090), $Cr(CO)_6$ (2000), $[V(CO)_6]^-$ (1859), and $[Ti(CO)_6]^{2-}$ (1748) for the isoelectronic series of the hexacarbonyls; $Ni(CO)_4$ (2058), $[Co(CO)_4]^-$ (1883), $[Fe(CO)_4]^{2-}$ (1730), $[Mn(CO)_4]^{3-}$ (1670), and $[Cr(CO)_4]^{4-}$ (1462) for the isoelectronic series of the tetracarbonyl derivatives.

$$\overset{-}{M}-\overset{+}{C}\equiv O \longleftrightarrow M=C=O$$

(**6**)

The number of carbonyl bands increases as the overall symmetry of the molecule decreases. Only one IR-active carbonyl stretching vibration is normally observed for species of high symmetry, such as octahedral (O_h) or tetrahedral (T_d) complexes (see the examples given above; the data for the negatively charged species refer to media with a strong solvating power for the cation).

In polynuclear metal carbonyls, the bonding modes (a), (b), and (c) (see Section 3) are characterized by a decrease of the carbonyl stretching frequency, in agreement with the reduction of C–O bond order from (a) to (c). For neutral compounds, ν_{CO} values for bonding modes (a)−(c) follow the trend: (a) 2200−1850, (b) 1850−1750, (c) 1750−1620 cm^{-1}.

^{13}C NMR spectra have been extensively used[67] for analytical and structural purposes in metal−carbonyl chemistry.

6 METAL CARBONYLS OF THE EARLY TRANSITION ELEMENTS

Early transition elements of groups 4 and 5 have a small number of d electrons in their gas-phase configuration and this valence shell electronic configuration influences the properties of their compounds. For neutral carbonyls of group 5, the central metal atom has a d^5 electronic configuration; the next inert gas electronic configuration can be attained by dimer formation (as in the unstable $M_2(CO)_{12}$ complexes observed at low temperature only) or by one-electron reduction to the stable hexacarbonylmetalate(−I) anions, $[M(CO)_6]^-$. For the elements of group 4 in the zerovalent species, the metal has a d^4 electronic configuration and can be stabilized by seven carbonyl groups [giving the hypothetical heptacarbonyl $M(CO)_7$] or by undergoing a two-electron reduction to the dianions $[M(CO)_6]^{2-}$. Although heptacarbonyltitanium(0), $Ti(CO)_7$, is unknown, the substituted derivatives $Ti(CO)_{7-n}L_n$ have been reported.[68,69]

The known binary carbonyls of groups 4 and 5 are listed in Table 4. The dinuclear $V_2(CO)_{12}$ is stable at low temperature only as it is prepared from metal vapor and CO at about 20 K. The stable carbonyl compound of

vanadium(0), a low-spin d^5 complex of formula $V(CO)_6$, is best prepared by the sequence shown in reaction (48) and in equation (49). Hexacarbonylvanadium(0) has been found to have a regular octahedral structure, and to be isostructural with the hexacarbonyls of group 6.

$$VCl_3 \xrightarrow[\text{[cot]}]{\text{red./CO}} [V(CO)_6]^- \quad (48)$$

$$[V(CO)_6]^- + H^+ \longrightarrow \tfrac{1}{2}H_2 + V(CO)_6 \quad (49)$$

The hexacarbonylvanadate(−I) anion is prepared at room temperature and atmospheric pressure by reducing VCl_3 with sodium in THF in the presence of catalytic amounts of cyclooctatetraene (cot); the actual reducing agent is presumably the cot^{2-} di-anion.[70] The reaction of equation (49) is carried out with dry HCl in a hydrocarbon solvent. Hexacarbonylvanadium(0) is black−green in the solid state and shows the expected magnetic behavior for a d^5, low-spin complex from room temperature to 66 K, in which the $^2T_{2g}$ electronic ground state is coupled to vibrational modes. Below 66 K down to liquid helium temperature, the magnetic moment reduces considerably, and the compound becomes substantially diamagnetic at the lowest temperature.[71,72] An X-ray diffraction study at 245 K[73] shows the compound to be isomorphous with the corresponding chromium analog (see Tables 3 and 4), thus confirming some earlier results.[74,75] The coordination geometry around vanadium is octahedral with a marginally significant tetragonal distortion.

Hexacarbonylvanadium(0) undergoes reduction to $[V(CO)_6]^-$, oxidation to vanadium(I) complexes, or disproportionation to vanadium(II) and vanadium(−I) or to vanadium(I) and vanadium(−I) in the presence of Lewis bases or aromatic hydrocarbons, respectively. The chemistry of $V(CO)_6$ is shown in Scheme 1. Thus, hexacarbonylvanadium behaves as an oxidizing agent toward a number of organometallic compounds, the driving force being the formation of the 18-electron species $[V(CO)_6]^-$. Reductions of biscyclopentadienyl derivatives, such as $NiCp_2$ and $MnCp_2$, by $V(CO)_6$ are also known. A chemical interaction was found between VCp^*_2, $Cp^* = \eta^5\text{-}C_5Me_5$, and $V(CO)_6$ forming the μ-isocarbonyl compound $VCp^*_2(\mu\text{-}OC)V(CO)_5$ containing the linear V–O–C–V arrangement.[76]

The hexacarbonylniobate(−I) and hexacarbonyltantalate(−I) anions are well established. The $[Nb(CO)_6]^-$ anion can be prepared at atmospheric pressure of CO from $NbCl_5$ by using a prereduction step with alkali metal/naphthalene at low temperature, followed by carbonylation of the intermediate at low temperature in DME as solvent.[77] Another method of preparation,[78] also operating at atmospheric pressure of CO, uses the reduction of $NbCl_5$ with Mg/Zn/pyridine at room temperature and gives yields as high as 48% of recrystallized $Na(THF)[Nb(CO)_6]$. The alkali metal derivatives of $[M(CO)_6]^-$, M = Nb, Ta, are rapidly oxidized by air; the PPN derivatives are stable in air for short periods of time. $PPN[Nb(CO)_6]$ and $PPN[Ta(CO)_6]$ are isostructural; the hexacarbonyl anions possess an almost exact octahedral geometry with the following M–C bond distances: Nb–CO, 2.089 Å; Ta–CO, 2.083 Å.

The oxidation of $[Nb(CO)_6]^-$ and $[Ta(CO)_6]^-$ by several halide-containing oxidants (HX, CuX, CuX_2, AgX, FeX_3)

results in a two-electron transfer (see equation 50) leading to the halide-bridged dimers of niobium(I) or tantalum(I). With silver(I) salts containing the poorly coordinating anions NO_2^- or BF_4^-, formation of the tertiary phosphine substituted neutral hexanuclear clusters (equation 51) is observed.[79] Bonding considerations on some of these systems have been presented.[80,81]

$$2[M(CO)_6]^- + 3X^- \longrightarrow [M_2X_3(CO)_8]^- + 4e^- \qquad (50)$$

$$M = Nb, Ta; X = Cl, Br, I$$

$$3NR_4[M(CO)_4(dmpe)] + 3AgX \longrightarrow Ag_3M_3(CO)_{12}(dmpe)_3 + 3NR_4X \qquad (51)$$

$$M = Nb, Ta; X = NO_2, BF_4$$

The hexacarbonylmetalates(−II) of group 4 can be synthesized by reducing the tetrachlorides with potassium in the presence of a cryptand. In the case of hafnium, the starting material is a tertiary-phosphine-carbonyl complex of the zerovalent metal (see equations 52 and 53). The cryptand/(metal cation) system, characterized by a large mass and a low charge density, presumably has a stabilizing effect on the carbonyl anion. Reactions of equations (52) and (53) are carried out with CO at atmospheric pressure.[16]

$$MCl_4(ether)_n \xrightarrow[\text{15-crown-5}]{K/C_{10}H_8/CO} [K(15\text{-crown-}5)]_2[M(CO)_6] \qquad (52)$$

$$M = Ti, Zr; ether = THF, n = 2; ether = DME, n = 1$$

$$M(CO)_4(trmpe) \xrightarrow[\text{cryptand 2.2.2}]{K/C_{10}H_8/CO} [K(cryptand)]_2[M(CO)_6] \qquad (53)$$

$$M = Ti, Zr, Hf$$

7 METAL CARBONYLS OF THE LATE TRANSITION ELEMENTS

The only neutral binary metal carbonyl of groups 10−12 is $Ni(CO)_4$. Some cationic-carbonyl derivatives of copper(I) and silver(I) have been detected in small equilibrium concentrations in strongly acidic aqueous solution. The formulas of these species, deduced from spectroscopic data,[82–85] are $M(CO)_n^+$ (M = Cu, Ag). The instability of $Pd(CO)_4$ and $Pt(CO)_4$ with respect to their decomposition to the metal (see equation 54) suggests that the strength of the M–CO bond is not sufficiently high to counterbalance the negative enthalpy change corresponding to the formation of the metal from $M(CO)_4$ and the positive entropy change due to CO evolution. The enthalpy change for the vaporization of nickel (430 kJ mol^{-1}) is higher than that of palladium (381 kJ mol^{-1}),[86–88] thus suggesting that Pd–CO bonds are particularly weak.

$$M(CO)_4 \longrightarrow M + 4CO \qquad M = Pd, Pt \qquad (54)$$

Studies on carbonyl derivatives of palladium(II), platinum(II), silver(I), and gold(I) have established the following points:

1. The halocarbonyl derivatives $Pd_2X_4(CO)_2$, $Pt_2X_4(CO)_2$, $PtX_2(CO)_2$, and AuX(CO) are characterized by carbonyl stretching vibrations at high frequencies, sometimes higher than CO itself ($\tilde{\nu}_{CO} = 2143\,cm^{-1}$) (see Table 5) with values of $\tilde{\nu}_{CO}$ usually decreasing in the sequence Cl > Br > I.
2. The tendency to form the halocarbonyls as a function of the halide decreases in the sequence Cl > Br > I. The carbonyl bromides of palladium(II), $Pd_2Br_4(CO)_2$, and gold, AuBr(CO), tend to decarbonylate in the solid state even under CO at atmospheric pressure, and the corresponding carbonyl iodides are unknown.
3. The values of the carbon−platinum coupling constants J_{Pt-C} decrease along the sequence Cl > Br > I, which may be explained by a corresponding decrease of the Pt–CO σ-bond strength in the same sequence.

The available data suggest a small π-contribution to the M−CO bond in these systems.

The Pd^{II}−CO bond strength has been estimated to be 100 kJ mol^{-1}, which is consistent with the values expected for a 4d element in the +II oxidation state on the basis of known thermochemical data for binary carbonyls of metals belonging to Groups 6−10 (see Section 8). In the absence of a significant π back-bonding contribution, the strength of the M–CO bond would not increase by decreasing the oxidation state. This prediction would therefore justify the observation that $Pd(CO)_4$ and $Pt(CO)_4$ have not been observed as stable species.

A predominant σ-contribution in M–CO bonds can generate a charge polarization within the M–CO bond such that the carbonyl carbon can become a site of nucleophilic attack. It has been pointed out[89] that metal carbonyls with force constants higher than 17.2 mdyn Å^{-1}, as estimated from the IR-active carbonyl stretching vibrations, should react with amines to give carbamoyl derivatives. Accordingly,

Table 5 Carbonyl stretching vibrations (IR) of halocarbonyls of palladium, platinum, and gold[2,84]

Compound	$\tilde{\nu}_{CO}$(cm^{-1})	Solvent
cis-$Pd_2Cl_4(CO)_2$[a]	2160	Toluene

[a]Geometry established by X-ray diffractometry.[84]

cis-$PtCl_2(CO)_2$, with CO force constants of 19.01 and 18.3 mdyn Å^{-1}, reacts with secondary amines to give the carbamoyl derivatives shown in equation (5).

Although the formation of Ag–CO bonds in solution had been established in several systems,[82–85] isolation and structural determination of products containing Ag–CO bonds are recent acquisitions.[3,90,91] The carbonyl derivatives of silver, $Ag(CO)(OTeF_5)_2B(OTeF_5)_2$, and $[Ag(CO)_2][B(OTeF_5)_4]$ have been crystallographically established. In the former compound,[90] silver is coordinated to carbon monoxide and to two oxygen atoms of the boron-containing ligand; the $[Ag(CO)_2]^+$ cation is constituted[91] by two-coordinated linear silver(I), whose unique IR carbonyl stretching vibration is observed at 2198 cm^{-1}. The $[Pt(CO)_4]^{2+}$ cation, isolated as the $[Pt(SO_3F)_6]^{2-}$ derivative,[92] has an IR–carbonyl stretching band at 2235 cm^{-1}.

8 METAL–CO BOND DISSOCIATION ENTHALPY (BDE)

The thermodynamic stability of metal carbonyls has attracted the interest of scientists for several decades.[93] The understanding of the nature of the M–CO bond should account for important observations, such as the isolation of stable metal carbonyls for metals in a wide range of oxidation states, +IV to −IV, the latter being encountered in the highly reduced carbonyl metalates. Reliable M–CO bond energies are essential in order to understand the behavior of these compounds, including their reactivity. For simplicity, mainly binary neutral metal carbonyls will be considered here, but the general considerations on this problem usually apply to substituted metal carbonyls as well and to compounds in oxidation states higher or lower than zero. For a neutral binary metal carbonyl and its formation from the corresponding metal, vaporization of the metal and its reaction with CO to form the final product (equations 55a and 55b) are the relevant steps to be considered. The enthalpy and entropy contributions to the free-energy change of the process can be evaluated.

$$M(s) \longrightarrow M(g) \qquad (55a)$$

$$M(g) + nCO(g) \longrightarrow M(CO)(g) \qquad (55b)$$

As far as equation (55a) is concerned, the enthalpy term is accurately known for most metals,[86,87] corresponding to the transfer of the solid metal to its state of a monoatomic gas in its high-spin ground-state configuration. Equation (55b) contains the negative value of the bond enthalpy, which, divided by the number of M–CO bonds in the molecule, gives the mean bond dissociation enthalpy. $M(CO)_n(g)$ differs from $M(CO)_n(s)$ or $M(CO)_n(l)$ by the heats of sublimation or vaporization, respectively.

Several experimental techniques, including thermochemistry and some spectroscopic methods, have been used to obtain these data or related ones, and pertinent review articles on the subject have appeared (*see* ***Bonding Energetics of Organometallic Compounds***).[94–97] A different approach to this problem is the evaluation of enthalpy terms according to second-law methods, by measuring equilibrium constants as a function of temperature. This method has been particularly useful for estimating thermodynamic parameters in metal–carbonyl cluster chemistry (see Section 2.5).

Table 6 Mean bond dissociation enthalpies (BDE) and calculated first ligand dissociation energies (FDE) of some binary metal carbonyls

Compound	BDE (kJ mol^{-1})[94,95]	FDE (kJ mol^{-1})[97]
$Cr(CO)_6$	107 ± 1	147
$Mn(CO)_6{}^+$	–	92
$V(CO)_6{}^-$	–	171
$Mo(CO)_6$	152 ± 1	119
$W(CO)_6$	178 ± 1	142
$Fe(CO)_5$	118 ± 2	–
$Ni(CO)_4$	147	106
$Pd(CO)_4$	–	27
$Pt(CO)_4$	–	38

Heats of atomization of metals have well-known trends within *typical* groups of transition elements (groups 6–9),[86,87] that is, they increase down a group from the lighter to the heavier element. By using a combination of several experimental techniques, two main conclusions concerning neutral metal carbonyls have been reached: (a) the M–CO bond enthalpy contribution increases[95] as the heat of atomization increases down a group (typical sequences: Cr–Mo–W; Fe–Ru–Os; Co–Rh–Ir); (b) the M–CO bond enthalpy is normally greater than the metal–metal bond enthalpy estimated from the heat of atomization. Table 6 reports the M–CO_t (CO_t, terminal CO) mean bond enthalpies for some of the common binary metal carbonyls and the calculated[97] first ligand dissociation energies. Within the neutral compounds with the same electronic configuration, the 4d compound generally has the lowest dissociation energy.

Point (b) is particularly relevant for systems such as $Co_2(CO)_8$, which exists in solution in an almost 1:1 ratio between the carbonyl-bridged form and the nonbridged form (see equation 25), and $Mn_2(CO)_{10}$, which is stable only in the nonbridged form both in solution and in the solid state. Single metal–metal bonds are not particularly strong for 3d systems; this may explain the experimental observation that $V(CO)_6$ is mononuclear, since intraligand repulsion in the dinuclear species would not be compensated by a sufficiently strong vanadium–vanadium bond.

9 REACTION MECHANISMS

In metal–carbonyl chemistry, two types of reactions have been studied from a mechanistic viewpoint: (a) substitution

reactions, where no change of oxidation state is involved, and (b) redox reactions (*see* ***Mechanisms of Reaction of Organometallic Complexes***). Substitutions (see equation 56) have been extensively studied, while a relatively smaller number of papers have appeared on electron-transfer reactions.

$$M(CO)_n + L \longrightarrow M(CO)_{n-1}L + CO \qquad (56)$$

For polynuclear metal carbonyls, similar processes have been studied to a great extent, especially for the decacarbonyls of group 7, $M_2(CO)_{10}$ (M = Mn, Re). A simple case of substitution is the isotopic exchange reaction, for which the enthalpy is substantially zero. The specific rate constants (or half-lives)[98] for such exchange reactions, under exclusion of light, of some selected metal carbonyls are in Table 7. Slowly reacting species [$Fe(CO)_5$, d^8 configuration; $Cr(CO)_6$, $Mo(CO)_6$, $W(CO)_6$, d^6 low-spin], moderately reactive [$V(CO)_6$, low-spin d^5, possibly subject to Jahn–Teller (*see Jahn–Teller Effect*) distortion], and fast reacting species [$Ni(CO)_4$, d^{10} configuration] can be recognized. The low reactivity of the hexacarbonyls of group 6 is consistent with the well-established observation that d^6, low-spin systems are substitutionally inert, independent of oxidation state. Substitution reactions frequently occur by a dissociative mechanism with a coordinatively unsaturated species being formally present in the rate-determining step (see equation 57).

$$M(CO)_n \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} M(CO)_{n-1} + CO \qquad (57)$$

Within compounds containing metals belonging to the same vertical sequence, that is, normally isostructural compounds with the same number of valence electrons for the central metal atom (for example, the hexacarbonyls of group 6), the order of reactivity is often 3d < 4d > 5d,[99] with the exception of the cyclopentadienyl derivatives of group 5, $MCp(CO)_4$ (M = V, Nb, Ta), for which the order of reactivity is V > Nb > Ta.[100] Relevant to these findings are the data provided in Table 6 showing that the calculated[97] first CO dissociation energy for the hexacarbonyls and the tetracarbonyls is lowest for the 4d term. Thus, at least for dissociative mechanisms, the order of

Table 7 Rate of CO exchange with some binary metal carbonyls[98]

		Rate	
Compound	t (°C)	k (s^{-1})	$\tau_{1/2}$
$Ni(CO)_4$	0	7.8×10^{-4}	–
$Fe(CO)_5$	25	–	4 y
$Cr(CO)_6$	117	2.0×10^{-5}	–
$Mo(CO)_6$	116	7.5×10^{-5}	–
$W(CO)_6$	142	2.6×10^{-6}	–
$V(CO)_6$	10	–	7 h

reactivity usually observed has theoretical support. This result is important for catalysis.

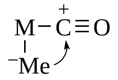
A special case of substitution reaction is the migratory insertion (*see Migratory Insertion*) reaction of alkyl or aryl metal carbonyls (see equation 58), by which an alkyl or aryl metal carbonyl is converted into an acyl or aroyl metal carbonyl by the action of a Lewis base. This reaction has been studied extensively, and in the case of $Mn(Me)(CO)_5$ is found to proceed through a coordinatively unsaturated tetracarbonyl resulting from methyl migration on to one of the terminal CO groups in a *cis* position, (see equation 59).[101]

$$MR(CO)_n + L \longrightarrow M(COR)(CO)_{n-1}L \qquad (58)$$

L = Lewis base

$$MnMe(CO)_5 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Mn(COMe)(CO)_4 \underset{-CO,\,k_{-2}}{\overset{+CO,\,k_2}{\rightleftharpoons}} Mn(COMe)(CO)_5 \qquad (59)$$

In the migratory insertion reaction, the central metal atom does not alter its oxidation state, and a new carbon–carbon bond is formed. As such, this reaction is believed to constitute a fundamental step in several carbon–carbon forming catalytic processes (hydroformylation (*see Hydroformylation*), homologation (*see Homologation Reactions*), carbonylation of methanol to acetic acid, alkene polymerization). Migratory insertions can be catalyzed by oxidizing agents[102] or Lewis acids under homogeneous or heterogenous conditions. In both cases, the electrophilic character of the carbonyl carbon is further enhanced, thus making this an even more favorable site of intramolecular attack by the alkyl group, as shown in (**7**).



(**7**)

For metal carbonyls, redox reactions (*see Redox Properties & Processes*) have been studied in a smaller number of cases, relative to substitution reactions. The simplicity of binary metal carbonyls and the possibility for these compounds to undergo electron transfers make them excellent substrates for studying redox processes in nonaqueous media. Convenient organometallic one-electron oxidants or reductants (number of valence electrons in parenthesis) are[103,104] $V(CO)_6$ (17)/$[V(CO)_6]^-$ (18); $[FeCp_2]^+$ (17)/$FeCp_2$ (18); $V(\eta^6\text{-arene})_2$ (17)/$[V(\eta^6\text{-arene})_2]^+$ (16); VCp_2 (15)/$[VCp_2L_2]^+$ (18); $CoCp_2$ (19)/$[CoCp_2]^+$ (18). These systems have the advantage that the uncharged species is soluble in organic solvents, including aromatic or aliphatic hydrocarbons. Most common binary metal carbonyls, with the exception of $V(CO)_6$, have redox couples complicated by the formation

of metal–metal bonded dimers in the oxidized form (see equations 60–63).

$$[Mn(CO)_5]^- \longrightarrow \tfrac{1}{2}Mn_2(CO)_{10} + e^- \quad (60)$$

$$[Re(CO)_5]^- \longrightarrow \tfrac{1}{2}Re_2(CO)_{10} + e^- \quad (61)$$

$$[Co(CO)_4]^- \longrightarrow \tfrac{1}{2}Co_2(CO)_8 + e^- \quad (62)$$

$$[V(CO)_6]^- \longrightarrow V(CO)_6 + e^- \quad (63)$$

Evidence for a single-event, two-electron transfer process has been gathered in the reaction between the two d^6 systems, $[Re(CO)_5]^-$ and $[Mn(CO)_6]^+$ (see equation 64), followed by redistribution (equation 65).[105]

$$[Re(CO)_5]^- + [Mn(CO)_6]^+ \longrightarrow [Re(CO)_6]^+ + [Mn(CO)_5]^- \quad (64)$$

$$[Re(CO)_6]^+ + [Mn(CO)_5]^- \longrightarrow Re_2(CO)_{10} + Mn_2(CO)_{10} + MnRe(CO)_{10} \quad (65)$$

1 INTRODUCTION

Homogeneous carbonylation catalysis involves the transition metal assisted addition of carbon monoxide (CO) to organic compounds to produce higher molecular weight carbonyl-containing products. Carbonylation chemistry was pioneered by Roelen (Ruhrchemie) and Reppe (IG Farben/Badische Anilin und Soda Fabrik (BASF)) in the late 1930s. Since then, it has developed into the highest volume and most important of the industrial homogeneous catalytic processes. The first 27 years of carbonylation catalysis involved the use of simple metal–carbonyl catalysts, high-reaction temperatures and pressures, and low-product selectivities.

The situation changed in the mid-1960s with Wilkinson and Heck's independent discoveries that organophosphine-substituted rhodium and palladium complexes, respectively, were active catalysts for carbonylation reactions under milder reaction conditions. Since then, significant advances in catalyst design have led to dramatic enhancements in both the rate and regioselectivity of carbonylation catalysts. A number of these improvements have had significant industrial applications, while many more of them have made carbonylation catalysis a very viable laboratory method for organic functionalizations.

Carbonylation catalysis encompasses a large and important area of chemistry. Unlike many other catalytic reactions, most of carbonylation chemistry is homogeneous, principally because homogeneous catalysts generally give higher rates and selectivities than heterogeneous systems (*see* ***Supported Organotransition Metal Compounds***). Numerous reviews and books have appeared on this subject, particularly with respect to the industrially important area of *Hydroformylation* catalysis. Some of the major books and reviews used in preparing this chapter are listed here. Falbe's book on 'New Syntheses with Carbon Monoxide' contains the most extensive compilation of references (almost 2000) on hydroformylation and several other important CO catalysis reactions up through 1978–79.[1] A comprehensive 15-year review of hydroformylation and carbonylation was published by Cornils *et al.* in 1995.[2] The material presented in this excellent review will not be explicitly discussed here. A thorough review of both academic and industrial developments in hydroformylation appears in *Rhodium Catalyzed Hydroformylation*, edited by van Leeuwen and Claver, published in 2000.[3] Asymmetric carbonylation reactions are discussed by Nozaki and Ojima in the second edition of *Catalytic Asymmetric Synthesis*, published in 2000.[4] The second edition of *Applied Homogeneous Catalysis with Organometallic Compounds*, edited by Cornils and Herrmann, was published in 2002.[5] Chapter 2 deals specifically with carbonylation and hydroformylation reactions and the reader is referred to this comprehensive survey for a summary of important advances in these areas. For the past several years, Ungváry has written an annual survey covering advances in the field of hydroformylation. The most recent of these reviews (2004) is cited here.[6]

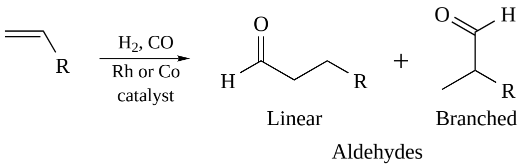
Most of the palladium chemistry mentioned was found in Heck's[7] classic work 'Palladium Reagents in Organic Synthesis'. Industrial perspectives came from interviews with industrial chemists and the 'Encyclopedia of Chemical Processing and Design', specifically the sections on 'Oxo Process Alcohols' and 'Butyraldehydes and Butyl Alcohols'.[8] If a reaction or result in this review is not referenced it came from one of the books mentioned here.[1,3,7,8]

There was no possibility of even briefly mentioning all the known catalytic-carbonylation reactions in this chapter – it is that huge an area of catalysis. Instead, an industrial orientation has been taken with topics covered more or less in order of their commercial, then academic, significance. About half of this review covers hydroformylation catalysis, which is the largest homogeneous process carried out in industry today. An attempt has been made to present a balanced mixture of the older classic work, new work, and some interpretations based on current knowledge. This review will not cover stoichiometric carbonylation reactions (*see* ***Organic Synthesis using Transition Metal Carbonyl Complexes***).

The most significant advances in carbonylation catalysis in the next several years[9] will undoubtedly occur in the area of novel ligand systems, new solvents, and asymmetric induction, which will be briefly covered here (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***).

2 ALDEHYDES AND ALCOHOLS–HYDROFORMYLATION

Hydroformylation, also known as the oxo reaction, is the largest homogeneous industrial process in the world, with over 8 billion kg of aldehydes and alcohols produced each year. Hydroformylation involves the reaction of alkenes with H_2 and CO to produce aldehyde products (equation 1). Hydroformylation was discovered by Otto Roelen in 1938 during an investigation of the origin of oxygenated products occurring in the cobalt-catalyzed *Fischer–Tropsch Process*. Roelen's observation that ethylene, H_2, and CO were converted into propanal and, at higher pressures, diethyl ketone marked the beginning of hydroformylation catalysis.



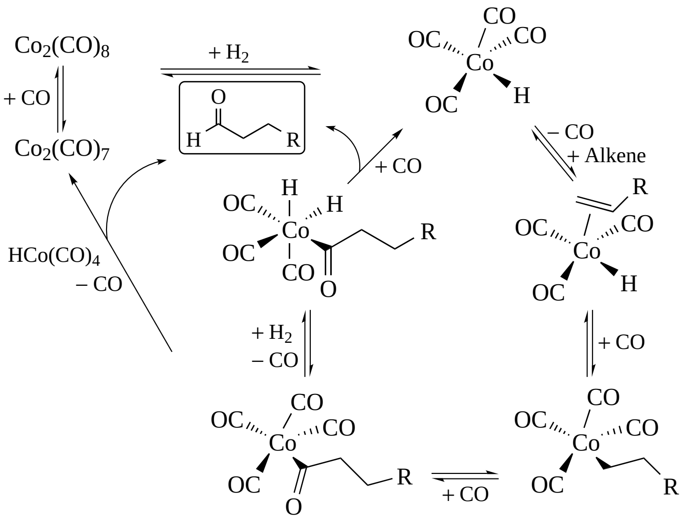
(1)

Cobalt catalysts completely dominated industrial hydroformylation until the early 1970s, when rhodium catalysts were commercialized. Most aldehydes produced are hydrogenated to alcohols or oxidized to carboxylic acids. Esterification of the alcohols with phthalic anhydride produces dialkyl phthalate plasticizers that are primarily used for polyvinyl chloride plastics – the largest single end-use. Detergents and surfactants make up the next largest category, followed by solvents, lubricants, and chemical intermediates.

2.1 $HCo(CO)_4$ Catalyst

Roelen's original research into hydroformylation involved the use of cobalt salts that, under H_2/CO pressure, produced $HCo(CO)_4$ as the active catalytic species (*see* ***Cobalt: Organometallic Chemistry***). In 1960 and 1961, Heck and Breslow[10,11] proposed what is now accepted as the general mechanism for cobalt-catalyzed hydroformylation (Scheme 1). Dissociation of CO from $HCo(CO)_4$ produces the 16e coordinatively unsaturated (*see* ***Coordination & Organometallic Chemistry: Principles*** and ***Electronic Structure of Organometallic Compounds***) complex $HCo(CO)_3$ to which alkene can bind. Alkene *Insertion* into the Co–H bond (*see* ***Mechanisms of Reaction of Organometallic Complexes***) produces either the linear or branched alkyl species (linear alkyl is shown in Scheme 1). Coordination of CO and subsequent alkyl migration produces the acyl intermediate. Loss of CO, followed by oxidative addition of H_2 to the cobalt center produces the dihydride species (*see* ***Hydride Complexes of the Transition Metals***). *Reductive Elimination* of aldehyde and coordination of CO regenerates the starting $HCo(CO)_4$ catalyst. This same general sequence of steps is the foundation for the proposed mechanisms of most other hydroformylation catalysts.

An alternate bimetallic pathway was also suggested, but not favored, by Heck and Breslow (also shown in Scheme 1). The acyl intermediate could react with $HCo(CO)_4$ to undergo intermolecular hydride transfer, followed by reductive elimination of aldehyde to produce the Co–Co bonded dimer $Co_2(CO)_8$. A common starting material for $HCo(CO)_4$-catalyzed hydroformylation, $Co_2(CO)_8$ is well-known to react with H_2 under catalysis reaction conditions to form two equivalents of $HCo(CO)_4$. The bimetallic hydride transfer mechanism is operational for stoichiometric hydroformylation with $HCo(CO)_4$ and has been proposed to be a possibility for slower catalytic hydroformylation reactions with internal alkenes.[12] The monometallic pathway involving reaction of the acyl intermediate with H_2, however, has been



Scheme 1

repeatedly shown to be the dominant mechanism for 1-alkenes and cyclohexene.[13,14]

Kinetic studies (*see Kinetic Methods*) support the mechanism with a general rate expression given in equation (2). The inverse dependence on CO pressure is consistent with the mechanistic requirement for CO dissociation from the various saturated 18e species to open up a coordination site for alkene or H_2 binding. When using a 1:1 ratio of H_2/CO, the reaction rate is essentially independent of pressure owing to the opposing orders of H_2 and CO. Increasing the H_2/CO ratio is of limited use for increasing the overall reaction rate, because $HCo(CO)_4$ is only stable under certain minimum CO partial pressures at a given reaction temperature.

$$\frac{\mathrm{d(aldehyde)}}{\mathrm{d}t} = k[\mathrm{alkene}][\mathrm{Co}][\mathrm{H_2}][\mathrm{CO}]^{-1} \qquad (2)$$

Indeed, the reaction conditions for $HCo(CO)_4$-catalyzed hydroformylation are largely governed by the thermal instability of $HCo(CO)_4$, which produces metallic cobalt if the CO partial pressure is not kept high enough. As the reaction temperature is increased, the CO partial pressure required to maintain stability of $HCo(CO)_4$ increases in a logarithmic fashion (see Figure 1). Thus, the usual reaction temperatures needed to obtain a reasonable reaction rate (110–180 °C) require rather high CO partial, and hence, total H_2/CO pressures (200–300 bar).

Increasing the CO partial pressure decreases the hydroformylation reaction rate and the amount of alkene isomerization side reactions (*see* ***Hydrogenation & Isomerization of Alkenes***), while increasing the aldehyde linear to branched product ratio. Pino proposed that the apparent marked difference between $HCo(CO)_4$-catalyzed hydroformylation at low and high CO partial pressures was due to the existence of two active catalyst species, $HCo(CO)_4$ and $HCo(CO)_3$, formed from the CO association/dissociation equilibrium shown in equation (3).

$$\mathrm{HCo(CO)_3 + CO \rightleftharpoons HCo(CO)_4} \qquad (3)$$

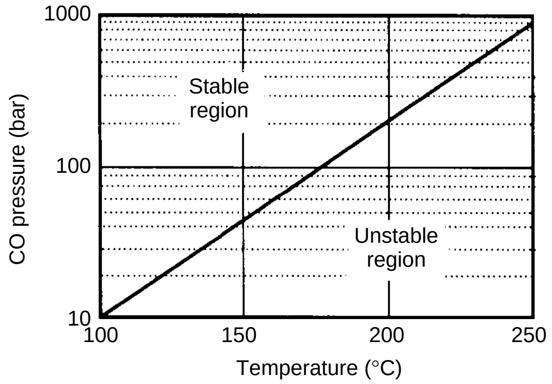


Figure 1 Stability of $HCo(CO)_4/Co_2(CO)_8$ species with respect to precipitation of cobalt metal (cobalt concentration is 0.4 wt%)

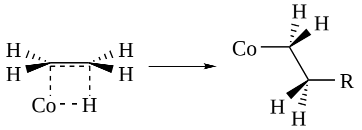
Pino suggested that $HCo(CO)_4$, favored under high CO partial pressures, could directly react with 1-alkenes to form the cobalt–alkyl species $RCo(CO)_4$.[15] The direct reaction of the 18e saturated $HCo(CO)_4$ with an alkene is somewhat unusual, but not unprecedented. A four-center interaction of the alkene double bond with the Co–H bond leading to direct alkene insertion to the alkyl species was suggested (equation 4).

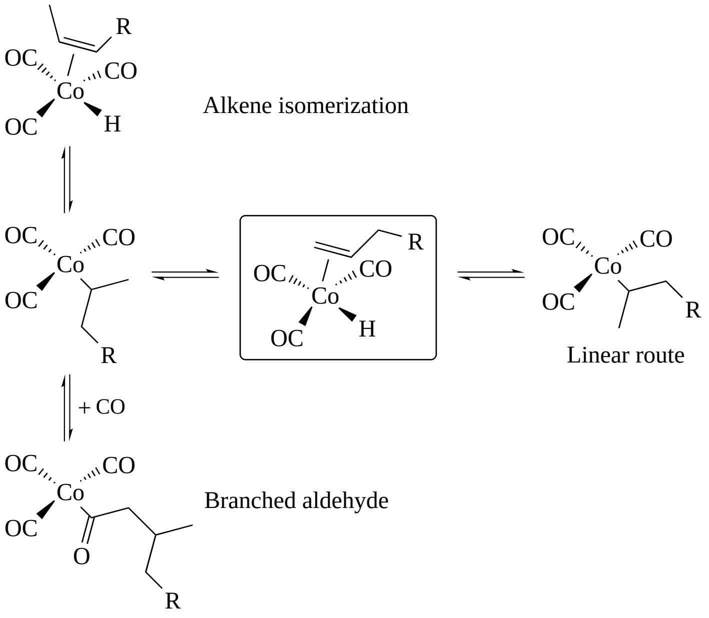


(4)

The extra steric bulk of $HCo(CO)_4$ (compared to $HCo(CO)_3$) should favor addition of the alkene to give linear alkyls. The lower probability of alkene reaction with the saturated $HCo(CO)_4$ catalyst is consistent with the reduced activity at higher CO partial pressures. One can also explain all these features with the 16e $HCo(CO)_3$ catalyst by proposing that alkene isomerization is more facile with the resulting 16e $RCo(CO)_3$ species that results after reaction with alkene (Scheme 2).

Under lower CO partial pressures a 16e $RCo(CO)_3$ species will have a long enough lifetime to allow reverse *β-Hydride Elimination* (*see* ***Mechanisms of Reaction of Organometallic Complexes***) and increase the possibility for alkene reinsertion to the branched alkyl species, which is slightly more favored thermodynamically. At this point, CO addition and insertion will yield a branched aldehyde, or another β-hydride elimination can give alkene isomerization. This second mechanistic explanation is in line with more recent results from Rh/PPh_3-catalyzed hydroformylation studies (see Section 2.4).

The regioselectivity of $HCo(CO)_4$ (or $HCo(CO)_3$) for producing the more valuable linear aldehydes varies with reaction conditions and alkene substrates used. With 1-alkenes one can typically get linear to branched aldehyde ratios of 3–4 to 1. There is a trade-off between rate and regioselectivity. High CO partial pressure slows the rate of catalysis, but increases the linear to branched aldehyde product ratio. Higher CO partial pressures also lower alkene isomerization side reactions. Higher temperatures increase the reaction rate, but lower the linear aldehyde product regioselectivity and increase various undesirable side reactions. Some aldehyde *Hydrogenation* to alcohols is usually observed (5–12%), although alkene hydrogenation is usually quite low ($\approx$1%), particularly under higher CO partial pressures. Aldehyde hydrogenation is not generally considered to be a negative side reaction, since the aldehyde products are usually hydrogenated to alcohols in a subsequent reaction step.

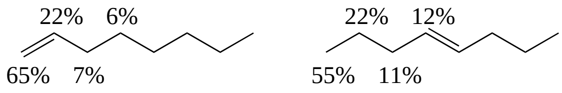


Scheme 2

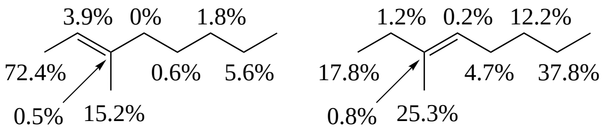
The aldehyde hydrogenation, however, consumes additional H_2, so H_2/CO ratios greater than 1:1 are used (1–1.5:1 is common).

Very high product regioselectivity is not, however, the major concern for most $HCo(CO)_4$-catalyzed industrial hydroformylations. Exxon Chemical Co. built the first hydroformylation plant located in the United States in 1948 in Baton Rouge, LA, based on high-pressure $HCo(CO)_4$ technology. Exxon uses propylene dimerization/oligomerization to produce a C_7 to C_{12} mixture of branched internal alkenes. This branched internal alkene mixture is then hydroformylated and hydrogenated to a C_8 to C_{13} alcohol mixture. The alkene isomerization ability of $HCo(CO)_4$ turns out to be quite important in this situation (*see* ***Hydrogenation & Isomerization of Alkenes***). $HCo(CO)_4$ is rather good at isomerizing double bonds to essentially all possible locations. This result can be clearly seen from the data shown in Scheme 3, which shows the percentage of aldehyde formed at each site for the $HCo(CO)_4$-catalyzed hydroformylation of 1-octene and 4-octene (150 °C/200 bar, 1:1 H_2/CO).[16]

Under these conditions, the linear to branched aldehyde ratio for the hydroformylation of 1-octene was 1.9:1. Starting with 4-octene one still gets a 1.2:1 linear to branched ratio. Thus, one can start with a considerably less-expensive mixture of terminal and internal alkenes and get a product distribution favoring the linear aldehyde. The product distribution in Scheme 3 can be nicely explained by invoking facile alkene isomerization, with the fastest hydroformylation occurring for double bonds in the 1-position. Labeling studies have shown that alkene isomerization generally occurs without dissociation of the alkene from the cobalt catalyst.[17]



Scheme 3



Scheme 4

Alkene branching has a considerable effect on the cobalt-catalyzed alkene isomerization and subsequent hydroformylation. In a study of various methylheptenes, Haymore and coworkers found that there was very little hydroformylation at the carbon center with the branch, even if it was part of the double bond. Scheme 4 shows data for the hydroformylation of two methylheptenes and percentage of aldehyde formed at each site.[18] Note that isomerization past the branching carbon is not a dominant reaction. Once again, terminal aldehydes are the favored products.

Side reactions of the product aldehydes to form heavier products generally occur, particularly at higher-reaction temperatures, and usually account for ≈9% of the product distribution. Aldol condensations, aldols, trimerizations, and Guerbet dimerizations of product alcohols are some of the more common ways to form heavy by-products. These side reactions are common to varying extents for all long-term

commercial hydroformylation reactions. Although industrial reactors are usually started with high-boiling solvents, after a while these heavy ends become the main solvent system for the reaction.

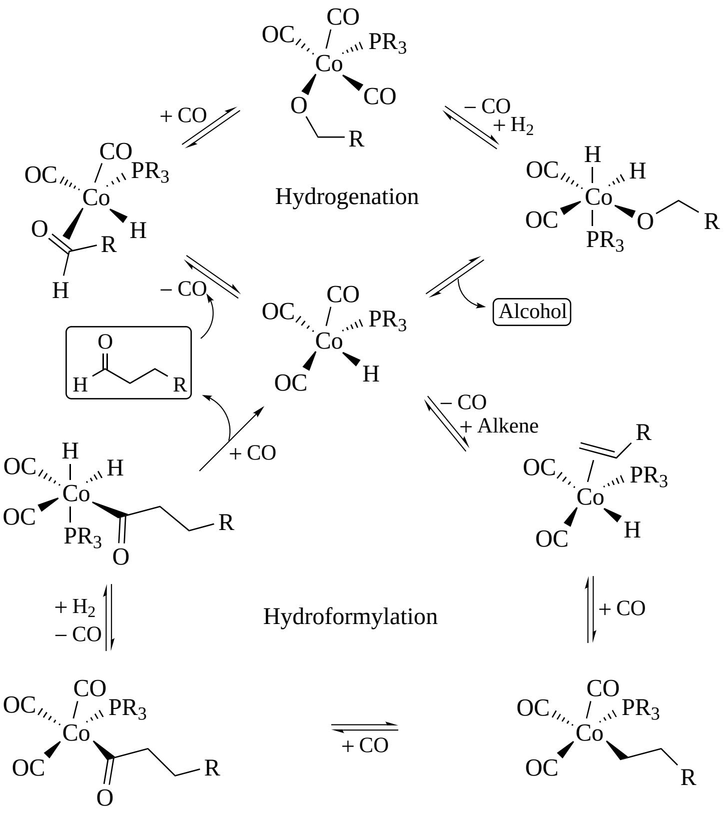
One of the major problems in any large-scale industrial homogeneous process, such as hydroformylation, is separation of the product from the catalyst at the end of the reaction. One advantage of $HCo(CO)_4$ technology is that catalyst separation and recycling is well established. The two major methods of separating catalyst from product involve oxidation of $HCo(CO)_4$ to water-soluble Co^{II} salts that are extracted from the product stream, and flash evaporation of volatile $HCo(CO)_4$ from the high-boiling products.

2.2 Cobalt Phosphine-modified Catalysts

The first and only major variation on $HCo(CO)_4$ hydroformylation catalysis involved research at Shell by Slaugh and Mullineaux, in which the addition of trialkylphosphine ligands (*see* ***Cobalt: Organometallic Chemistry*** and ***Phosphorus: Organophosphorus Chemistry***) caused a dramatic change in the rate and regioselectivity.[19] The electronic effect of substituting an electron-donating alkylated phosphine for one of the carbonyl ligands, to produce $HCo(CO)_3(PR_3)$, results in stronger Co–CO bonding. This causes a dramatic reduction in the CO partial pressures required to stabilize the catalyst. Instead of 200–300 bar of H_2/CO pressure needed for $HCo(CO)_4$, the monophosphine-substituted catalyst $HCo(CO)_3(PR_3)$ only needed 50–100 bar pressure, and could be run at higher temperatures without any decomposition of catalyst to cobalt metal.

Another electronic effect is that the electron-donating phosphine increases the hydridic nature of the hydride ligand ($HCo(CO)_4$ is quite acidic) and dramatically increases the hydrogenation capabilities of the $HCo(CO)_3(PR_3)$ catalyst. This effect means that aldehydes produced from the initial hydroformylation are subsequently hydrogenated by $HCo(CO)_3(PR_3)$ to produce alcohols as the final product. Less electron-rich phosphines, such as PPh_3, give less hydrogenation to the alcohol product, and lower linear regioselectivities. The increased hydrogenation ability, however, also results in increased alkene hydrogenation that can range from 10–20% of the product distribution, depending on the phosphine ligand used and the exact reaction conditions. Because of the aldehyde hydrogenation step, additional H_2 is needed, so H_2/CO ratios of 2:1 (or slightly higher) are used. The proposed hydroformylation and hydrogenation mechanisms are both shown in Scheme 5.

The final electronic effect of phosphine substitution is that the higher stability of the $HCo(CO)_3(PR_3)$ catalyst, due to



Scheme 5

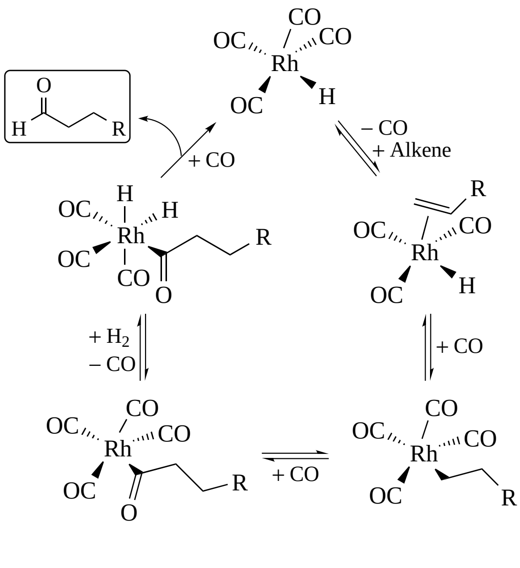
stronger Co–CO bonding, means that this catalyst is less active than $HCo(CO)_4$ (about 5–10 times slower). Just as with the unmodified cobalt catalyst, CO dissociation from the saturated 18e species is needed to open up an empty coordination site on the cobalt to allow coordination of alkene and H_2. Higher-reaction temperatures, therefore, are used in conjunction with longer-reaction times and larger reactor volumes.

From a steric viewpoint, the considerably bulkier trialkylphosphine ligand should, and does, favor formation of linear products. While linear to branched ratios of only 2–3:1 are typically found for $HCo(CO)_4$, higher regioselectivities of 7–8:1 occur for $HCo(CO)_3(PR_3)$. There is a phosphine *Cone Angle* cutoff at about 132°, after which the steric effects of the phosphine ligand do not increase the product linear regioselectivity any further.

Phosphine-modified cobalt hydroformylation is only used commercially by Shell. It is tightly coupled to Shell's Higher Olefins Process (SHOP, *see* ***Metathesis Polymerization Processes by Homogeneous Catalysis***) that produces a C_4 through C_{20} mixture of linear, internal alkenes for hydroformylation to detergent-grade alcohols.

2.3 $HRh(CO)_4$ Catalyst

In 1952, it was discovered by Schiller that rhodium salts generated highly active hydroformylation catalysts. It was from these early studies that rhodium was estimated to be 1000 to 10 000 times more active than cobalt. Rhodium was also found to be very selective to aldehydes, with little hydrogenation to alcohols observed under normal catalysis conditions. It was suggested early on that $HRh(CO)_4$ was the active catalyst species, analogous to $HCo(CO)_4$, and the same monometallic mechanism was proposed (Scheme 6).



Scheme 6

Table 1 Hydroformylation of 2-pentene as a function of metal and partial CO pressure[a]

P_{CO} (bar)	$Co_2(CO)_8$	$Rh_4(CO)_{12}$
4–5	 12, 12 / 35, 5, 35	 26, 25 / 25, 14, 10
100	 13, 7 / 48, 6, 26	 48, 16 / 7, 28, 1

[a]The percentage of aldehyde product formed at each site is indicated.

Perhaps not too unexpectedly, the linear to branched aldehyde regioselectivity of $HRh(CO)_4$ is lower than that found for $HCo(CO)_4$, consistent with the larger size of a rhodium atom relative to cobalt. This results in less steric crowding about the rhodium center, leading to less steric differentiation for the alkene insertion step into the M–H bond to form a linear or branched alkyl group. With 1-pentene, $HCo(CO)_4$ gives a linear to branched aldehyde ratio of 4:1 under optimum conditions, while $HRh(CO)_4$ can only reach a 1.6:1 ratio. As with $HCo(CO)_4$, $HRh(CO)_4$ is an active isomerization catalyst, but its lower regioselectivity leads to more extensive distributions of the aldehyde products. The isomerization ability is related to the partial CO pressure, with considerably more isomerization occurring at lower partial CO pressures. (Table 1 illustrates this for the hydroformylation of 2-pentene from the work of Pino and coworkers.) As with $HCo(CO)_4$, this is explained by the formation of higher amounts of the 16e unsaturated $HRh(CO)_3$ and its longer lifetime under low CO partial pressures.

$HRh(CO)_4$ is used by Ruhrchemie in the hydroformylation of certain branched alkenes that can only give a single product due to the location of the branch that restricts both alkene isomerization and product regioselectivity. In this special case, the high activity of $HRh(CO)_4$ is not off-set by poor aldehyde regioselectivity.

Another similarity between $HCo(CO)_4$ and $HRh(CO)_4$ is that they are only stable under certain reaction conditions. Unlike $HCo(CO)_4$, $HRh(CO)_4$ does not usually precipitate out as metallic rhodium, but rather forms stable rhodium carbonyl clusters such as $Rh_4(CO)_{12}$ and $Rh_6(CO)_{16}$. Indeed, just as $Co_2(CO)_8$ is a common catalyst precursor for cobalt hydroformylation, $Rh_4(CO)_{12}$ is often used as a starting species for rhodium hydroformylation.

Unlike $HCo(CO)_4$ and (acyl)$Co(CO)_4$ species, which are readily observed via FT-IR spectroscopy, the rhodium monometallic analogs are more difficult to observe because of their higher reactivity.[20] The ready formation of easily observable and isolable rhodium carbonyl clusters has led to some conflicting reports on whether $HRh(CO)_4$ is the true catalyst.

Garland has reported a detailed kinetic and mechanistic study of the unmodified rhodium catalyst system using in situ FT-IR techniques and has concluded that the active catalyst

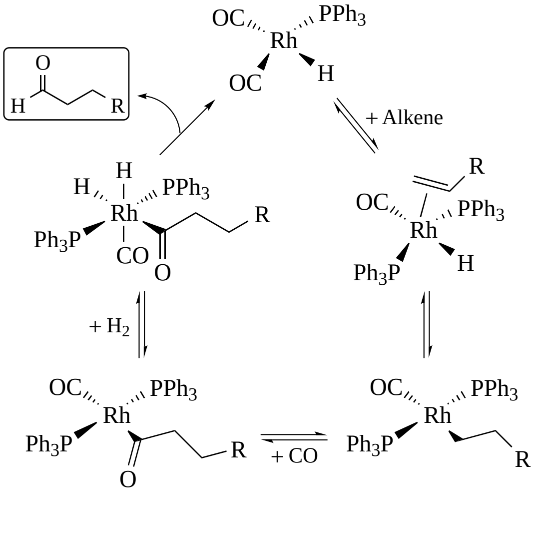
is indeed $HRh(CO)_4$, or more precisely, $HRh(CO)_3$.[21] The rate-determining step in the catalytic cycle is hydrogenolysis of the (acyl)$Rh(CO)_4$ species, although the concentration of $HRh(CO)_4$ is dependent on cluster fragmentation/reformation equilibrium. In particular, Garland's kinetic data support cluster fragmentation equilibria in the presence of alkenes (equation 5).

$$Rh_4(CO)_{12} + 2CO \rightleftharpoons \{Rh_4(CO)_{14}\} + H_2 \rightleftharpoons 4(acyl)Rh(CO)_4 \quad (5)$$

2.4 Rhodium Phosphine Catalysts

In 1965, Osborn, Young, and Wilkinson reported that Rh^I–PPh_3 complexes were active and highly regioselective hydroformylation catalysts for 1-alkenes, even at ambient conditions. Although Slaugh and Mullineaux had filed a patent in 1961 that mentioned Rh/phosphine combinations for hydroformylation catalysis, it was Wilkinson's work that really ignited serious interest in rhodium phosphine hydroformylation catalysts. The initial catalyst system was derived from *Wilkinson's Catalyst*, $RhCl(PPh_3)_3$, but it was rapidly discovered that halides were inhibitors for hydroformylation. It is best, therefore, to start with rhodium precursor complexes that do not contain halides. $HRh(CO)(PPh_3)_3$ and $Rh(acac)(CO)_2$ are two commonly used starting materials for hydroformylation. The currently accepted core catalytic mechanism for Rh/PPh_3 hydroformylation is shown in Scheme 7, and is essentially a hybrid of Wilkinson's original associative and dissociative mechanisms. The various steps are directly analogous to Heck's mechanism for $HCo(CO)_4$ (see Scheme 1).

Wilkinson noted that $HRh(CO)(PPh_3)_2$ was very selective for the formation of aldehyde products (no alcohol formation, no alkene hydrogenation or isomerization) and that very high linear to branched aldehyde selectivities of 20:1 for a variety



Scheme 7

Table 2 Rate constants and regioselectivities for the hydroformylation of 1-hexene using $Rh(acac)(CO)_2$ with different PPh_3 concentrations[a]

[Rh] (mM)	[PPh_3] (M)	PPh_3/Rh ratio	k_{obs} (min^{-1} mM Rh^{-1})	Linear:branched ratio
0.5	0.41	820	0.032	11
1	0.82	820	0.016	17

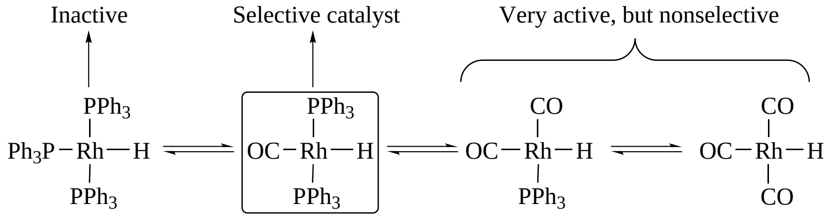
[a]Reaction conditions: 90 psig, 1:1 H_2/CO, 90 °C.

of 1-alkenes could be obtained under ambient conditions (25 °C, 1 bar, 1:1 H_2/CO). At higher temperatures the rate increased, but the regioselectivity dropped (9:1 at 50 °C). Running under 80–100 bar of H_2/CO decreased the linear to branched aldehyde selectivity to only 3:1.

Pruett (at Union Carbide) quickly provided the next critical discovery that, along with the work of Booth and coworkers at Union Oil, allowed commercialization of the $HRh(CO)(PPh_3)_2$ technology. They found that the use of rhodium with excess phosphine ligand created an active, selective, and stable catalyst system at 80–100 psig and 90 °C.[22] Union Carbide, in conjunction with Davy Powergas and Johnson Matthey, subsequently developed the first commercial hydroformylation process using rhodium and excess PPh_3. The need for excess phosphine arises from the facile Rh–PPh_3 dissociation equilibrium shown in Scheme 8. Loss of PPh_3 from $HRh(CO)(PPh_3)_2$ generates considerably more active, but less regioselective, hydroformylation catalysts. The addition of excess phosphine ligand shifts the phosphine dissociation equilibrium back towards the more selective $HRh(CO)(PPh_3)_2$ catalyst. This explains why higher CO partial pressures lower the product regioselectivity, in marked contrast to the observation made in the case of $HCo(CO)_4$-catalyzed hydroformylation.

There has been considerable discussion on the exact nature of the rhodium species that yields high product selectivity. Wilkinson originally proposed that high regioselectivities resulted from alkene coordination to the bisphosphine species $HRh(CO)_2(PPh_3)_2$ to generate a 20e six-coordinate complex. Alkene insertion into the Rh–H bond would then produce the 18e $Rh(alkyl)(CO)_2(PPh_3)_2$ complex. This mechanism is commonly referred to as Wilkinson's associative pathway. Since 20e species are generally not favored as intermediates in organometallic mechanisms, the 16e species $HRh(CO)(PPh_3)_2$ has become the generally accepted selective catalyst (see Scheme 7).

The regioselectivity of $HRh(CO)(PPh_3)_2$ is strongly related to the concentration of PPh_3 in solution (up to a certain point) and the H_2/CO ratio used. Commercial hydroformylation reactions are run using solutions that have PPh_3 concentrations of 0.3 M or higher. This corresponds to PPh_3 weight percentages of 8–50% of the total solution in commercial reactors. The effect of PPh_3 concentration on the rate and selectivity for the hydroformylation of 1-hexene can be seen in Table 2.



Scheme 8

Note that doubling the PPh_3 concentration cuts the rate constant in half, even though the rhodium concentration was also doubled! The selectivity, on the other hand, increases to 17:1 for the C_7 aldehyde linear to branched ratio. The 'ultimate' experiment of running $HRh(CO)(PPh_3)_2$ in molten PPh_3 has been done with propylene, giving a 16:1 linear to branched aldehyde ratio. Commercially, propylene is run with PPh_3 concentrations around 0.4 M, which gives a linear to branched selectivity of ≈8–9:1. Lower CO partial pressures also would be expected to favor higher regioselectivities, and this is indeed the case. Rh/PPh_3 reactions are often run with an excess of hydrogen (2:1 H_2/CO ratios are common). Too high a hydrogen partial pressure, or too low a CO partial pressure, however, will increase the alkene hydrogenation and isomerization side reactions to an unacceptable level.

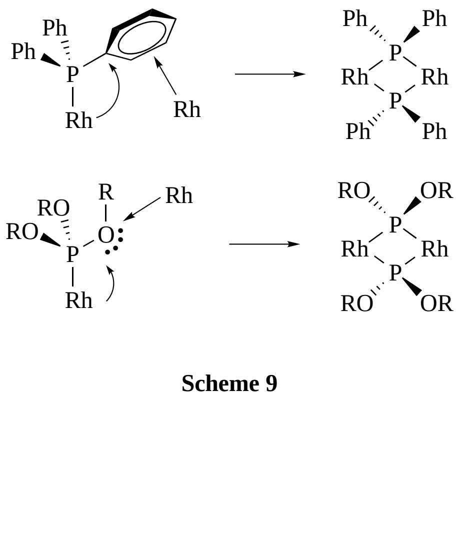
It was assumed early on, in analogy to the $HCo(CO)_4$ catalyst system, that the rate-determining step was H_2 addition to the Rh^I–acyl species. This assumption has been disputed by several authors. Kastrup and coworkers concluded from ^{31}P NMR studies that the rate-determining step could be the initial coordination of alkene to the $HRh(CO)(PPh_3)_2$ catalyst species.[23] Moser and coworkers, in a similar vein, proposed that the rate-determining step is CO dissociation from $HRh(CO)_2(PPh_3)_2$ to once again generate the 16e species $HRh(CO)(PPh_3)_2$.[24] Combining both of these proposals, Unruh concluded that several of the fundamental steps in Rh/PPh_3 hydroformylation appear to have similar rate constants, making it difficult to specify one overall rate-determining step, as they may probably vary with the exact reaction conditions. The complexity of the phosphine/CO ligand dissociation/association processes and the many catalytically active rhodium complexes present was most clearly pointed out by Tolman and Faller, who presented a three-dimensional mechanistic scheme for the hydroformylation of alkenes by Rh/PPh_3 complexes.[25] Scheme 7, in contrast, only indicates the core catalytic cycle that is believed to give the highest product aldehyde regioselectivity.

The other important reason for adding excess phosphine ligand is to minimize ligand fragmentation reactions that lead to catalyst deactivation. If a 14e highly unsaturated species such as $HRh(CO)(PPh_3)$ is formed, the very electrophilic metal center can attack the PPh_3 ligand (either intra- or intermolecularly) (*see Electrophilic Reaction*). This leads to cleavage of the P–Ph bond and formation of either alkyldiphenylphosphines or, in the worst case, phosphide-bridged dimers which are inactive for hydroformylation (Scheme 9).

This fragmentation process has been studied and proceeds by oxidative addition of the P–Ph bond to an unsaturated Rh center.[26,27] A separate PPh_3-activation process involving *Orthometalation* of the phenyl group can also occur. Triarylphosphine ligands and phosphite ligands are particularly susceptible to this fragmentation because of the availability of π- or lone-pair electron density on the ligands that can interact with an empty Rh orbital. The fact that they are moderate to poor electron-donating ligands also enhances the electrophilicity of the rhodium center.[28] Trialkylphosphine ligands should be relatively inert to these types of Rh-induced fragmentations due to the lack of any π-electron density on the ligand. The considerably stronger σ-donation ability of alkylated phosphines also works to decrease the electrophilicity of the rhodium center. Unfortunately, trialkylphosphine ligands generally lower both the rate and selectivity of rhodium hydroformylation catalysts.

The electronic and steric properties of the phosphine ligand(s) can have dramatic effects on the rate and selectivity of the rhodium catalysts. As mentioned above, electron-rich alkylated phosphines generally have a negative effect on the rate and regioselectivity, while more electron deficient phosphines such as PPh_3 and phosphites (*see Electron Deficient Compound*) generate more active and regioselective catalysts (Table 3).

Some of the values in Table 3 are deceptive. The very low activity of P(O-*p*-$MeOC_6H_4)_3$ may well be caused by ligand



Scheme 9

Table 3 Relative rates and regioselectivities for the hydroformylation of 1-octene using $HRh(CO)(PR_3)_2$ catalysts with different phosphine ligands[a]

Phosphine	Cone angle (°)	Rel. rate	Linear:branched ratio
PPh_3	145	7.7	4.6
$P(OPh)_3$	128	5.4	6.1
P(O-*o*-$MeC_6H_4)_3$	141	5.2	3.6
P(O-*p*-$ClC_6H_4)_3$	128	4.9	13.3

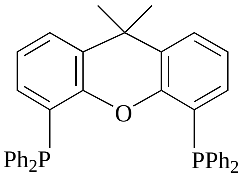
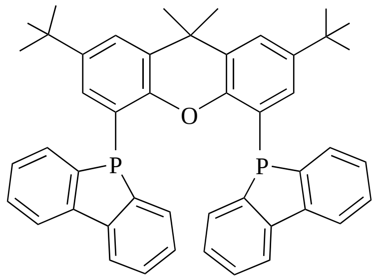
fragmentation and catalyst deactivation. The low linear to branched selectivity for the very bulky P(O-*o*,*o*-$Me_2C_6H_3)_3$ ligand probably results from phosphite dissociation to form small amounts of very active $HRh(CO)_4$ that hydroformylates with low regioselectivity. Under the proper conditions, phosphite ligands produce extremely active rhodium catalysts (see Section 2.7). Unfortunately, phosphite ligands are also the most susceptible to rhodium-induced fragmentations. New developments in the exploration of catalytic intermediates by in situ high pressure IR (HP-IR) techniques have been reported by Kamer and coworkers.[29] The hydroformylation of 1-alkenes with phosphite-supported rhodium complexes was studied in situ with a rapid-scan IR technique. The predominant species in this reaction was identified as $RhC(O)R(CO)_3L$(L = 2-*tert*-butyl-4-methylphenylphosphite). Labeling experiments were carried out where it was possible to study the individual elementary steps in the catalytic cycle.

Chelating phosphines (*see* ***Coordination & Organometallic Chemistry: Principles***) have interesting effects on hydroformylation. $R_2P(CH_2)_xPR_2$ ($x = 2-4$) ligands with alkyl or aryl substituents generally form very poor hydroformylation catalysts that give low rates and selectivities, as well as extensive alkene isomerization and hydrogenation side reactions. However, several investigations have shown that chelating phosphines with large bite angles ($\beta_n \sim 100-130°$) (*see Bite Angle*) can influence the activity and selectivity in rhodium-catalyzed hydroformylation reactions. van Leeuwen and coworkers have discovered that by increasing the bite angle of the bisphosphine ligand in complexes of the general formula $[RhL_2(CO)_2]$ (L_2 = bisphosphine), the steric bulk at the metal increases and this ultimately leads to the preferential formation of the linear aldehyde.[30] Xantphos-type ligands ((**1**), natural $\beta_n \sim 102-123°$) have been crucial in the study of bite angle effects on the activity and selectivity of hydroformylation reactions. Ligands such as DPB-xantphos (**2**) and POP-xantphos (**3**) have shown good activity for the selective rhodium-catalyzed hydroformylation of internal alkenes to linear aldehydes.



(**1**)



(**2**)

Stereoselectivity in hydroformylation reactions, as a result of the supporting ligand set (e.g. large bite angle diphosphines or chiral diphosphines) or by stereocontrol of the substrate has also been discussed by Breit.[31] Rhodium complexes supported by large bite angle diphosphines such as bisbi, biphephos and xantphos, shown in Scheme 10, are now well-established

systems for the hydroformylation of olefins yielding high regioselectivity for the formation of the linear isomer. In order to prepare chiral products via hydroformylation reactions, branched products are essential, so a successful catalyst for asymmetric hydroformylation must therefore show simultaneously excellent regiocontrol as well as stereocontrol. Although systems involving substrate-based stereocontrol or catalyst-directing groups have been successful, additional research will be necessary for the development of target-oriented synthetic systems.

An integrated molecular orbital/molecular mechanics method (IMOMM) was utilized to explore trends in regioselectivity for rhodium-catalyzed hydroformylation supported by xantphos-type ligands.[32] A key intermediate in the reaction, [RhH(CO)(alkene)(diphosphine)], was studied through eight possible reaction pathways and corresponding transition states for alkene insertion. By canceling the effects of the phenyl substituents on the ligand, it was discovered that the nonbonding interactions between the diphenylphosphino substituents and the substrate affect the regioselectivity of the reaction. Orbital effects, or the bite angle, have an overall smaller direct influence in this area.

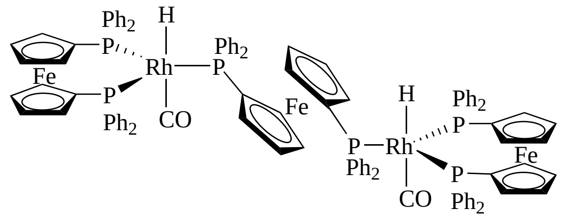
Unruh and Christenson studied the unusual chelating phosphine ligand 1,1′-bis(diphenylphosphino)ferrocene and found several interesting effects on Rh-catalyzed hydroformylation.[33] The effect of excess ligand on rate and selectivity is shown in Table 4.

Table 4 Rates and regioselectivities for the hydroformylation of 1-hexene using $Rh(acac)(CO)_2$ with 1,1′-(Ph_2P)ferrocene[a]

P_2:Rh ratio	1.0	1.25	1.5	2.0	3.0
Linear: branched ratio	2.2	2.8	5.2	5.2	5.2
k_{obs} (h^{-1} mM Rh^{-1})	5.8	3.1	1.4	1.5	1.5

[a]Reaction conditions: 165 psig, 110 °C, 1:1 H_2/CO.

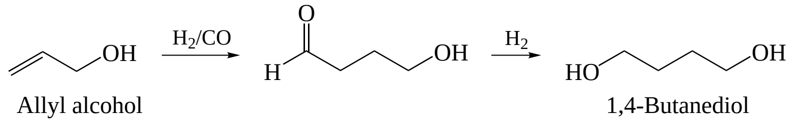
This effect was interpreted as implying that three phosphine ligands needed to be coordinated to the rhodium center during the coordination of the alkene and insertion into the Rh–H bond to form the linear alkyl. Species (**4**) was proposed to explain the optimum 1.5:1 ligand to rhodium ratio for the higher selectivity. The rate and selectivity was also found to increase as electron-withdrawing substituents were added to the *para* positions on the phenyl rings of the 1,1′-bis(diphenylphosphino)ferrocene ligands. Going from H to CF_3 groups caused the rate to almost double and increased the selectivity from 5.4:1 to 11.4:1.



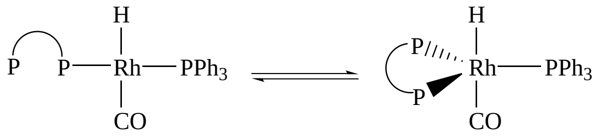
(**4**)

Matsumoto and Tamura (at Kuraray Co.) have demonstrated that the combination of simple bis(diphenylphosphino)alkane ligands and PPh_3 has a very positive effect on catalyst stability and the reduction of unwanted side reactions.[34] This is most evident in the hydroformylation of a reactive alkene substrate such as allyl alcohol. The use of $HRh(CO)(PPh_3)_2$ in the presence of excess PPh_3 leads to relatively rapid catalyst deactivation to unidentified species. The addition of just over 1 equivalent of dppb, for example, leads to a stable, active hydroformylation catalyst.[35] Use of dppb either by itself, or in quantities higher than 2 equivalents, leads to catalyst deactivation and/or poor activities and selectivities. ARCO Chemical Co. licensed the Kuraray technology to build the first commercial plant (1990) for the hydroformylation of allyl alcohol to produce 1,4-butanediol (Scheme 11).

It is not exactly understood how the mixed ligand Rh/dppb/PPh_3 catalyst system functions. Matsumoto proposed that the arm-on, arm-off equilibrium shown in Scheme 12 is operational. A species such as (**5**) would function much like a normal $HRh(CO)(PPh_3)_2$ catalyst, but the ability to reform the chelate to form a slightly more electron-rich complex (**6**) would tend to inhibit alkene isomerization and/or degradation reactions which require 16e unsaturated species. ^{31}P NMR studies of Rh/chelating phosphine complexes indicate that a variety of species can form, the most dominant of which are

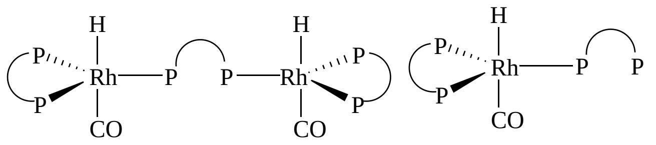


Scheme 11



(5) (6)

Scheme 12



(7) (8)

HRh(CO)(η^2-P_2)(PPh_3) (**6**), HRh(CO)(η^2-P_2)(μ-P_2)RhH(η^2-P_2)(CO) (**7**), and HRh(CO)(η^2-P_2)(η^1-P_2) (**8**).[36]

One important variant of Rh/PPh_3 catalysis is the water-soluble catalyst system developed by Kuntz at Rhone-Poulenc. By using a sulfonated PPh_3 ligand, $P(C_6H_4\text{-}m\text{-}SO_3^{-}Na^{+})_3$ (tppts), a highly water-soluble rhodium catalyst is generated, $HRh(CO)(tppts)_3$. In aqueous solution, the catalyst essentially has a -9 charge, making it totally insoluble in all but the most polar organic solvents. Excess phosphine ligand is required for good regioselectivities, as with conventional Rh/PPh_3 catalysts, but somewhat lower concentrations are generally required. Shorter chain alkenes (C_2–C_6) are water soluble enough that migration into the aqueous catalyst phase occurs to give hydroformylation. Remigration of the aldehyde product back into the more soluble organic phase allows easy separation of product from catalyst. Rather high linear to branched regioselectivities of 16–18:1 for propylene can be obtained via this water-soluble catalyst. Rates are somewhat slower than with conventional Rh/PPh_3 catalysts owing to lower alkene concentrations in the water phase. The process is limited, of course, to the shorter chain alkenes that have some appreciable water solubility. Alkenes higher than 1-heptane are not soluble enough in water to use this catalyst system. Ruhrchemie–Hoechst currently operates several hydroformylation plants based on this water-soluble rhodium-catalyst technology. The large natural bite angle diphosphine ligand, xantphos, has been modified to yield a water-soluble version, 2,7-bis(SO_3Na)-xantphos.[37] The rhodium-catalyzed hydroformylation of propene, 1-hexene, and 4-styrene supported by this ligand has been reported by van Leeuwen and coworkers. This system was found to be active and highly regioselective for the formation of linear products.

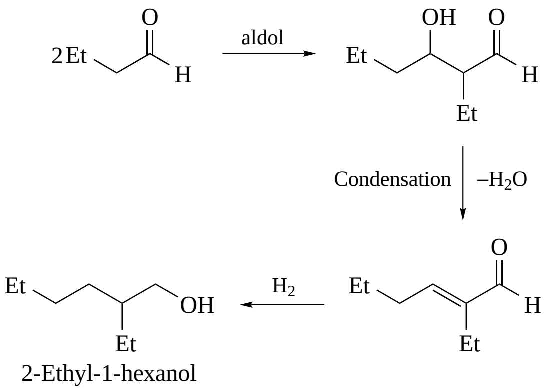
Rh/PPh_3-catalyzed hydroformylation is responsible for just over 50% of all oxo alcohols produced. Propylene is the largest single alkene hydroformylated to produce butylaldehyde, which can be hydrogenated to produce butanol, or dimerized by an aldol condensation and then hydrogenated to form 2-ethyl-1-hexanol (Scheme 13), the largest single product produced by hydroformylation (over 2.3 billion kg a year). 2-Ethyl-1-hexanol is usually reacted with phthalic anhydride to produce dialkyl phthalic esters that are used as plasticizers to keep poly(vinyl chloride) plastics soft and flexible.

2.5 Platinum–Tin Phosphine Catalysts

Although rhodium and cobalt complexes are the only ones used in industrial hydroformylation, the next most studied transition metal catalyst involves the use of mixed platinum/phosphine/$SnCl_2$ complexes (*see* ***Platinum: Organometallic Chemistry***). In 1975, Hsu and Orchin[38] reported that $HPt(SnCl_3)(CO)(PPh_3)_2$ gave high selectivity to linear alkenes. The hydroformylation of 1-pentene, for example, gave a 19:1 linear to branched aldehyde product ratio at 100 °C and 3000 psi.

Schwager and Knifton patented a $PtCl_2/SnCl_2/PPh_3$ catalyst system in 1973 and published a paper on it in 1976.[39] They reported that the most effective catalyst composition contained $5SnCl_2$, $2PPh_3$, and $1PtCl_2$. Temperatures greater than 100 °C led to excessive alkene isomerization, while partial CO pressures greater than ≈750 psig caused a fairly dramatic drop in reaction rate. Partial H_2 pressures greater than ≈750 psig increase the amount of aldehyde hydrogenation to alcohol, which leads to deactivation of the catalyst. The very negative effect of alcohol is due to its preferential coordination to $SnCl_2$, removing it from the Pt center and leading to catalyst deactivation. Polar solvents also have a negative effect on the rate of catalysis, presumably for similar reasons. Solvents with intermediate polarity, such as acetophenone, methyl ethyl ketone, or methyl isobutyl ketone, work the best.

The active hydroformylation catalyst is believed to be the square-planar 16e complex $HPt(SnCl_3)(CO)(PPh_3)$ and one proposed mechanism is shown in Scheme 13. Although the general mechanism closely follows the fundamental steps seen for Rh/PPh_3 catalysts (see Scheme 7), the general rate equation (equation 6) indicates that there are certainly some differences. The $SnCl_2$ can react with one of the chlorides to form a



Scheme 13

coordinated $SnCl_3^-$ ligand. The tin is not needed for alkene insertion into the Pt–H bond, nor for CO insertion into the resulting alkyl to generate the acyl species. $SnCl_2$ is needed, however, for H_2 addition to the Pt center and elimination of the product aldehyde. The first few steps in Scheme 13 could, therefore, be written without the $SnCl_3$ ligand. The role of the $SnCl_3$ ligand is believed to be the removal of electron density from the Pt center to help dissociate a CO ligand from an 18e saturated five-coordinate species, such as $Pt(acyl)(Cl)(CO)(PPh_3)_2$. This would open up a coordination site to allow H_2 oxidative addition to the Pt center and subsequent elimination of aldehyde product.

$$\frac{d(\text{aldehyde})}{dt} = k[\text{alkene}][\text{Pt}]^{1.5}[\text{H}_2][\text{CO}]^{-0.5} \qquad (6)$$

Although the $Pt/Sn/PPh_3$ catalyst system has been described as 'highly active', this activity is relative to that of Pt catalysts without $SnCl_2$, which are extremely slow. Hydroformylation rates for $Pt/Sn/PPh_3$ range from about 25 to 50 turnovers/h for 1-alkenes at 70 °C and 1500 psi. This rate can be compared to Rh/PPh_3, which produces 500 turnovers/h with 1-hexene giving a linear to branched aldehyde product ratio of 17:1 at 90 psig and 90 °C.

Interest in Pt/Sn hydroformylation arose from Stille's asymmetric hydroformylation with chiral chelating phosphine ligands that gave >96% enantiomeric excess (*ee*) for the branched aldehyde products of substrates such as vinyl arenes and vinyl acetate (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***). Unfortunately, the very low rates, poor branched to linear selectivities, and need for an aldehyde-trapping agent limited the commercial appeal of this catalyst. Note that this platinum catalyst uses an optically active-chelating phosphine, which implies that both phosphines can remain coordinated during the catalytic cycle, unlike that shown in Scheme 14.

More recently, an excellent review of sulfur-containing ligands in a variety of homogeneously catalyzed reactions, including platinum–tin hydroformylation, was published by Claver and coworkers and so this area will not be discussed here.[40] The development of amine and arsine analogues of xantphos-type ligands and their application in platinum–tin catalyzed hydroformylation has been reported by van Leeuwen and coworkers.[41] The amine-based ligands do not exhibit good activity probably due to the electron-donating capability of the diphenylamine group. The arsine-based systems, however, show comparable activities to xantphos-supported systems due to the formation of $[(ligand)Rh(CO)_2H]$ and $[(ligand)Rh(CO)_2]_2$ complexes. In the case of Pt–Sn catalyzed hydroformylation of 1-octene under mild conditions, xantarsine and the mixed phosphine–arsine xantphosarsine ligands (**9**) exhibit superior activity and selectivity compared to xantphos. A comparison of results for platinum–tin and rhodium-catalyzed reactions with various ligands is shown in Table 5.

Parahydrogen has been utilized as a mechanistic probe in a number of reactions involving hydrogen. The application of parahydrogen-induced polarization (PHIP) in hydroformylation has been reported by Eisenberg and coworkers.[42] Hydroformylation of 1-hexene in the presence of *cis*-$[PtCl_2(CO)(PPh_3)]$-$SnCl_2$ using parahydrogen yields the expected aldehyde product in which the aldehydic resonance exhibits net emission in the ^1H NMR spectrum. This is the first observation of a PHIP effect for a single-proton transfer process.

Table 5 Hydroformylation of 1-octene with rhodium and platinum–tin complexes supported by amine, arsine and phosphine ligands[a]

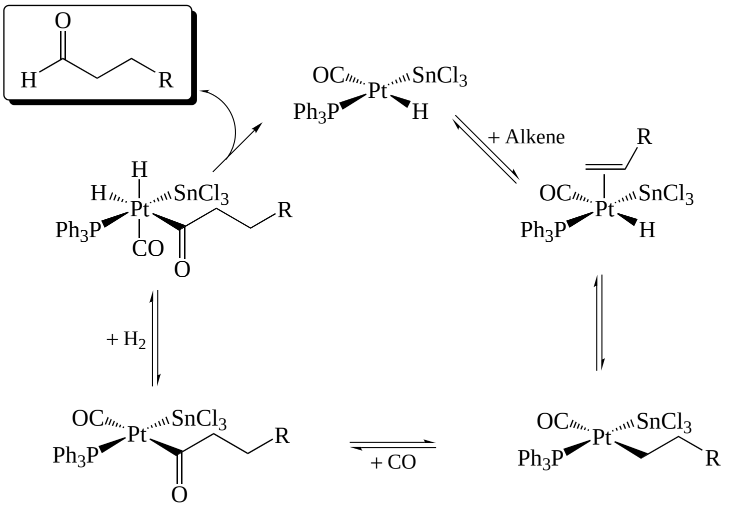
(**9**)

2.6 Polymetallic Catalysts

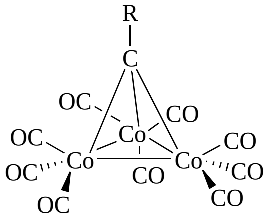
There have been numerous reports on dimer and cluster catalysis for hydroformylation. Indeed, it was realized early on that cobalt– and rhodium–carbonyl dimers and clusters were viable catalyst precursors for modified or unmodified hydroformylation catalysts. Muetterties proposed the cluster-surface analogy, which stated that molecular metal clusters may be reasonable models of heterogeneous metal surfaces in catalysis (*see* ***Polynuclear Organometallic Cluster Complexes*** and ***Dinuclear Organometallic Cluster Complexes***).[43] It was recognized that on metal surfaces, cooperativity between two or more metal centers in activating substrates and in doing catalysis often played an important factor in the catalytic activity of heterogeneous catalysts.

This proposal ignited a worldwide effort by transition metal dimer and cluster chemists to show that polymetallic systems could be effective homogeneous catalysts. Pittman and



Scheme 14

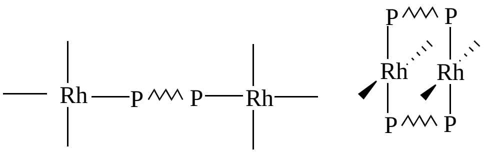
coworkers reported that 1-pentene could be hydroformylated by the intact cobalt clusters (**10**).[44]



(**10**)

These clusters gave linear to branched aldehyde ratios of between 1 and 5:1 (≈2.5 being typical) at temperatures of 90–150 °C and pressures of 400–1100 psi. The highest linear aldehyde regioselectivities were found, as with monometallic cobalt catalysts, at lower temperatures and higher pressures. The intact clusters could be isolated in near-quantitative yields after the catalysis. One important piece of evidence that fragmentation to $HCo(CO)_4$ was not occurring was obtained from the influence of phosphine ligands on the chemoselectivity of the catalysis. The addition of 2–4 equivalents of PPh_3 improved the stability of the cluster (similar to the monometallic catalysts), but did not increase hydrogenation activity to produce alcohol products, quite unlike monometallic $HCo(CO)_3(PR_3)$ catalysts.[45] Recent high-pressure IR studies of phosphine-substituted analogs of (**7**) show that there is no observable cluster fragmentation under catalytic conditions (150 °C, 600 psi), even over extended periods of time (2 days).[46]

Sanger and coworkers reported an unusual effect of certain bisphosphine ligands, $Ph_2P(CH_2)_nPPh_2$, on the activity of $HRh(CO)(PPh_3)_2$ hydroformylation catalysts.[47] The addition of 0.25 equivalents of $Ph_2P(CH_2)_nPPh_2$ ($n = 2–4$) per equivalent of $HRh(CO)(PPh_3)_2$ caused an increase in the catalytic activity of 90–150%. Addition of more than 0.3 equivalents, however, caused a decrease in the activity relative to the starting $HRh(CO)(PPh_3)_2$ catalyst. Di- and polyphosphine-bridged rhodium species, such as (**11**) and (**12**), were spectroscopically identified at about the same time.



(**11**) (**12**)

This observation led to the proposal that tethering two rhodium centers together via the bisphosphine ligands was producing some sort of bimetallic cooperativity between the two metal centers. An intramolecular hydride transfer, analogous to the intermolecular hydride transfer proposed by Heck (Scheme 1), enhanced by the proximity of the two metal centers, seemed a very likely possibility.

Fragmentation has been a major and continuing problem in polymetallic catalyst systems. Longoni and coworkers reported in 1984 that the $Co_2Rh_2(CO)_{12}$ mixed-metal cluster was more active than either the parent $Co_4(CO)_{12}$ or $Rh_4(CO)_{12}$ cluster species.[48] This higher activity was proposed to be caused by heterobimetallic cooperativity between the Co and Rh centers in the cluster. Garland, however, showed that the higher activity of the $Co_2Rh_2(CO)_{12}$ mixed-metal cluster was simply due to the more facile fragmentation of this cluster into reactive $HRh(CO)_4$ monometallic catalyst species.[49]

Hidai and coworkers in the mid-1980s also observed a 'cooperative' mixed-metal effect for $Co_2(CO)_8$ and $Ru_3(CO)_{12}$ cluster mixtures.[50] They observed a rather dramatic 27-fold

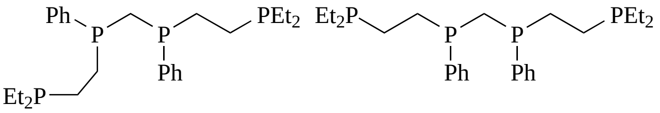
increase in the rate for the hydroformylation of cyclohexene with a 9.9:1 Ru:Co ratio relative to $Co_2(CO)_8$ alone. More modest rate increases (≈3 times at an optimum Ru:Co ratio of 1:1) were seen for the hydroformylation of 1-hexene. The linear to branched aldehyde product ratio, however, was the same as for $Co_2(CO)_8$. Discrete Co/Ru clusters, however, were not proposed. Hidai suggested instead that the clusters fragmented, and that the Heck bimetallic intermolecular hydride transfer mechanism (see Scheme 1) was responsible for the rate increases. $[HRu(CO)_4]^-$ has been shown to react much more readily with (acyl)$Co(CO)_4$ to eliminate aldehyde than $HCo(CO)_4$, probably because it is more nucleophilic.[51] Ru is also believed to activate H_2 more readily than cobalt. Thus, it was proposed that the Ru/Co cooperativity was in the form of an intermolecular hydride transfer to facilitate the elimination of aldehyde product.

One cluster system that has given very high product regioselectivities is $[HRu_3(CO)_{11}]^-$, reported by Süss–Fink and coworkers.[52] This cluster catalyst has linear to branched aldehyde regioselectivities of up to 70:1 for the hydroformylation of propylene. The very high selectivity, coupled with the fact that monometallic Ru hydroformylation catalysts do not have high product regioselectivities, strongly points to the presence of intact clusters performing the catalysis. One can then ask whether the hydroformylation is occurring only on a single-metal center, or whether one is having bi- or polymetallic cooperativity in the catalysis. Süss–Fink has discussed the possibility of bimetallic cooperativity, but strong evidence either way has not been found. Unfortunately, the activity of this cluster catalyst is extremely low (e.g. only 50 turnovers over the course of 66 h at 10 bar H_2/CO/propylene and 70 °C in diglyme), limiting its practical appeal.

A bimetallic hydroformylation catalyst that has attracted interest is the thiolate-bridged rhodium complex $Rh_2(\mu\text{-}SR)_2(CO)_2(PR_3)_2$ studied by Kalck.[53] This complex is a rather active hydroformylation catalyst for 1-alkenes, giving rates that are faster than $HRh(CO)(PPh_3)_2$. (Kalck has claimed that $Rh_2(\mu\text{-}SR)_2(CO)_2(PR_3)_2$ is four times faster than $HRh(CO)(PPh_3)_2$, but no excess PPh_3 was used for $HRh(CO)(PPh_3)_2$; this probably leads to deactivation of the monometallic catalyst by PPh_3 fragmentation.) Reaction conditions are typically mild for a Rh-based catalyst: 5 bar 1:1 H_2/CO and 80 °C. IR and ^{31}P NMR studies of the catalyst under hydroformylation conditions only show the presence of $Rh_2(\mu\text{-}SR)_2(CO)_2(PR_3)_2$ or $Rh_2(\mu\text{-}SR)_2(CO)_4$. Some excess PPh_3 is needed to keep the bimetallic catalyst in the $Rh_2(\mu\text{-}SR)_2(CO)_2(PR_3)_2$ state, since the tetracarbonyl-substituted bimetallic species $Rh_2(\mu\text{-}SR)_2(CO)_4$ is inactive for hydroformylation under mild conditions. The apparent high activity of this bimetallic catalyst, coupled with the lack of observable fragmentation reactions, led Kalck to propose the bimetallic mechanism shown in Scheme 15. The mechanism relies on several intramolecular hydride transfers, the first which leads to formation of the Rh–alkyl complex, the second transfer assisting in the elimination of aldehyde product. Ab initio molecular orbital studies have been performed on this system, providing some support for the various mechanistic steps.[54]

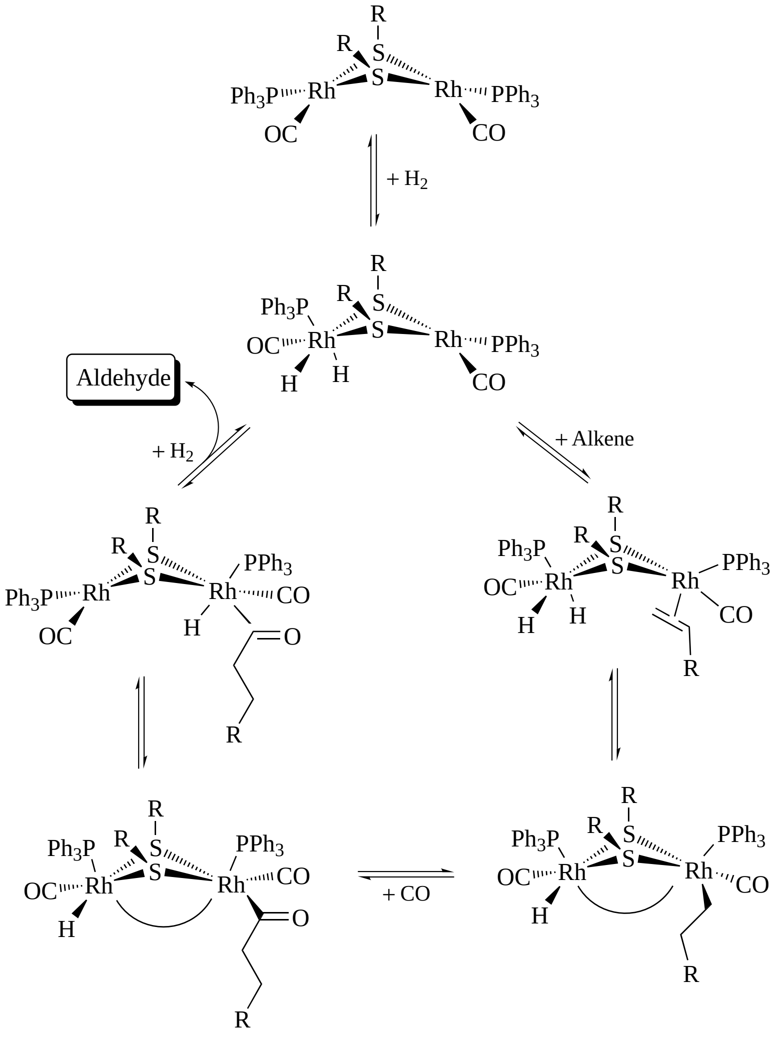
There are, however, a number of experimental observations on this bimetallic catalyst that could indicate that fragmentation to generate monometallic catalyst species is occurring. Foremost is that the selectivity of $Rh_2(\mu\text{-}SR)_2(CO)_2(PR_3)_2$ is essentially the same as that seen for monometallic Rh/PPh_3 catalysts. Furthermore, the effect on rate and regioselectivity of adding excess PPh_3 to the bimetallic catalyst almost exactly parallels the monometallic rhodium catalyst. There is a catalytic induction period for $Rh_2(\mu\text{-}SR)_2(CO)_2(PR_3)_2$ that would be consistent with the need to wait for fragmentation to generate monometallic complexes. Kalck has observed that when the two dimer complexes $Rh_2(\mu\text{-}pz)_2(CO)_2(PR_3)_2$ (pz = pyrazolate) and $Rh_2(\mu\text{-}SR)_2(CO)_2(PR_3)_2$ are mixed together, the mixed-bridge bimetallic complex *cis*-$Rh_2(\mu\text{-}pz)(\mu\text{-}SR)(CO)_2(PR_3)_2$ is slowly produced. This observation implies that some sort of dissociative/reassociative equilibrium process may be taking place.

Another bimetallic rhodium complex that may provide an indisputable example of bimetallic cooperativity in hydroformylation catalysis has been reported by Stanley and coworkers.[55] They designed a novel binucleating tetraphosphine ligand (et,ph-P4; (**13r**), (**13m**)) that can both bridge and chelate two transition metal centers, producing bimetallic complexes that only have a single, very conformationally flexible bridging group.



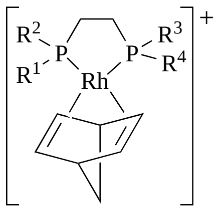
racemic-et,ph-P4 (**13r**)   *meso*-et,ph-P4 (**13m**)

It was found that [*racemic*-$Rh_2(nbd)_2$(et,ph-P4)]$(BF_4)_2$ (nbd = norbornadiene) was a catalyst precursor to a highly active and regioselective hydroformylation catalyst for 1-alkenes under mild conditions. The bimetallic catalyst gave hydroformylation rates for 1-hexene that were ≈40% faster than the Rh/PPh_3 monometallic catalyst, and a linear to branched aldehyde regioselectivity of 28:1, relative to 17:1 for $HRh(CO)(PPh_3)_2$ with 0.82 M PPh_3 (conditions: 90 °C, 90 psig 1:1 H_2/CO). Since neither the *rac*-$Rh_2(nbd)_2$(et,ph-P4)$^{2+}$ precursor complex, nor the proposed active catalyst species *rac*-$Rh_2H_2(CO)_2$(et,ph-P4), have a Rh–Rh bond it was fairly straightforward to prepare mono- and bimetallic model systems to test whether the two metal centers were working independently or if the complex was fragmenting to generate active monometallic species. The hydroformylation activity of a series of monometallic complexes (**14**) and spaced bimetallic complexes (**15**) and (**16**) were studied. These were



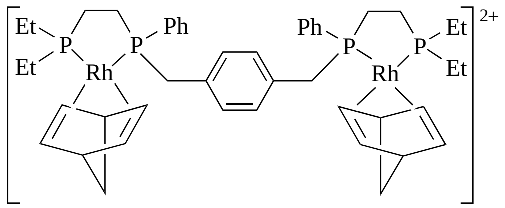
Scheme 15

all found to be very poor hydroformylation catalysts, giving extremely low rates and selectivities.



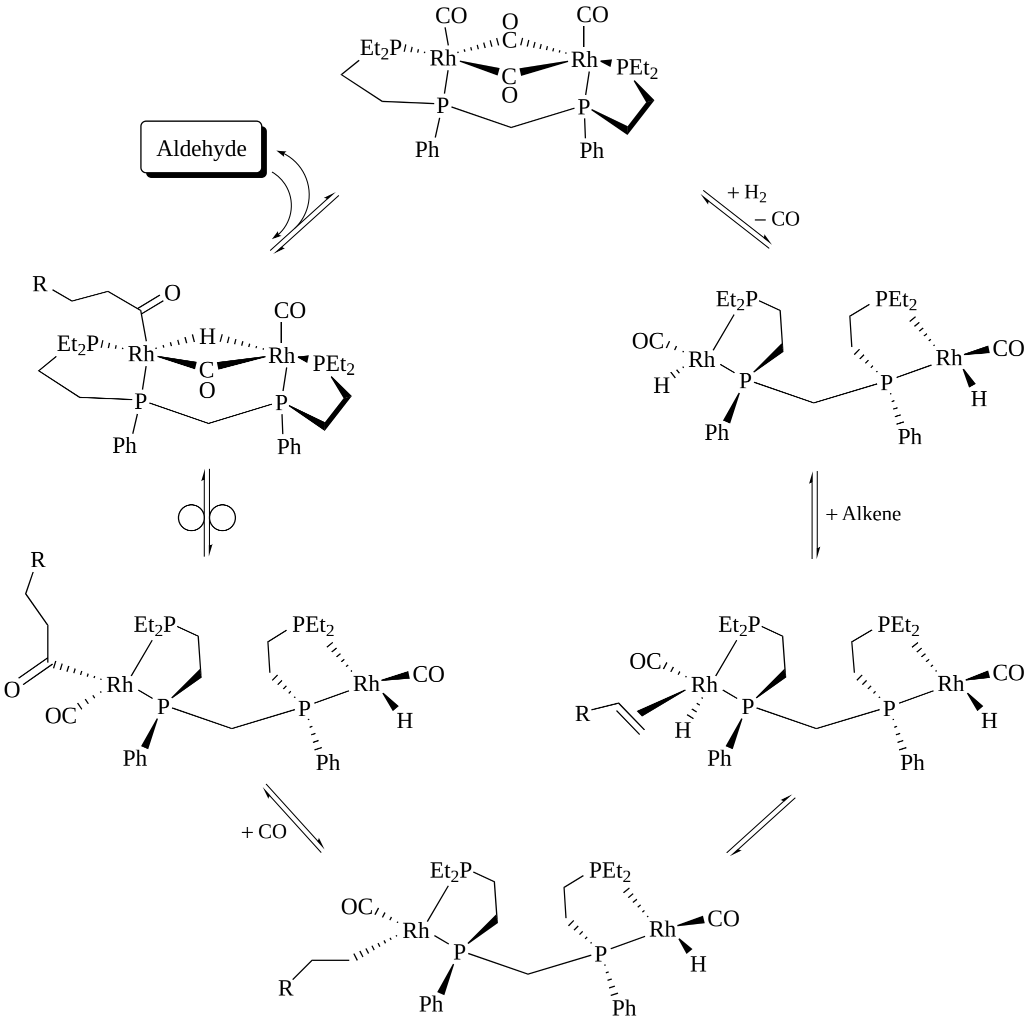
(**14**)

This led Stanley to propose the bimetallic cooperativity mechanism shown in Scheme 16. The key bimetallic cooperativity step involves rotation about the central bridging methylene group to give a H^-/CO double-bridged intermediate (or transition state) species, which directly leads to an

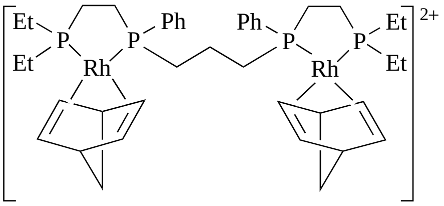


(**15**)

intramolecular hydride transfer to the acyl-coordinated rhodium center. Reductive elimination of the aldehyde product forms the Rh–Rh bonded dimer species shown at the top of the cycle. H_2 addition regenerates the nonmetal-bonded bimetallic catalyst *rac*-$Rh_2H_2(CO)_2$(et,ph-P4). A key kinetic and mechanistic prediction from this bimetallic mechanism is that if alkenes add to both rhodium centers within the same time period, there will be no hydride to transfer from



Scheme 16



(**16**)

one rhodium center to the other. Thus, the catalyst should be inhibited by high concentrations of alkene. This is indeed the case and represents another relatively dramatic difference between this bimetallic catalyst and monometallic Rh/PPh_3 catalysts.

The rhodium-catalyzed hydroformylation of 1-hexene using a polar-phase solvent system (30% water by volume in acetone) has resulted in improvements in rate and chemoselectivity for catalysts supported by the tetraphosphine ligand et,ph-P4.[56] A cationic rhodium dimer comprising this ligand, $[rac\text{-}Rh_2H_2(\mu\text{-}CO)_2(CO)_4(\text{et,ph-P4})]^{2+}$, is shown to be an active catalyst for this reaction. A turnover frequency (TOF) of 73 min^{-1} and a chemoselectivity of 33:1 (linear:branched product) were found for this dimer with virtually no side-product formation (*cf.* pure acetone system: TOF 20 min^{-1}, 25:1 l:b; side-product formation: 2.5% isomerization and 3.4% hydrogenation). The water is believed to prevent the dissociation of the phosphine, which would lead to deactivation of the catalyst, but since many higher alkenes and some aldehydes are not water soluble, this efficient reaction seems somewhat limited in scope.

The synergistic effect often observed in bimetallic systems was further explored by Garland and coworkers.[57] The hydroformylation of 3,3-dimethylbut-1-ene to form 4,4-dimethylpentanal in >95% selectivity at room temperature with $[Rh_4(CO)_{12}]$-$[Mn_2(CO)_{10}/HMn(CO)_5]$ as catalyst co-precursors was investigated using in situ FT-IR spectroscopic techniques and kinetic studies revealing evidence of a bimetallic catalytic binuclear elimination reaction (CBER).

Only the monometallic complexes, $RCORh(CO)_4$, $Rh_4(CO)_{12}$, $Rh_6(CO)_{16}$, $HMn(CO)_5$ and $Mn_2(CO)_{10}$, were observed during the reaction. In addition, the kinetic data is consistent with a unicyclic catalytic reaction mechanism (i.e. mononuclear intermediates, equations 7 and 8). Product formation is most probably due to interactions between a rhodium-acyl intermediate, for example, $RCORh(CO)_4$, and a hydrido-manganese species:

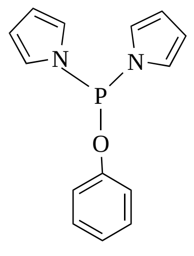
$$HMn(CO)_4 + RCORh(CO)_3 \longrightarrow RCHO + RhMn(CO)_7 \quad (7)$$

$$HMn(CO)_5 + RCORh(CO)_4 \longrightarrow RCHO + RhMn(CO)_8 \quad (8)$$

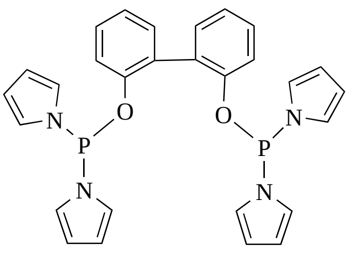
The [Rh–Mn] bimetallic system exhibits higher activity for hydroformylation (≈500% higher) compared to the rhodium-only system. The presence of the manganese is responsible for a decrease in the induction period and prevents deactivation via cluster formation.

2.7 Novel Catalyst and Solvent Systems

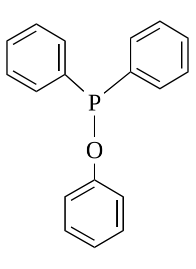
New monodentate and bidentate phosphorus amidite (**17a, b**) and phosphinite ligands (**18a, b**) have been synthesized and utilized as supporting ligands in the rhodium-catalyzed hydroformylation of 1-octene in order to study electronic influences on the activity and selectivity of the reaction.[58] Monodentate ligands gave rise to systems with a moderate selectivity for linear product while catalysts supported with ligands with high π-acidity resulted in an increase in reaction rate. Reactions supported by the bidentate amidite ligand gave both high activity and regioselectivity for linear aldehyde (l:b ∼ 100:1) and modest selectivity for isomerization (7%).



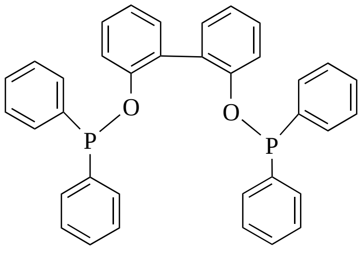
(**17a**)



(**17b**)



(**18a**)



(**18b**)

As a further development in the exploration of the role of solvent in hydroformylation systems, the use of supercritical carbon dioxide ($scCO_2$), ionic liquids and fluorous systems has been reported. A review by Jessop, Ikariya, and Noyori presents information about the utility of $scCO_2$ in a variety of homogeneous reactions.[59]

Both modified and unmodified rhodium catalysts have shown good activity and selectivity for the hydroformylation of 1-octene in $scCO_2$.[60] With respect to the unmodified catalyst, higher reaction rates can be achieved compared to organic solvents or liquid CO_2 under similar conditions. These modified systems exhibit higher regioselectivities compared to conventional solvent systems.

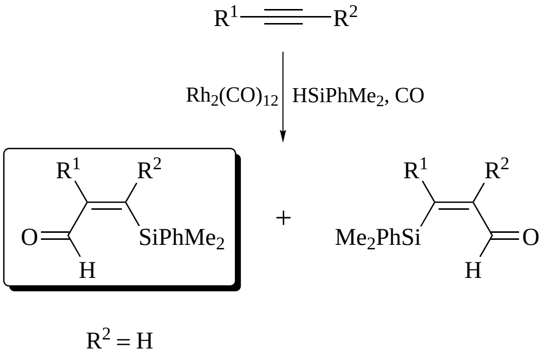
The hydroformylation of 1-hexene by supported ionic liquid catalysis (SILC) was recently reported by researchers at ExxonMobil.[61] In this system, the active catalyst $HRh(CO)(tppti)_3$ (tppti = tri(m-sulfonyl)triphenyl phosphine tris(1-butyl-3-methyl-imidazolium)) is contained within the ionic liquid phase while excess tppti ligand is immobilized in the support material. TOF values of 65 min^{-1} were obtained with silc while an unsupported biphasic ionic liquid medium gave TOF values of 23 min^{-1}.

The utility of a biphasic fluorous system with $Rh(acac)(CO)_2/P(C_6H_4\text{-}4\text{-}OCH_2C_7F_{15})_3$ as the catalyst precursor in the hydroformylation of 1-octene has been reported by Bultó and coworkers.[62] In this system, selectivities of 99% and regioselectivities for the linear aldehyde up to linear/branched = 2.8 were achieved with TOF values of 380 h^{-1}. Although loss of rhodium was observed after the first run, the system could be recycled twice without diminishing activity or selectivity.

2.8 Silylformylation

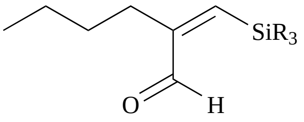
In 1989, Matsuda[63] and Ojima[64] independently reported a new hybrid reaction for alkynes that combined *Hydrosilation* (*see* ***Hydrosilation Catalysis***) and hydroformylation catalysis. This reaction produces 3-silyl-2-alkenals and is called silylformylation (see Scheme 17). Matsuda used $Rh_4(CO)_{12}$ as the catalyst, and $HSiPhMe_2$ was used as the hydrogen source instead of H_2. Typical reaction conditions were 100 °C and 150–450 psig CO and rather high catalyst activity was seen. The regioselectivity strongly favored silyl group addition to the carbon of the alkyne that was the least hindered or substituted. Thus, when R^2 = H, only one product was formed, usually in high yields. The Z:E *Regioselectivity* was also generally very good. Very bulky substituent groups on the alkyne can block catalysis.

Ojima used $Rh_4(CO)_{12}$ and the heterometallic catalyst $Co_2Rh_2(CO)_{12}$ (which forms $CoRh(CO)_7$ under the catalytic conditions and is believed to be the actual catalyst) for the silylformylation of 1-hexyne with a variety of $HSiR_3$ reagents. Although the reaction could be performed under ambient conditions, higher-product yields were obtained under 150 psig of CO. It was also found that $Co_2Rh_2(CO)_{12}$ gave



Scheme 17

higher yields (93–100%) of silylformylated products relative to $Rh_4(CO)_{12}$. When $HSi(OMe)_3$ was used as the silane, only hydrosilylation was seen for the $Rh_4(CO)_{12}$, while $Co_2Rh_2(CO)_{12}$ gave some (20–40%) of the silylformylation product. Only (*Z*)-1-silyl-2-formyl structures (**19**) were found.

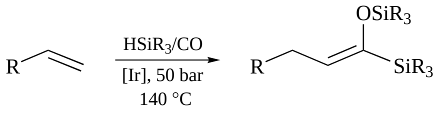


(**19**)

As monometallic Rh complexes also catalyze this reaction (although sometimes much more slowly) under conditions where clusters are unlikely to form, it appears that only a single-metal center is really required for this reaction. Ojima's $CoRh(CO)_7$ catalyst has been studied in considerable detail for the hydroformylation of fluoroalkenes,[65] and it has been concluded that although the active catalyst is $CoRh(CO)_7$, only the rhodium center is actively involved in the catalysis. A monometallic mechanism, patterned after hydroformylation, is shown in Scheme 18.

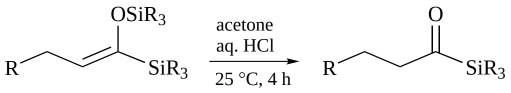
Note that in order to obtain the high regioselectivities observed for this catalytic process, the silyl group must transfer first to the terminal, less-hindered carbon center of the alkyne. If hydride transferred first, one would expect to see considerably poorer regioselectivities (see Section 2.3).

The silylformylation of alkenes to produce enol silyl ethers by $[IrCl(CO)_3]_n$ or $Ir_4(CO)_{12}$ has been reported by Murai and coworkers (equation 9).[66]

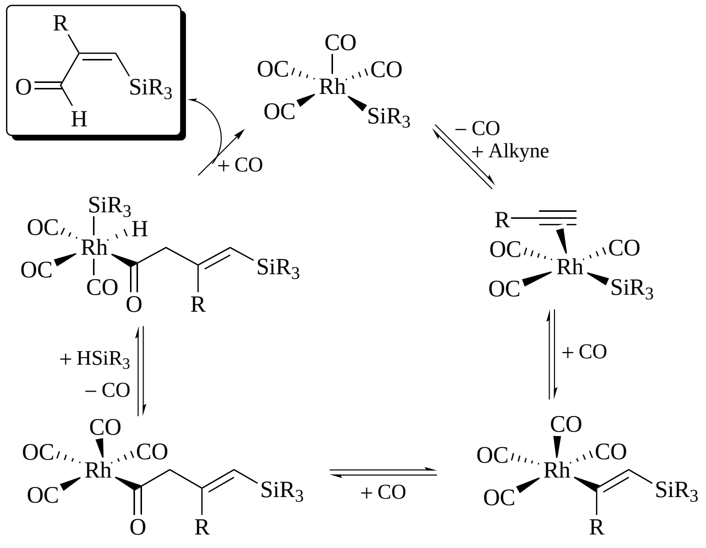


(9)

In this case, alkene insertion into the Ir–H bond is likely to occur first, producing a linear alkyl species. CO insertion would produce an acyl species, which would then be followed by reductive elimination of the acylsilane product. Enolization, followed by rapid reaction of $HSiR_3$ with the OH group, traps out the enol silyl ether. The H_2 produced from this silylation step is used to hydrogenate some of the starting alkene. Thus, the maximum yield will generally be only 66% of the enol silyl ether product. The enol silyl ethers can be readily converted into silyl ketones (equation 10).

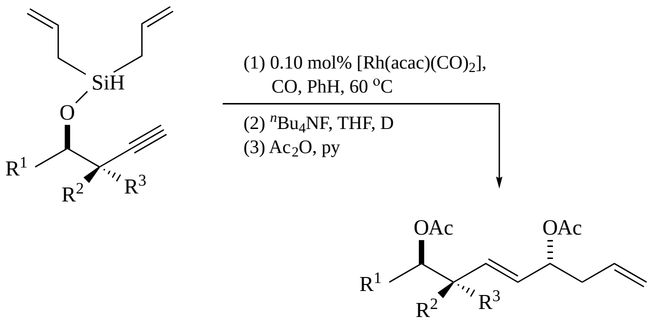


(10)

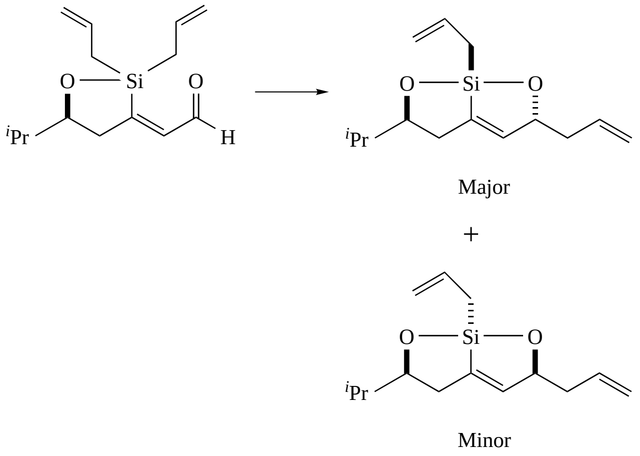


Scheme 18

The tandem silylformylation-allylsilylation of a diallylsilyl ether has been reported by Leighton, using [Rh(acac)$(CO)_2$] as the catalyst (equation 11).[67] This method was optimized and extended to propargylic systems where good diastereoselectivity can be achieved using the isopropyl derivative. A mechanism is proposed for the stereoselectivity involving coordination of the silicon by both of the oxygen atoms (equation 12).



(11)



(12)

3 CARBOXYLIC ACIDS, ESTERS, AND ACYL HALIDES

The production of carboxylic acids via carbonylation catalysis is the second most important industrial homogeneous group of processes. Reppe developed most of the basic carbonylation chemistry in the 1930s and 1940s. The first commercial carbonylation process was the stoichiometric $Ni(CO)_4$-based hydroxycarbonylation of acetylene to give acrylic acid (see Section 3.5 for details). This discovery has since evolved into a true Ni-catalyzed process, used mainly by BASF. The introduction of rhodium catalysts in the 1970s revolutionized carboxylic acid production, particularly for acetic acid, much in the same way that Rh/PPh_3 catalysts changed the importance of hydroformylation catalysis.

3.1 Monsanto Acetic Acid Process

The second largest homogeneous catalytic industrial process is the carbonylation of methanol to produce acetic acid. Prior to 1970, acetic acid was made using cobalt catalysts (BASF process), requiring rather severe conditions. In 1970, Monsanto commercialized a rhodium–carbonyl iodide catalyst that is commonly called the Monsanto Acetic Acid Process (although in 1986, Monsanto sold the acetic acid plant and technology to British Petroleum). As with hydroformylation catalysis, rhodium is 10^3 to 10^4 times more active than the corresponding cobalt catalyst, which means that much lower CO pressures and moderately lower temperatures are required. Perhaps most importantly, the rhodium catalyst gives extremely high selectivities to acetic acid (see Table 6).[68]

The mechanism has been extensively studied by Forster and coworkers[69] at Monsanto and is shown in Scheme 19. It is actually a double catalytic cycle involving the HI-catalyzed conversion of MeOH to MeI and H_2O at the beginning of the Rh-catalyzed carbonylation reaction, and regeneration of HI at the end of the Rh cycle by hydrolysis of the acyl iodide.

The reaction rate is independent of CO pressure and is first-order in both rhodium and MeI. The rate-determining step is the oxidative addition of MeI to the $[Rh(CO)_2I_2]^-$ catalyst. Thus, the production of MeI from methanol, catalyzed by HI, is critically important. Iodide ligands are considered to be quite important in this reaction due to the HI-catalyzed conversion of MeOH to MeI and their good donor abilities on the Rh center. The negative charge on the $[Rh(CO)_2I_2]^-$ catalyst is believed to be critical in assisting the oxidative addition of MeI to the rhodium center. The resulting alkyl species, $[Rh(CO)_2(Me)I_3]^-$, is extremely reactive towards CO insertion to form the acyl complex.

Efforts to optimize rhodium-based systems for methanol carbonylation led to the development of new supporting ligands containing phosphorus and sulfur donor atoms, both thiolates and thioethers, such as those used in the preparation of complexes (**20**) and (**21**). Ligands such as 2-diphenylphosphinothiolate have been shown to give rise to complexes that exhibit higher activities, up to four times faster, for the carbonylation of methanol compared to $[Rh(CO)_2I_2]^-$.[70,71]

Zoeller and coworkers at Eastman Chemical Company Research Laboratories have reported an efficient system for the carbonylation of ethylene based on a iodide-promoted

Table 6 Comparison of cobalt- and rhodium-catalyzed carbonylation of methanol to acetic acid

Conditions	Cobalt	Rhodium
Concentration	$\approx 10^{-1}$ M	$\approx 10^{-3}$ M

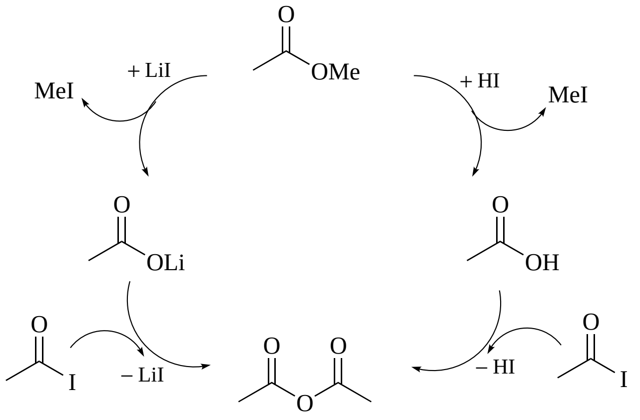
(**21**)

$[Mo(CO)_6]$ complex.[72] The molybdenum intermediates were studied using in situ IR as part of an extensive mechanistic investigation. The following intermediates were identified in the reaction mixture: $[Mo(CO)_6]$, $[Mo(CO)_5I]^-$ and $[Mo(CO)_4I_3]^-$. Hydrogen, which at low concentrations increases the rate of the reaction, was found to reduce $[Mo(CO)_4I_3]^-$ to the zero-valent complex, thus regenerating the catalyst.[73]

3.2 Tennessee Eastman Acetic Anhydride Process

A very closely related process is the Tennessee Eastman (Kodak) carbonylation of methyl acetate to produce acetic anhydride.[74] The rhodium-catalyzed portion of the mechanism is the same as shown in Scheme 19. Differences occur in the iodide-promoted pre- and post-rhodium reactions shown in Scheme 20.

One pathway involves reaction of methyl acetate with HI to produce MeI and acetic acid. The MeI is carbonylated by $[Rh(CO)_2I_2]^-$ to give acyl iodide, which can then react with acetic acid to produce acetic anhydride and regenerate HI.



Scheme 20

Alternatively, LiI can react with methyl acetate to give MeI and Li acetate. Carbonylation of MeI, again by $[Rh(CO)_2I_2]^-$, produces acyl iodide, which can react with lithium acetate to produce acetic anhydride and LiI. The importance of LiI is seen by the fact that at high lithium concentrations the rate of the catalysis is first-order with respect to MeI and rhodium concentrations. This observation, once again, is consistent with a rate-determining oxidative addition of MeI to the rhodium catalyst. At low lithium concentrations the rate approaches zero order in rhodium and methyl iodide, indicating that formation of methyl iodide from reaction of iodide and methyl acetate is now the rate-limiting step. Thus, the lithium iodide plays a very important role in the catalysis. Lithium is the most effective counter cation, with sodium being approximately 2.5 times slower.

The main difference between the Monsanto acetic acid process and Tennessee Eastman acetic anhydride process is the presence of water in the acetic acid process, which produces HI and acetic acid. In both reactions, a small amount of H_2 is added to the CO stream to act as a reducing agent to keep the catalyst in the more active Rh^I oxidation state. An engineering problem with both processes is the highly corrosive nature of the HI/iodide mixture, requiring the use of special chemically resistant alloys, pumps, and seals.

3.3 The BP Cativa™ Process

For approximately 30 years, the most successful industrial process for the carbonylation of methanol relied on an iodide-promoted rhodium catalyst. This technology, originally developed by Monsanto and acquired by BP Chemicals in 1986, is responsible for the majority of the acetic acid synthesized industrially. Since then, the most important development in industrial carbonylation chemistry is the Cativa™ process, announced by BP Chemicals in 1996.[75]

The Cativa™ process is based on a promoted iridium catalyst, and offers a considerable improvement over the rhodium-based system as a result of increased catalyst stability at lower water concentrations, decreased by-product formation, higher rates of carbonylation, high selectivity (>99% based upon methanol), and improved yields on carbon monoxide.[76] This is a more cost-effective process for methanol carbonylation owing to lower energy consumption and fewer purification requirements. Implementation of this new process has now been achieved in four plants worldwide.

Although the carbonylation of methanol using an iodide-promoted iridium complex was first reported by Monsanto researchers Roth and Paulik[77] in 1968, and its mechanism studied by Forster[78] and others, it was the rhodium system that was initially developed for commercialization. A more complex mechanism for iridium, involving both anionic and neutral intermediates was discovered, but it would take over twenty years to commercialize an iridium-based system for methanol carbonylation (Scheme 21). In the Cativa™ process, the iridium complex is promoted by two distinct classes of compounds. These comprise iodide complexes of transition and main group metals, such as zinc, cadmium, mercury, indium, and gallium and transition metal carbonyl complexes such as tungsten, rhenium, ruthenium, and osmium. A synergistic effect between the promoters and iodide salts has also been observed at low water concentrations.

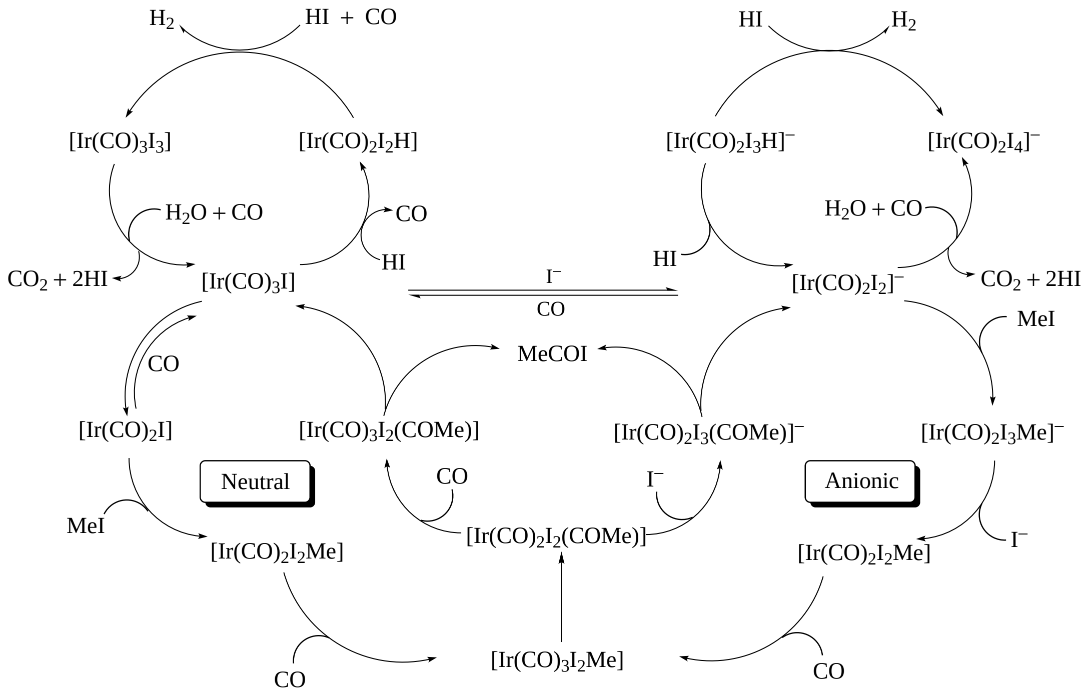
Model studies[76] in aprotic solvents have shown that oxidative addition is 120 times faster with iridium complexes than with the corresponding rhodium complexes while the migratory insertion rate is higher for rhodium by a factor of 10^5 at 100 °C than iridium. The migratory insertion step, which is rate-determining in the Cativa™ process, is enhanced by the use of promoters, thus achieving a higher reaction rate. Batch autoclave studies were carried out to explore the effect of *p*CO, water, methyl iodide, and methyl acetate concentrations on the reaction system. In addition, spectroscopic studies have identified the key intermediate in the catalytic cycle as $[Ir(CO)_2I_3Me]^-$. The Sheffield University research group headed by Maitlis and Haynes, in collaboration with BP Chemicals, has published a comparison of both systems, where differences in the stability of this key intermediate, $[M(CO)_2I_3Me]^-$ (M = Rh, Ir), are crucial to the reaction.[79] The increased stability of the iridium complex is related to the stronger metal–carbon bond typically seen for iridium compared to rhodium. Additional corroboration was obtained from a static and dynamic density functional theory study of the migratory insertion step in methanol carbonylation, $[M(CO)_2I_3(CH_3)]^-$ to $[M(CO)I_3(COCH_3)]^-$ (M = Rh, Ir), reported by Ziegler and coworkers.[80]

In order to more fully understand the mechanism for the promotion of carbonylation in the Cativa™ process, a recent comprehensive study utilizing spectroscopic methods and ab initio calculations was carried out to explore the role of the promoters.[81] The acceleration of the migratory insertion step is the result of iodide abstraction from the iridium center in *fac,cis*-$[Ir(CO)_2I_3Me]^-$ by the promoters to yield the neutral species $[Ir(CO)_3I_2Me]$ in the presence of CO. It was determined that the migratory insertion of carbon monoxide in $[Ir(CO)_3I_2Me]$ is ≈700 times faster than for the anionic species $[Ir(CO)_2I_3Me]^-$.

3.4 Homologation of Carboxylic Acids

In 1981, Texaco announced the ruthenium/H_2/CO-catalyzed homologation of carboxylic acids. Homologation refers to a chain-extension reaction that increases the carbon number of the carboxylic acid (*see Homologation Reactions*). The particular reaction that was initially studied was the conversion of acetic acid to propionic acid. The proposed mechanism shown in Scheme 22 is based on a Ru^{II}/Ru^{IV} cycle, similar to that suggested by Knifton and coworkers at Texaco.

The reaction conditions are somewhat more severe relative to the rhodium-catalyzed acetic acid process: >200 °C and 100–250 bar 1:1 H_2/CO. The mechanism is not fully

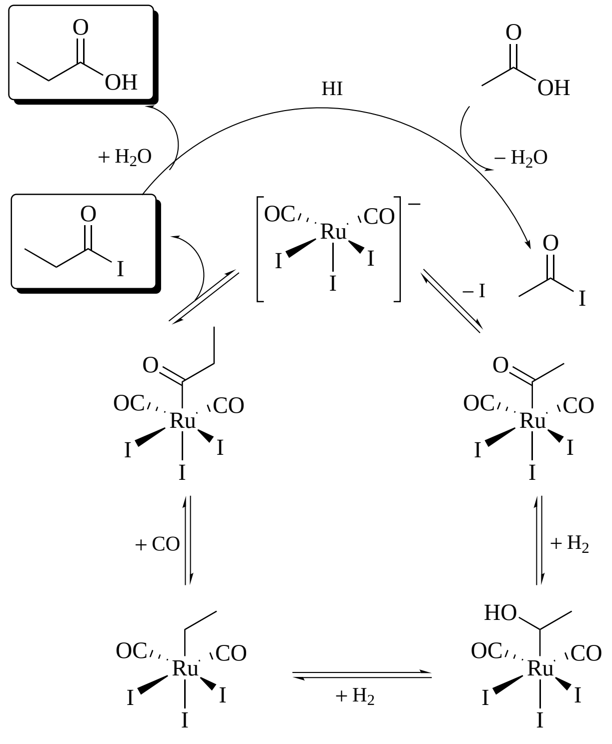


<u>Organic reactions</u>

$$MeOH + HI \longrightarrow MeI + H_2O$$

$$MeCOI + H_2O \longrightarrow MeCOOH + HI$$

Scheme 21



Scheme 22

understood, because of the many-sided equilibria present and the difficulty of mechanistic studies under the higher pressures required. Labeling studies have confirmed that the carbonyl group in the carboxylic acid product does indeed come from CO insertion into an alkyl species. Ruthenium is well-known to heterolytically activate H_2 (to give H^- on the metal and free H^+), and this cleavage may well be the route taken here. Protonation of the oxygen atom of the carbonyl group in conjunction with a hydride transfer to the α-carbon would lead one nicely to the proposed Ru–CH(OH)CH_3 intermediate. Repeating this same process would then give the Ru–CH_2CH_3 alkyl species.

Interestingly, in spite of the fact that two equivalents of H_2 are formally required for a one-carbon atom homologation, the optimum yield of propionic acid occurs for a 1:1 H_2/CO ratio. The additional hydrogen needed undoubtedly comes from a Ru-catalyzed *Water Gas Reaction* that converts some CO and H_2O into CO_2 and H_2. CO_2 is one of the side products observed in this reaction. Additional homologation steps occur at higher temperatures and pressures. This homologation reaction also appears to be quite general for higher-chain acids as the starting materials.

The potential industrial significance of this catalytic reaction lies in the fact that acetic acid is readily synthesized from *Synthesis Gas* (via methanol). The ability to homologate

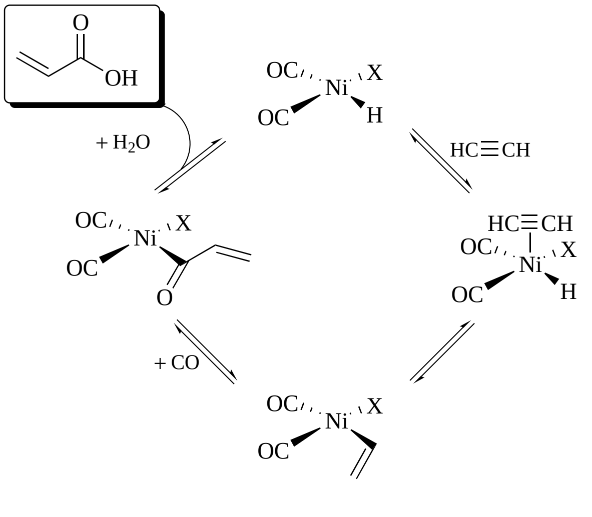
acetic acid to higher carbon chain acids means that industry would not have to be dependent on petroleum feedstocks for longer chain carboxylic acid syntheses. The relatively good hydrogenation ability of Ru, however, lowers the total selectivity of the reaction by giving ethanol, ethane, and propane as side products, along with ethyl acetate and ethyl propionate ester products. Linear acids, however, are the dominant products, with only traces of chain branching observed.

3.5 The Hydrocarboxylation of Alkenes and Alkynes

The reaction of an alkene (or alkyne), CO, and H_2O to directly produce a carboxylic acid is called Reppe carbonylation chemistry or, more recently, hydrocarboxylation (*see Reppe Reaction*). An excellent review of palladium-catalyzed Reppe carbonylation systems has been published recently by Kiss,[82] and coverage of this important material will not be repeated here. This catalytic reaction has been known for quite some time, although the stoichiometric $Ni(CO)_4$-based carbonylation of acetylene was the first commercial carbonylation process implemented (equation 13). The extreme toxicity of $Ni(CO)_4$, however, has limited practical applications (*see* ***Nickel: Organometallic Chemistry***). Co, Rh, and Pd catalysts have certainly replaced $Ni(CO)_4$ in smaller-scale laboratory reactions, though for historical reasons a number of the fundamental mechanisms discussed in this section are based on $Ni(CO)_4$.

$$4HC{\equiv}CH + 4H_2O + Ni(CO)_4 + 2HCl \longrightarrow 4H_2C{=}CHCO_2H + NiCl_2 + H_2 \quad (13)$$

The Ni-catalyzed production of acrylic acid from acetylene produces 320 million kg year^{-1}. The BASF process operates at 40–55 bar and 180–204 °C using a $NiBr_2$/Cu halide catalyst in THF solution. The details of the catalytic mechanism are not fully understood, but the core nickel-catalyzed cycle is shown in Scheme 23.



Scheme 23

An interesting variant of the above reaction occurs when allylic derivatives (halides, ethers, alcohols, etc.) are present as well. 2,5-Dienoic acids are catalytically produced in high yields under ambient conditions.[83,84]

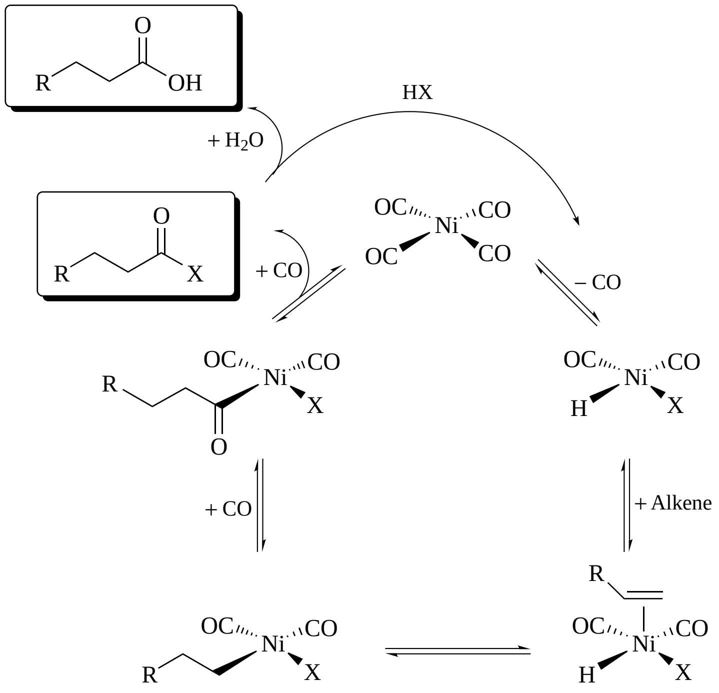
$HCo(CO)_4$ will also catalyze the hydrocarboxylation of acetylene to produce acrylic acid, but under higher pressures (100–200 bar, 100 °C) an efficient second hydroxycarboxylation occurs to produce succinic acid in over 80% yield (equation 14).

(14)

The $HCo(CO)_4$-catalyzed hydrocarboxylation of alkenes has also been known for a long time. The mechanism is analogous to that presented for hydroformylation (Scheme 1), except that H_2O is used instead of H_2. Hydrocarboxylation is generally slower than hydroformylation, and it is believed that the concentrations of the intermediate species are quite low relative to those seen for hydroformylation. Pyridine has a rate-enhancing effect that is believed to be due to the facile cleavage of the (acyl)$Co(CO)_4$ intermediate. This reaction forms [pyridine–acyl]$^+$ $[Co(CO)_4]^-$, which is more rapidly hydrolyzed by water to form the product carboxylic acid and $HCo(CO)_4$.

The hydrocarboxylation reactions discussed above have been proposed to involve direct addition of water to the metal center prior to elimination of the product, analogous to the oxidative addition of hydrogen to a metal center at the end of a hydroformylation catalytic cycle. Another class of hydrocarboxylation reactions is more analogous to the halide-promoted Monsanto acetic acid process, where one has a reductive elimination of an acyl halide species that is rapidly hydrolyzed with free water to generate the carboxylic acid and HX.

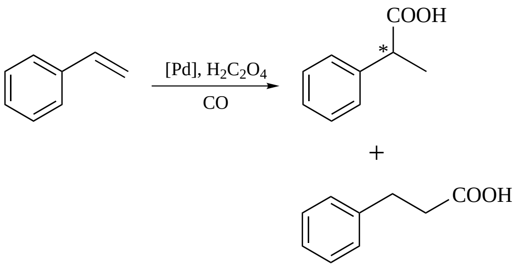
One of the first mechanistic proposals for the hydrocarboxylation of alkenes catalyzed by nickel–carbonyl complexes came from Heck in 1963 and is shown in Scheme 24.[85] An alternate possibility suggested by Heck was that HX could add to the alkene, producing an alkyl halide that would then undergo an oxidative addition to the metal center, analogous to the acetic acid mechanism (Scheme 19). Studies of Rh- and Ir-catalyzed hydrocarboxylation reactions have demonstrated that for these metals, the HX addition mechanism, shown in Scheme 24, dominates with ethylene or other short-chain alkene substrates.[86] Once again, HI is the best promoter for this catalytic reaction as long as there are not any other ligands present that are susceptible to acid attack (e.g. phosphines).



Scheme 24

Hydrocarboxylation reactions generally do not have very high regioselectivities when carried out with C_4 or higher alkenes, due to alkene isomerization side reactions catalyzed by both acid and metal. Thus, many of the reactions done industrially involve substrates such as acetylene and ethylene where isomerization side reactions will not present any problems.

The regioselectivity of the palladium-catalyzed hydrocarboxylation of styrene can be controlled by variation of the phosphine ligand set.[87] For monodentate phosphines, the cone angle (θ) is an important consideration, whereas in the case of chelating diphosphines the bite angle (β_n) is a controlling factor for the selectivity of the reaction. Palladium complexes comprising basic monophosphines such as PMe_3 show no activity for the hydroxycarbonylation of styrene whereas 98% conversion and regioselectivities of up to 84% for the branched isomer can be achieved with palladium complexes supported by PPh_3 (equation 15). A preference for the formation of the linear isomer is observed when diphosphines are employed in the reaction, although higher temperatures and pressures are required to achieve similar activities to the corresponding monodentate systems (Table 7). Chelating diphosphines with bite angles ~102° have exhibited the best activities for this reaction (95–99% conversion), while those with small bite angles ~90° tend to give low conversions (5–28%). By modifying the supporting ligand set and adjusting reaction conditions, it may be possible to influence the regioselectivity of the reaction to yield either mainly branched or mainly linear product.



(15)

3.6 Carboxylic Acids from Aldehydes: Amidocarbonylation

Oxidation of aldehyde products produced from hydroformylation is a major industrial route to carboxylic acids. The Hoechst–Celanese Corporation, for example, produces considerable quantities of linear C_7 and C_9 carboxylic acids from the Rh/PPh_3-catalyzed hydroformylation of 1-hexene and 1-octene.

Another route to carboxylic acids from aldehyde products (once again, generally produced via hydroformylation catalysis) was discovered by Wakamatsu and coworkers. They reported the carbonylation of aldehydes and primary organic amides to produce *N*-acylamino acids (equation 16).[88] The reaction is efficiently catalyzed by $HCo(CO)_4$ at 100 °C and 140 bar of 3:2 H_2/CO (hydrogen is needed to help stabilize $HCo(CO)_4$). Yields of over 90% of the appropriate

Table 7 Hydrocarboxylation of styrene with $[PdCl_2(PhCN)_2]$ supported by monophosphines or diphosphines[a]

Phosphine	θ or $\beta_n{}^b$(°)	% Conversion	Branched:linear ratio
PPh_3	145	96	84:16
P(p-Tol)$_3$	145	98	69:31
PPh_2(o-Tol)	161	76	100:0

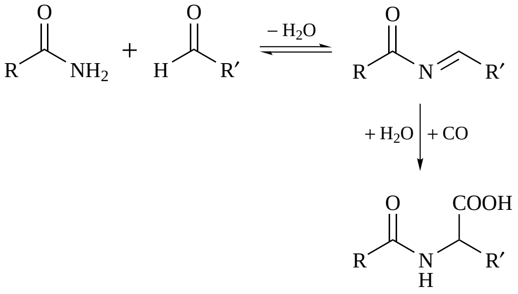
Xantphos	110[a]	99	19:81

[a]Reaction conditions: 4:1 monophosphine to Pd, 30 bar CO, 100 °C; 10:1 diphosphine to Pd, 75 bar CO, 150 °C. [b]Calculated bite angle.

N-acylamino acid can be obtained. This reaction has subsequently been referred to as amidocarbonylation and offers a viable alternative to the conventional Strecker reaction (which uses HCN and NH_3) for preparing α-amino acids from aldehydes.



(16)

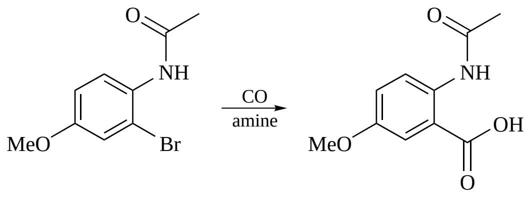
There has been considerable interest from both academics and industry in this reaction since 1980. There are a wide number of uses for the amido acid products: surface-active agents and specialty surfactants (C_{10}–C_{16} amido acids), intermediates for aspartame sweeteners (phenylalanine), food additives (monosodium glutamate), and chelating agents (iminoacetic acid and polyamido acids). Knifton (Texaco) has done extensive studies of this reaction,[89] as have Ojima and coworkers.[90]

The proposed mechanism is shown in Scheme 25.[91] The coupling of this reaction with hydroformylation, for example, allows the conversion of an alkene directly into an N-acetyl product. Thus, the reaction of trifluoropropylene and acetamide produces N-acetyltrifluoronorvaline in 80% yield with 96% selectivity.

3.7 Carboxylic Acids from Organic Halides

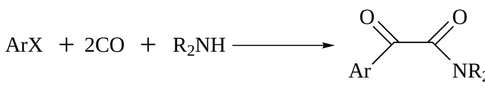
Palladium-catalyzed carbonylation reactions have assumed increasing importance over the last 30 years, particularly for smaller-scale laboratory and fine chemical syntheses (*see* ***Palladium: Organometallic Chemistry***). There is an enormous amount of work on palladium-catalyzed reactions, and it would be impossible to cite many specific examples. It is possible, however, to generalize the mechanism for producing carboxylic acids, esters, amides, and so on from organic halides as shown in Scheme 26. The catalysis starts with a Pd^0 phosphine complex that dissociates a PPh_3 to open up a coordination site in order to oxidatively add the organic halide. Pd^0 species are often electron-rich and reactive enough to undergo an oxidative addition to an aryl halide. Coordination of CO, followed by an alkyl migration, produces the acyl complex, which can react with a variety of reactants to produce the product of choice. Not shown in Scheme 26 is that the acyl complex will react with H_2 to eliminate aldehyde products.

Carbonylation of aryl bromides with palladium catalysts in aqueous solutions to produce carboxylic acids is a general reaction. Typical reaction conditions are 100–130 °C, 3 bar of CO, 2–36-h reaction time using a $PdCl_2(PPh_3)_2/PPh_3$ catalyst (0.1–1 mol%). A base, such as an amine, is needed in slightly greater than stoichiometric quantities to trap out the HX acid produced in the reaction. The presence of an acetamido group ortho to the bromide significantly accelerates the reaction. Yields can be quite good, and there are usually no selectivity problems with these types of oxidative addition reactions. One example reaction is shown in equation (17).

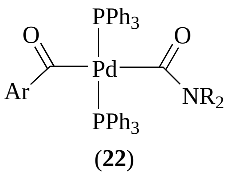


(17)

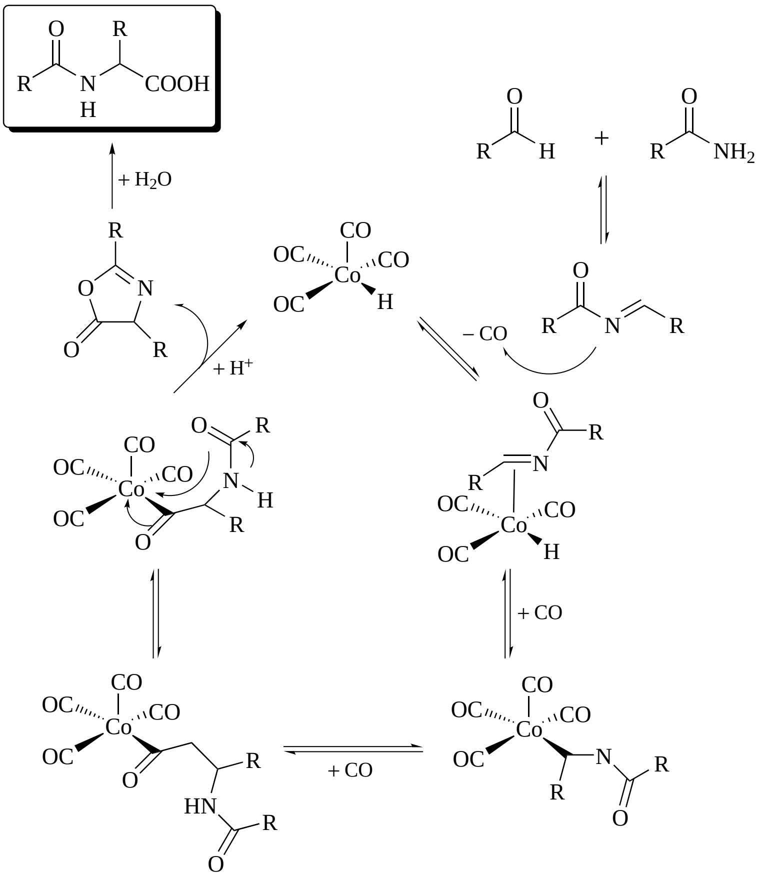
Amides and esters are formed in good yields through reaction of a primary or secondary amine or alcohol with the Pd–acyl complex. Amine reactions are, in general, more rapid and give better yields of products compared to the alcohol analogs. Interestingly, α-ketoamides can be formed under the proper conditions (equation 18). The use of alkyl- or alkylarylphosphine ligands, higher CO pressures (10 bar), and lower temperatures (room temperature) favor the double carbonylation. Long reaction times are often required, but high yields can be obtained in many cases. The mechanistic details of this reaction are not fully understood, but it is probably not a double CO insertion. Rather, it is believed that reductive elimination occurs from a double acyl species such as (**22**).



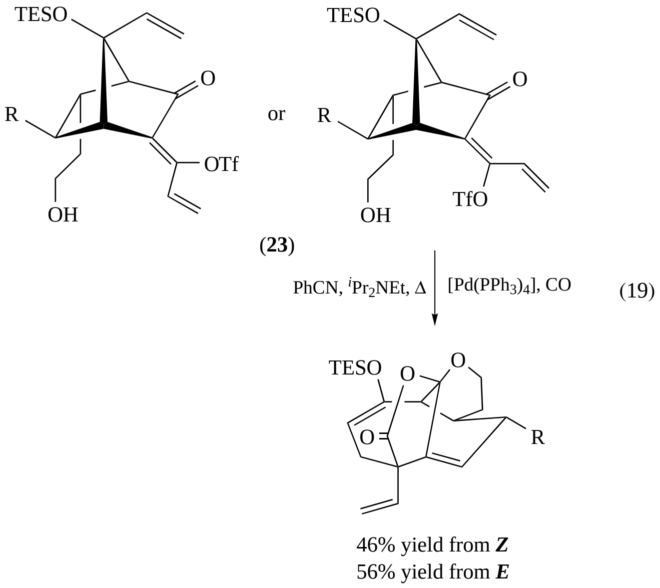
(18)



(**22**)

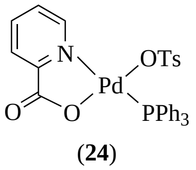


Scheme 25



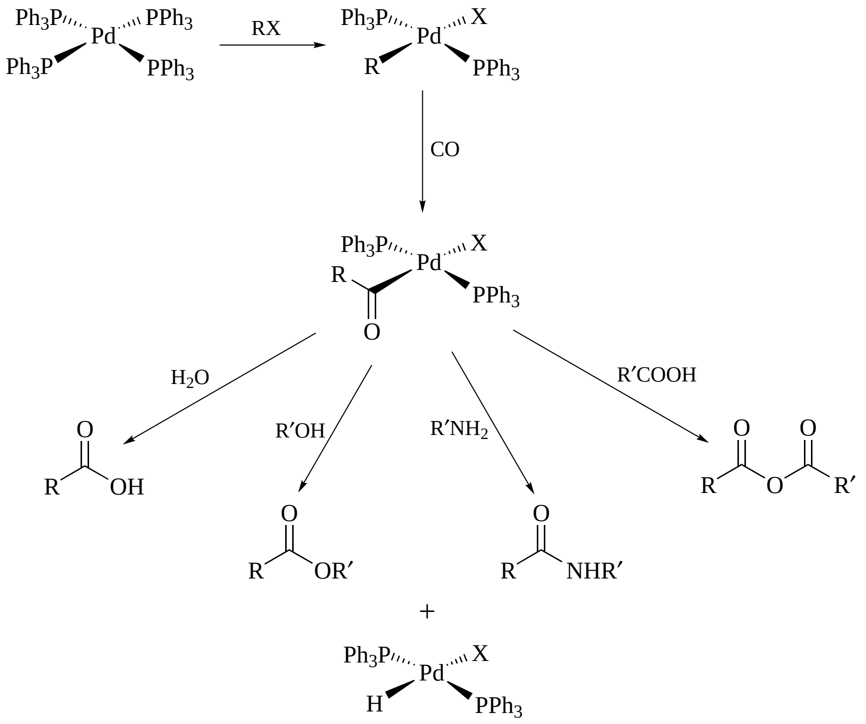
enol triflate by a tandem carbonylation–Cope rearrangement reaction to yield the CP core structure is shown in equation (19). Surprisingly, both the *E* and *Z* isomers of (**23**) are effective precursors in this transformation using a palladium–phosphine complex, possibly through an allylic intermediate.

A pyridine-2-carboxylato (N–O) complex of palladium(II) with a labile tosylato ligand has been shown to act as an efficient carbonylation catalyst for a series of alcohols and olefins.[93] The catalyst precursor, [Pd(N–O)(OTs)(PPh_3)] (**24**), in conjunction with promoters (e.g. LiI, LiCl, TsOH), is active for the carbonylation of primary, secondary and tertiary alcohols as well as functionalized terminal olefins with good selectivity and turnover frequency. This reaction has been further discussed in a report dealing with the kinetic modeling of this and other catalytic-carbonylation reactions.



(**24**)

An interesting example of the use of catalytic carbonylation in the total synthesis of natural products has been reported by Leighton and Bio.[92] The carbonylation of a *Z*-tetrasubstituted



Scheme 26

The kinetic modeling study of 1-(4-isobutylphenyl)ethanol (IBPE) carbonylation using a homogeneous palladium complex has been reported by Chaudhari.[94] The three key steps (formation of the active substrate; formation of the active catalyst; catalytic carbonylation of active substrate) were studied in detail. The average carbonylation rate depends on several factors, so a dynamic analysis, where the concentrations of both the catalyst species and the intermediates were varied, was carried out.

A two-phase system for the carbonylation of benzyl alcohol using a water-soluble palladium complex supported by trisulfonated triphenylphosphine ligands (tppts = $P(C_6H_4$-m-$SO_3Na)_3)$ and a Brønsted acid cocatalyst has been reported by Sheldon and coworkers.[95] The complex, $[Pd(tppts)_3]$ is an effective carbonylation catalyst for benzyl alcohol under mild conditions (100 °C; tppts/Pd molar ratio: 12; TsOH/substrate: 2). The only product obtained is phenylacetic acid in 77% yield with ≈100% selectivity. This system has also been applied to the carbonylation of IBPE to yield ibuprofen, which is currently prepared industrially using a palladium/triphenylphosphine-supported catalyst in organic solvents. Although the selectivities are lower for the biphasic system at this point, it is possible that further optimization of the biphasic system will bring the selectivities up to current industrial levels in the future.

The catalytic silylative carbonylation of aryl iodides using a bimetallic catalyst system, $[PdCl_2(PPh_3)_2$-$Co_2(CO)_8]$, has been reported by Hidai and coworkers.[96] The carbonylation of 4-iodotoluene (p-TolI) in the presence of carbon monoxide, triethylsilane, and the bimetallic [Pd–Co] system gave rise to p-$TolCH_2OSiEt_3$ (76% yield, 85% conversion). Upon addition of triethylamine, however, the product distribution changed to yield 1,2-di(p-tolyl)-1,2-bis(triethylsiloxy)ethane as the major product (57% yield, 70% conversion), along with p-$TolCH_2OSiEt_3$ and p-tolualdehyde as minor products. Neither metal complex was an active catalyst on its own, therefore a synergistic effect is clearly at work here. The corresponding PCy_3-supported palladium complex is active in the hydroformylation of internal alkynes, although higher activity can be achieved with the bimetallic system $[PdCl_2(PCy_3)_2$-$Co_2(CO)_8]$. The authors suggest a mechanism that involves two separate but linked catalytic cycles, each based upon one of the two metals.

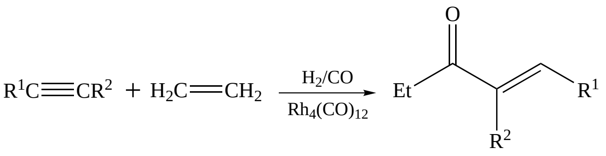
4 KETONES

4.1 Ketones from Alkenes and Alkynes

Ketones are sometimes seen as by-products in hydroformylation, particularly when the alkene concentration is very high and the H_2/CO pressure is low. This product is most favored for ethylene (producing diethyl ketone), but yields drop-off quickly with higher-chain alkenes. It turns out that there are actually few good catalytic routes to acyclic ketones from

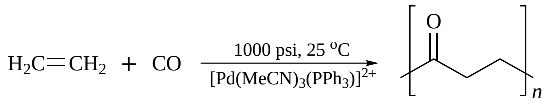
alkenes or alkynes. One of the best examples involves the reaction of butadiene with CO, an alkyl halide, and base, which is catalyzed by $[Co(CO)_4]^-$.[97] The proposed mechanism is shown in Scheme 27. The reaction is highly regio- and stereospecific, with the acyl group always being added to the least-substituted carbon of the least-substituted double bond. The *trans*-acyl diene is the only product formed.

α,β-Unsaturated ketones can be obtained from the $Rh_4(CO)_{12}$-catalyzed reaction of alkynes and alkenes (equation 20). Terminal alkynes react with particularly high regio- and stereospecificity to give *trans*-α, β-unsaturated ketones.[98]



(20)

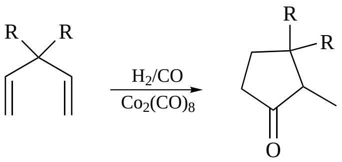
One of the more exciting developments in the catalytic production of ketones was the work of Sen on the Pd^{II}-catalyzed production of polyketones from ethylene and CO (equation 21).[99] Sen used $[Pd(MeCN)_3(PPh_3)]^{2+}$ as the catalyst and proposed that the mechanism consisted of the initial formation of some sort of Pd–H complex ($CHCl_3$ was used as the solvent) which inserts ethylene to produce a Pd–alkyl species. Carbonylation then occurs to produce a Pd–acyl complex. The rate-determining step is believed to be coordination and insertion of ethylene into the Pd–acyl moiety to produce Pd–$CH_2CH_2(CO)CH_2CH_3$. Alternating CO and ethylene insertions lead to a polyketone. β-Hydride elimination terminates the chain-growth process.



(21)

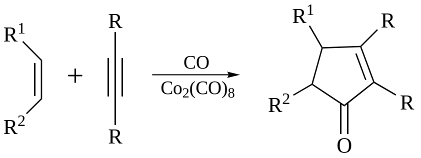
The cationic nature of the Pd catalyst is believed to be quite important to prevent CO and ethylene from binding too strongly to the metal center. Use of more basic phosphines leads to catalyst deactivation, consistent with this observation. Brookhart and coworkers have described a better characterized, highly active 'living catalyst' that can be used on a variety of alkenes to produce high molecular weight polyketones (20 000 to 60 000) with a very narrow polydispersity of 1.08.[100] The catalyst precursor used was $[Pd(Me)(MeCN)(N_2)]^+$ (N_2 = bipyridine or phenanthroline), and the active catalyst species in solution is believed to be $[Pd(acyl)(CO)(N_2)]^+$. Once again, the rate-determining step was identified as the alkene insertion into the Pd–acyl species.

There are a few more catalytic routes to cyclic ketones known, usually involving alkynes and cobalt or rhodium carbonyl catalysts. Spirocyclopentanones can be prepared in high yields according to equation (22).[101]



(22)

Pauson and Khand discovered the very important class of alkyne/alkene/CO cyclization catalytic reactions catalyzed, once again, by $Co_2(CO)_8$ (*see Pauson–Khand Reaction*).[102] This reaction produces α,β-unsaturated cyclopentanones (equation 23). With unstrained alkenes the reaction works best in a stoichiometric setting, but with strained alkenes like norbornadiene the reaction can be made catalytic. These reactions have been fairly extensively studied, and the reaction proceeds through an alkyne-bridged $Co_2(CO)_6$ dimer species. Unsymmetrical alkynes lead to mixtures of the various substituted α,β-unsaturated cyclopentanone products.



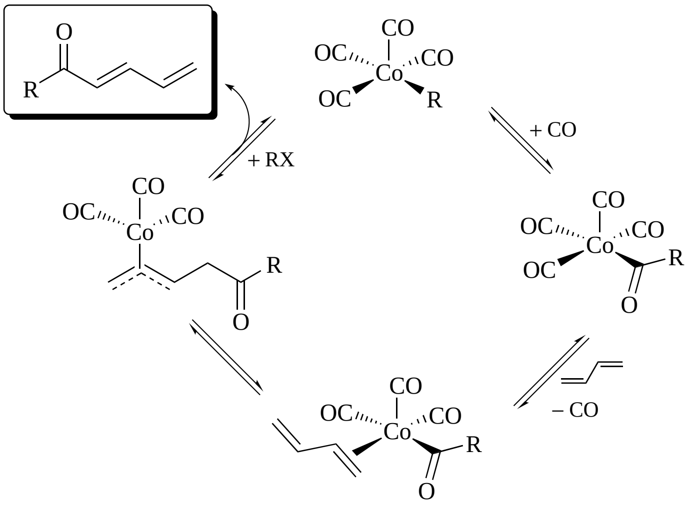
(23)

A Pauson–Khand type reaction of enynes, where the CO source is an aldehyde, has been reported by Morimoto and coworkers.[103] This CO-transfer carbonylation system was carried out with monomeric or dimeric rhodium complexes supported by monodentate or chelating phosphine ligands (e.g. $[RhCl(cod)]_2$/dppe or dppp; $[RhCl(CO)PPh_3]$). This reaction is successful for a series of enynes and aldehydes (Scheme 28).

The area of double carbonylation has been recently reviewed by des Abbayes and Salaün.[104] Both stoichiometric and catalytic systems are surveyed, covering monometallic complexes of Co, Pd, Fe and Ni, although the main emphasis is on catalytic monometallic systems of Co and Pd with a variety of substrates (amines, alcohols, organic halides). A general scheme for the double carbonylation of organic halides with a palladium is shown below (Scheme 29).

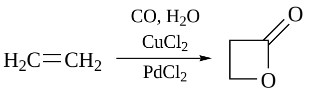
5 LACTONES AND LACTAMS

The importance of lactone and lactam rings in biological systems has prompted considerable interest in their stoichiometric and catalytic preparation (*see* ***Organic Synthesis using Transition Metal Carbonyl Complexes*** and ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***). One of the simplest reactions is the production of four-membered lactones from ethylene, CO, and water, catalyzed by $PdCl_2$ (equation 24). Stoichiometric amounts of

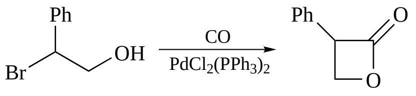


Scheme 27

$CuCl_2$ need to be used to reoxidize the Pd^0 back to Pd^{II}. The carbonylation of halide-containing alcohols is a better reaction as it takes place under mild conditions and often in good yields (equation 25).

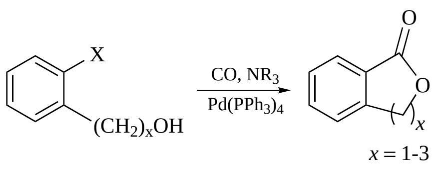


(24)



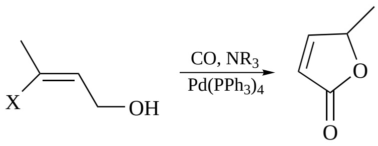
(25)

There has been more interest in the five-membered ring systems which, as one might expect, generally give better yields. A general synthesis for aryl lactones with five- through seven-membered rings is shown in equation (26). By using a primary or secondary amine, instead of an alcohol functional group, the analogous lactams can be prepared. As with the acyclic syntheses, the lactam preparations are somewhat more facile and give generally better yields.

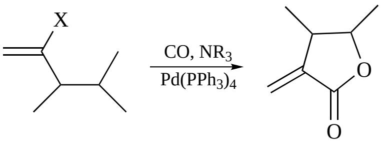


(26)

The cyclocarbonylation of vinylic halides (usually the bromide or iodide) is another route to lactones and lactams. 1,2-Substituted vinyl compounds produce lactones where the double bond is incorporated into the ring (equation 27), while 1,1-substituted vinyl substrates give an *exo* double bond (equation 28). The 1,2-substituted vinyl reactions can be run under ambient conditions (24–72 h), producing high yields of products. The 1,1-vinyl substrates require higher temperatures and pressures (70 °C, 30 psi) for the cyclocarbonylation reaction.

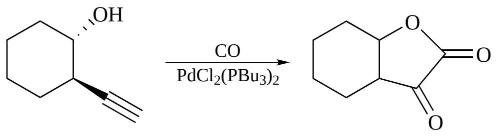


(27)



(28)

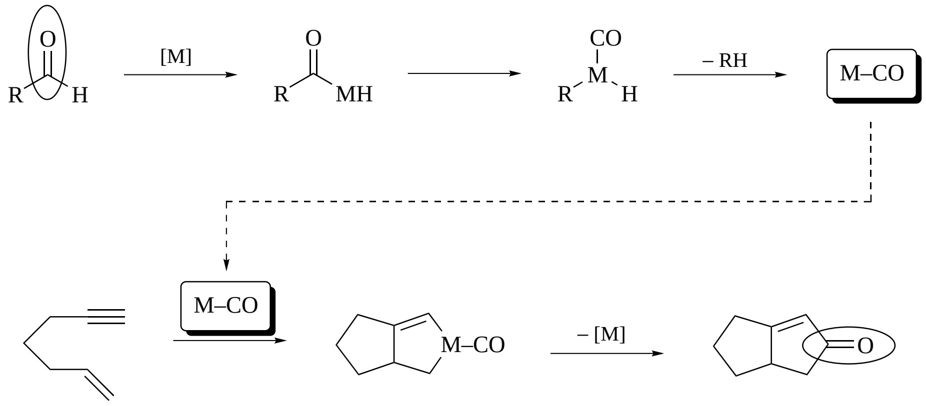
Alkyne alcohols can be cyclocarbonylated to produce lactones (equation 29). A $PdCl_2/P(n\text{-}Bu)_3/SnCl_2$ catalyst system has been shown to be quite efficient for this reaction at 75 °C and 8 bar CO pressure.[105]



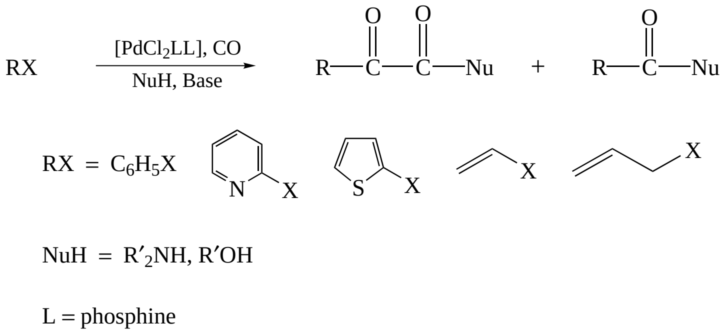
(29)

The proposed mechanism for this reaction is shown in Scheme 30. Coordination of the alcohol OH group to the Pd^{II} center causes deprotonation to produce the alkoxide-coordinated species. CO insertion produces the alkoxyacyl species, which reacts with the alkyne group to produce the cyclized vinyl–Pd species, which is then protonated off the Pd center.

Pd will catalyze the ring expansion of azirines with CO to form bicyclic β-lactams under mild conditions (equation 30). The Pd catalyst seems to always produce the bicyclic complex shown in equation (30). $Rh_2(CO)_4Cl_2$,

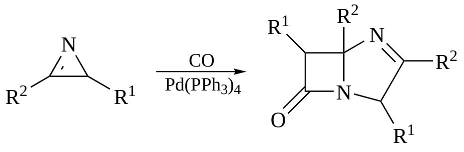


Scheme 28

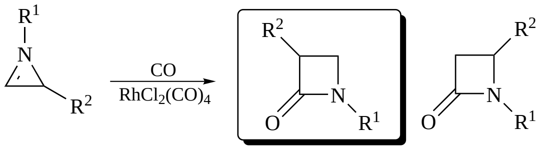


Scheme 29

however, will regioselectively ring-expand 2-arylaziridines to the monocyclic four-membered lactam (equation 31). None of the isomeric lactam is produced in the rhodium-catalyzed reaction.[106]

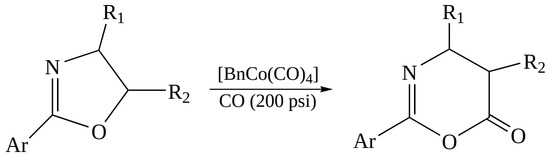


(30)



(31)

Finally, ring-expanding carbonylation reactions using cobalt have been reported by various groups. In the first of these, the synthesis of 4,5-dihydro-1,3-oxazin-6-ones by a ring-expanding carbonylation reaction of 2-aryl-2-oxazolines with a cobalt catalyst has been reported by Xu and Jia.[107] This is the first example of the application of catalytic carbonylation to 2-oxazolines leading to the synthesis of an important intermediate in peptide synthesis (equation 32). On the basis of ^{1}H NMR experiments, the catalyst, $BnCo(CO)_4$ (Bn = benzyl), is believed to dissociate the benzyl group to generate a $Co(CO)_4$ radical as the active catalyst.



(32)

R_1 = H, Me; R_2 = H, Me, Ph
Ar = Ph, *m*-F-Ph, *p*-tolyl, *o*-tolyl, thiophen-2-yl, furan-2-yl

This area has been further advanced by Coates and coworkers.[108] The synthesis of succinic anhydrides by β-lactone carbonylation using a Lewis acidic cation in conjunction with an anionic cobalt carbonyl complex has been reported (equation 33).

1 INTRODUCTION

Cation-activated enzymes are those that require a cation for maximal activity but for which that cation is generally not a direct component of the enzyme reaction mechanism. They were originally identified by Evans and Sorger in a study of activation of enzymes by monovalent metal cations.[1] These activating cations convert the enzyme to a form with enhanced catalytic activity. When a cation is part of the enzyme mechanism, its requirement is essential and no reaction occurs in its absence. On the other hand, if the enzyme is cation-activated, the presence of the cation merely increases the activity of the enzyme from a finite value, that is, the enzyme generally works (but not as well) in the absence of the activating cation.[2] A simple example, to be described here, is provided by the activation of pyruvate kinase by potassium ions that bind 6–8 Å from the active site of the enzyme.[3] Reviews on aspects of the subject of cation-activated enzymes by Suelter,[2] Woehl and Dunn,[4] and Larsen and Reed[5] are highly recommended.

The cations involved in such activation are usually metal ions or ammonium ions. Metal ions are generally utilized by enzymes for a variety of reasons, of which the most important are to maintain the stereochemistry of the active sites of the enzymes, and to aid in electrophilic catalysis and electron-transfer reactions. Metal ions that serve a cation-activating function in enzymes may be classified as cofactors because they generally act by binding at sites distinctly separate from the catalytic site. This type of modulation of protein function by cations can therefore be considered to be the result of allosteric (‘other site’) interactions wherein binding to one site affects the properties of a distant site in the enzyme (possibly the active site). The cation, on binding, therefore acts as an allosteric effector, and converts the enzyme from a fairly inactive conformation to a conformation that manifests appreciably increased catalytic activity.[4]

Monovalent metal ions generally bind oxygen atoms that are found in the carboxylate groups of aspartate or glutamate, the hydroxyl groups of threonine or serine, or the main-chain carbonyl groups of a protein. If the metal ions bind directly to the substrate, they may serve to position it for action. They can also act to stabilize some feature of the protein structure.[1] For example, many enzymes have ‘open’ and ‘closed’ conformations, thereby controlling the access of substrate to the active site. Activating cations may assist in such control, perhaps modulating the conformational transition between open and closed conformations.

Identification of activating cations is often fraught with problems. It was pointed out by Markham that ‘A difficulty in assessing the literature on monovalent cation activation of any enzyme is that potentially interacting ions are commonly present as counterions to the substrates and as buffer components’.[6] This means that it is important to note if specific precautions were taken to control the ionic environment of the enzyme during study before concluding that the enzyme is cation-activated in vivo. Recent X-ray crystallographic studies of enzymes have provided much of the structural evidence we have for cation activation by monovalent cations. The location of the cation in the enzyme and its relationship to the active site are found by this method. Such monovalent cations are less likely than divalent ions to be directly involved in catalytic mechanisms and therefore their activating ability can be identified more readily. There are, however, problems since ions such as Na^+ are not appreciably better X-ray scatterers than are water molecules (since the power of an atom to scatter X-rays depends on its atomic number, water 10, Na^+ 10, $NH_4{}^+$ 11). For example, ammonium ions are commonly used in crystallization of mother liquors. However, ammonium ions are difficult to identify except in very high-resolution structures or those determined by neutron diffraction, where hydrogen atoms can be located, and therefore ammonium ions differentiated from water molecules and sodium ions. A method for identifying Na^+ sites in proteins, involving valence calculations based on interatomic distances, has been proposed by Nayal and Di Cera.[7]

The activating cation presumably acts by helping the protein to maintain a productive conformation, and examples are provided by structural studies of enzymes that exhibit this property. Pauling suggested that complementarity between the structure of the enzyme active site and the transition state of the reaction is responsible for the lowering of activation energies of enzyme-catalyzed reactions.[8] Cation activation may aid this by ensuring that the active site has the correct

three-dimensional structure for as good complementarity as is possible, given the amino acid sequence of the enzyme. The activation may be accomplished by binding of the cation directly to the substrate, or binding at a distant site. All gradations of these possibilities are encountered in structural studies. Woehl and Dunn[4] characterized two types of mechanisms of cation activation of enzymes: those in which the cation plays a static structural role and, on binding, activates by stabilizing the conformation of the enzyme that is catalytically active, and those in which the cation plays a dynamic role and, on binding, selectively acts to assist those enzyme conformational transitions that can lead to complementarity between the active site and the transition state of the reaction to be catalyzed. Thus if a cation binds selectively to the conformation of the enzyme that is complementary to the transition state structure for an important step in the reaction being catalyzed, then activation will occur. For example, Wells and Di Cera[9] suggest that when sodium binds to human α-thrombin, an enzyme that it activates, there is a significant change in protein conformation. Woehl and Dunn[4] remark that 'activation by such mechanisms represents the fine-tuning of highly evolved catalysts. Because Na^+ and K^+ are ubiquitous in biological milieu, there is logic to the evolution of enzyme systems that take advantage of the presence of these metal ions as activating cofactors'.

2 CHARACTERISTICS OF METAL IONS COMMON IN CELLS

Many cations are available for activation of enzymes. Among the most abundant in the body are the four cations Na^+, K^+, Mg^{2+}, and Ca^{2+}. They are found in living cells and extracellular fluids at millimolar concentrations. For Na^+ and Ca^{2+}, the concentrations are intermediate between those in seawater and those in freshwater. Potassium ions are present in high concentrations in the cell (95% of the total potassium ions in the body are intracellular), and magnesium ions are found in about the same concentration in both cells and the extracellular fluids around them. Cation-activated enzymes that are found within cells (where the K^+ concentration is greater than that of Na^+) generally utilize K^+, while those outside the cell (where the Na^+ concentration is greater than the K^+ concentration) utilize Na^+. For example, as will be described later, while most monovalent cation-activated enzymes prefer K^+ to Na^+, the blood-clotting enzyme, thrombin, which is an extracellular enzyme, prefers Na^+. Woehl and Dunn point out that the dissociation constants for Na^+ and K^+ binding are well below the physiological concentration of these ions.[4] This means that the binding sites for activating cations are saturated and their existence is 'a permanent feature of catalysis.' In general, it is found that activating properties are maintained if K^+ is replaced by $NH_4{}^+$ and Rb^+. The replacement is poor for an exchange with Na^+ and succeeds in maintaining activating properties rarely, if at all, when K^+ is exchanged for Li^+.[1]

Biological effects are different for Na^+ and K^+. The smaller ionic radius and therefore higher charge density on Na^+ gives this ion a more favorable hydration free energy. The strength of the ligand field at the metal site and the ionic radius of the metal ion can provide part of the basis for selectivity in the metal ion binding to proteins. The four cations Na^+, K^+, Mg^{2+}, and Ca^{2+} are simple, each with a single oxidation state (+1 or +2). They lack easily excitable, unshared valence electrons. They bind ligands by electrostatic interactions rather than other types of binding and they are classified as 'hard', because they are not readily polarized and are deformed only with difficulty (*see* ***Hard & Soft Acids and Bases***).[10] They tend to bind to 'hard' ligands, notably those containing oxygen atoms. Ligands bind these cations less readily by way of nitrogen atoms and very rarely, if at all, by way of 'soft' sulfur atoms. Ammonium ions are the same size as Rb^+, similar to K^+. The monovalent cations have weak positive charges and therefore would be expected to be more readily controlled. They are frequently found near divalent cations, often with bridging ligands. The positive charge of K^+ in peroxidases may exert an electrostatic effect that can influence the redox properties of a distant center.

Metal ions lose water from their hydration spheres when they bind to complexing agents or to biological macromolecules. The strength of binding of a monovalent metal ion to a site on a protein molecule is determined by the competition between water molecules and metal ions for the site. Selectivity will occur as a result of ionic size and the strength and nature of the attractive forces in the protein site. For example, a large rigid cavity for binding would favor a large cation, particularly if the directionalities of unpaired electrons in the cavity were appropriate for binding that metal ion. Furthermore, shielding of the cavity from a solvent would also be advantageous.

The four ions have different sizes, as shown in Table 1. Of these, magnesium is the smallest. In addition, the coordination numbers of these cations, that is, the number of liganding atoms that can pack around the cation in the first coordination sphere vary, ranging from six for magnesium to higher values and near eight for potassium. Na^+ and K^+, however, have only a weak tendency to form complexes. On the other hand, Mg^{2+} and Ca^{2+} have moderate tendencies to complex formation, particularly magnesium that has a high charge-to-radius value (the highest of any biologically important cation). They are therefore utilized to an advantage in the action of many enzymes.

Proteins bind these four cations with strengths that depend on the size of the cation and its charge. The higher the charge, the better the cation binds; the binding of potassium and sodium ions is poorer than that of magnesium and calcium ions. The size is also important and a protein often provides a pocket of the correct size so that it can distinguish between

Table 1 Sizes and charge-to-radius ratios of cations[11–13]

Cation	Ionic radius (Å)	Charge-to-radius ratio	Metal-oxygen distance (Å)	Average coordination number
Mg^{2+}	0.65	3.1	1.95	6.0
Ca^{2+}	0.99	2.0	2.25	6.4
Na^{+}	0.95	1.1	2.23	7.3
K^{+}	1.33	0.8	2.46	7.9

the two types of cations. It is shown in Table 1 that each of the four cations has very different characteristics with respect to size and charge, and these differences are utilized effectively by enzymes. For example, in pyruvate kinase there are two types of cation-binding sites. One binds cations smaller than Mn^{2+} (Mg^{2+}, Ni^{2+}, Co^{2+}, and Zn^{2+}), as for example, at the ATP-binding site, while the other binds larger cations (Ca^{2+}, Cd^{2+}, K^{+}) at the substrate-binding site.

Magnesium has a much higher affinity for water than do the other three cations. It is found in many crystal structures as Mg^{2+} $(H_2O)_6$, that is, octahedrally surrounded by six water molecules. Its high affinity for phosphate groups is often commented on in texts, and its complex with ATP (Mg-ATP) is a very important component of many enzymatic reactions. Surprisingly, however, in the crystal structure of $Mg_3(PO_4)_2{\cdot}22H_2O$ there are no $Mg{\cdots}O{-}P$ interactions, but each magnesium and each phosphate ion are surrounded by water molecules.[14] From this, it may be inferred that magnesium prefers to bind water molecules over phosphate groups. Since magnesium shows such a partiality for water, it is not surprising that it has a slower rate of water exchange than do the other three cations (10^{-6} s compared with 10^{-7} to 10^{-10} s for sodium, potassium, and calcium ions).

It is found, from crystal-structure determinations, that Na^{+} and K^{+} do not have spatial restraints on the coordination of ligands in the way that Ca^{2+} and Mg^{2+} do. Therefore, when monovalent cations bind functional groups on a protein, they do not tend to reorganize those groups in the way that divalent metal cations will. This was shown by an analysis of the manner by which cations bind to carboxylate groups in crystal structures.[15] It was found that sodium and potassium ions bind both in the plane of the carboxylate group and around it, out of the plane. On the other hand, magnesium and calcium ions tend to bind only in the plane of the carboxyl group. Of these two, in general, only calcium ions share the two oxygen atoms of the carboxylate group equally. This latter ability may explain the tendency of calcium ions to cross-link proteins (via carboxyl groups, as in blood clotting), while magnesium does not. In addition, the binding of ligands to magnesium ions is almost invariably octahedral and rigid. By contrast, calcium, sodium, and potassium ions, with more variable coordination numbers, show more flexibility in the geometry of ligand binding than do magnesium ions.

3 CONTROL OF CATION CONCENTRATIONS IN CELLS

The four cations Na^{+}, K^{+}, Mg^{2+}, and Ca^{2+}, while abundant in the body, are controlled by it. All the processes and their controls whereby animals maintain their internal biochemistry in a uniform and stable manner are described by the term ‘homeostasis’ (*see* ***Metallochaperones & Metal Ion Homeostasis***). These processes comprise the basis of life, and the maintenance of the size of a cell is very important so that it does not dry out or become so full of material that it swells and eventually bursts. This maintenance is done by control of the movement of ions in and out of the cell. The movement of water molecules across membranes that are permeable to water but not to solute (dissolved materials) is called osmosis. Water moves to the side of the membrane with the lower concentration of water (higher solute concentration), thereby diluting the solute.

In order to maintain the cytoplasmic concentrations of Na^{+} below and K^{+} above those in the extracellular fluid, it is advantageous to have active transport, that is, a process requiring energy. Active transport requires a coupled input of energy and this is the method needed in the cell because the flow of cations is from lower to higher concentrations, the opposite of that for passive transport. Sodium ions have to be pumped out of the cell in spite of the fact that their concentration is higher outside the cell than within it. There is also a steep chemical gradient to be overcome when pumping potassium ions into the cell. The system that controls cation concentrations by active transport is called a pump, and the pump that controls the balance of sodium and potassium ions is called a ‘sodium pump’, the (Na^{+}, K^{+})-ATPase. When a cell swells, the pump is activated.

The (Na^{+}, K^{+})-ATPase is a mammalian enzyme that pumps sodium ions out of the cell and potassium ions into the cell. It requires Mg^{2+}, which acts as a substrate and as a regulator. The energy for this process of pumping ions against the electrochemical gradient is obtained from the free energy of hydrolysis of ATP (12 kcal of energy liberated for every mole of ATP converted to ADP). The net result is that three sodium ions are eliminated from the cell for every two potassium ions that are brought into it.

Calcium ions are also transported into the cell by a pump, which is a Ca^{2+}-dependent ATPase. This pump is necessary because the calcium ion concentration is four orders of magnitude higher outside than inside living cells. Calmodulin regulates the level of calcium ions and hence the calcium pump. When the calcium concentration decreases, calcium is dissociated from calmodulin and the calcium pump is inactivated. The structure of such a pump from the sarcoplasmic reticulum is reported at 8 Å resolution.[16,17] This pump couples ATP hydrolysis with cation transport. The protein contains 10 transmembrane helices. A distinct cavity was located that led to the putative calcium-binding site, suggesting a path for a calcium passage.

The control of K^+ is illustrated by the 3.2 Å crystal structure of a potassium channel.[18] This allows potassium ions but not sodium ions to diffuse through a lipid bilayer that they would not normally permeate. An X-ray diffraction analysis has shown that the channel resembles an 'inverted tepee' or cone with the wide part opening to the outside of the cell membrane. This wide part is, however, almost filled by membrane-spanning α-helices that provide dipoles that aid K^+ movement through the channel and a 'selectivity filter' that provides a narrow opening with a diameter adjusted to favor K^+ and repel Na^+. As K^+ enters, it is dehydrated and coordinates to main-chain carbonyl groups. The pore is long enough to accommodate two K^+ that repel each other so that the inner one progresses into a wider aqueous chamber and on to the interior of the cell.

4 SODIUM- AND POTASSIUM-ACTIVATED ENZYMES

The crystal structures of several sodium- and potassium-activated enzymes have now been determined and the position of the monovalent cation established. Structural data are listed in the Protein Data Bank (PDB).[19] They provide a clue (but not an absolute proof) to their location within the enzyme on activation. Further biochemical studies may be necessary to verify this finding. Some examples of these structures are presented here. The first example (thrombin) is a sodium-activated enzyme, but the others are potassium-activated enzymes.

4.1 Thrombin

Thrombin, the final enzyme in the coagulation cascade, is a serine protease that causes blood clotting. It cleaves and converts fibrinogen to an insoluble fibrin clot so that wound repair can commence. It can also behave as an anticoagulant when protein C is brought into the picture. The enzyme cleaves at specific arginine residues aided in its selectivity by nearby sites on the enzyme. Human α-thrombin is a sodium-activated enzyme, in that its activity is greatly increased in the presence of Na^+. Wells and Di Cera[9] point out that the blood stream concentrations are higher for Na^+ than K^+ and that thrombin has adjusted to this environment. The binding of monovalent cations has been shown spectroscopically to facilitate a change in the conformation of the enzyme. Na^+ switches the enzyme between two conformational states, one of which activates fibrinogen and the other cleaves protein C. This function is referred to as an allosteric switch because the Na^+ converts the thrombin from a slow (Na^+-free) form that cleaves protein C to a fast (Na^+-bound) form that enhances substrate binding and fibrinogen cleavage.[20] Both forms are normally found in the blood because the Na^+ concentration is not high enough to saturate the site. A decrease in Na^+ reduces fibrinogen cleavage and therefore slows the clotting time.

Thrombin binds sodium better than potassium. The cation is bound by backbone carbonyl groups of Arg221a and Lys224 and by four buried water molecules.[21,22] One water molecule connects the sodium ion to OD2 of Asp819; this accounts for the primary specificity of the enzyme. When sodium is released, Asp819 reorients and this perturbation extends to the catalytic site.

It is not necessarily the strength of monovalent cation binding that determines the activating ability. This was demonstrated by Di Cera and coworkers.[23] They were able to convert thrombin from a sodium-specific enzyme to a potassium-specific enzyme. This was done by site-directed mutagenesis by redesigning a loop in the backbone that defines the geometry near the cation-binding site and controls access to it. They found, however, that, while the mutant enzyme bound K^+ better than Na^+, it was still preferentially activated by K^+ rather than Na^+.

4.2 2,2-Dialkylglycine Decarboxylase

This enzyme catalyzes a decarboxylation and transamination converting 2,2-dialkylglycine with pyruvate into a ketone, L-alanine, and carbon dioxide. It is activated by K^+ and inhibited by Na^+ and Li^+. The enzyme has a structure made up of a dimer of dimers. The catalytic site is near the interface between monomers of the dimeric unit and involves residues from both subunits.[24–26] There are two monovalent cation sites per monomer, one structural and the other regulatory. The regulatory K^+ causes changes in the active site, especially near Ser80 and Tyr301. Crystal structures have been reported, one with K^+ and Na^+, another with two Na^+ in the metal ion sites and the results were compared. Hohenester showed that Li^+ behaves like Na^+, while Rb^+ behaves like K^+. When potassium is replaced by sodium, the link to Ser80 is lost and its hydroxyl group is replaced by water. This change is caused by the ion size and coordination number. It results in a large change in conformation and a change at the catalytic site. Na^+ or Li^+ binding at the regulatory site is strongly inhibitory because of insertion of extra water molecules as metal ion ligands.

4.3 Pyruvate Kinase

Pyruvate kinase catalyzes the conversion of phosphoenolpyruvate and ADP to pyruvate and ATP. A proton is taken up in the reaction. The enzyme binds one K^+ and two Mg^{2+} ions. The 2.9 Å crystal structure shows that the K^+ interacts directly with the migrating phosphoryl group and indirectly with residues in the active site.[27,28] Activity with Na^+ is about 9% that of K^+. Figure 1 shows the geometry of the active site. Oxalyl phosphate is a substrate for pyruvate

kinase and the ATP-oxalate complex (shown in the figure) is the product of the reaction. Each oxygen atom of the γ-ATP interacts with a metal ion, and it is possible that this prepares the phosphorus for nucleophilic attack. One oxygen atom of the oxalate is 3 Å from the γ-phosphorus of ATP, and is in position for an in-line transfer of the phosphoryl group from ATP to oxalate. This alignment is aided by the metal ion binding.

Many pyruvate kinases show the active-site geometry illustrated in Figure 1, but others, such as those from *Escherichia coli* and *Corynebacterium glutamicum* do not require monovalent cations for activation. In these, Glu117 in the K^+ binding site is replaced by lysine. This lysine behaves as an 'internal monovalent cation', that is, a tethered ammonium ion, for which the single positive charge takes the place of K^+.[29] Significantly, this experiment provides confirmation of the activation site of K^+.

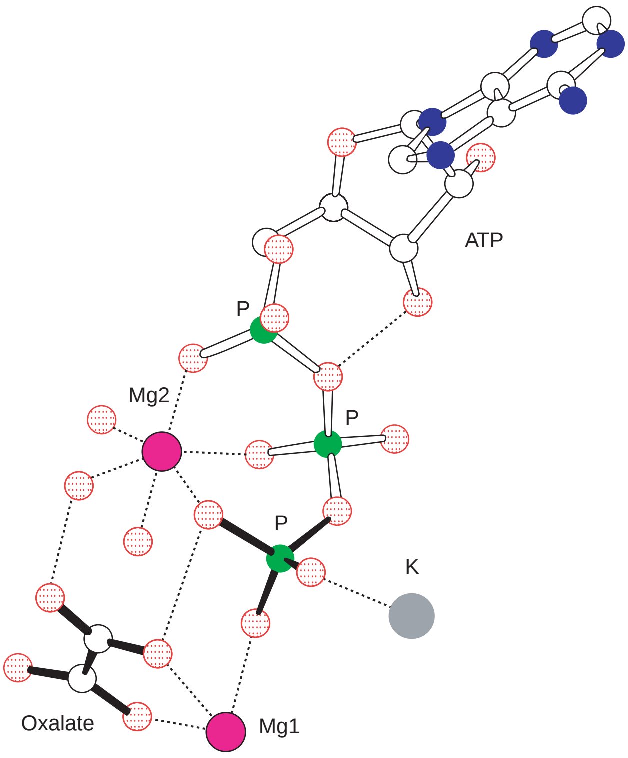

Figure 1 The active site of pyruvate kinase, drawn from PDB file 1A49, showing bound Mg^{2+}, K^+, ATP, and oxalate.[28] The bonds of the oxalate and the γ-phosphate of ATP are black. Mg1 is coordinated by two oxygen atoms of oxalate, one of the γ-phosphate of ATP, oxygen atoms of Glu271 and Asp295, and one water molecule. Mg2 is coordinated by three oxygen atoms of ATP and three water molecules. K is coordinated to the carbonyl group of Thr113, Ser76, Asp112, Asn74, the γ-phosphate of ATP (as shown), and a water molecule. Note that the K^+ interacts with a substrate. In this and Figure 2, drawn with the program ICRVIEW,[54] atoms of O are stippled, of N are filled, and of C are open

4.4 Diol Dehydrase

Diol dehydrase is a bacterial enzyme that catalyzes the dehydration of 1,2-diols to aldehydes. The structure at 2.1 Å showed that the enzyme binds K^+.[30,31] The K^+ has seven ligands: the two hydroxyl groups of the substrate, propane-1,2-diol, and five oxygen atoms of active-site residues. It is thought that the K^+ positions the substrate within the active-site cavity and also provides space between radical intermediates and amino acid residues in the active site, thereby protecting the enzyme from radical attack. The K^+ may also participate in the migration of the hydroxyl group on C2 to C1 of the radical form of 1,2-propanediol. The structure of glycerol dehydrase has approximately the same features.[32]

4.5 Inosine Monophosphate Dehydrogenase

In inosine monophosphate dehydrogenase, the monovalent metal ion accelerates the hydride transfer step of the reaction with apparently few other effects on the enzyme structure. Probably the monovalent cation is involved in helping position the nicotinamide cofactor. The active site and location of the potassium ion are shown in Figure 2.[33] Mycophenolic acid in this diagram is an inhibitor that is thought to lock inosine monophosphate into the active site, as shown. Note the large distance between the inhibitor (in the active site) and the K^+.

4.6 Tryptophanase

This enzyme cleaves L-tryptophan to give indole, pyruvate, and ammonia by β-elimination and deamination. It is activated by various monovalent cations, especially ammonium ions ($NH_4^+ > K^+ > Cs^+ > Na^+ > Li^+$).[4] The enzyme is a tetramer. Its catalytic sites, as well as the K^+-binding sites, lie

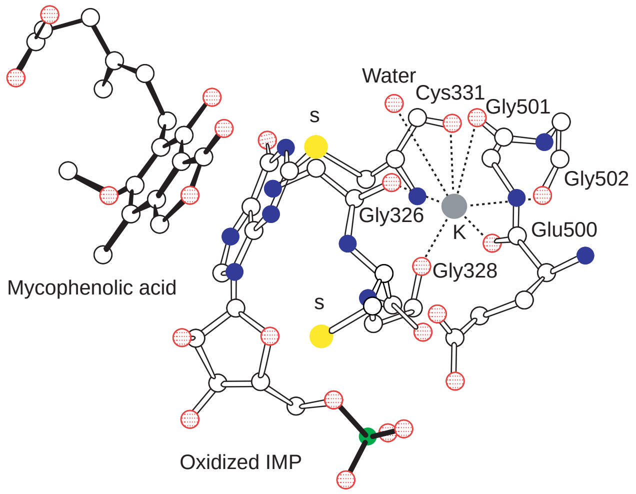

Figure 2 The active site of inosine monophosphate dehydrogenase, drawn from PDB file 1JR1.[33] This shows the inhibitor mycophenolic acid at the active site, stacking against PLP. The K^+ site is distant from the active site

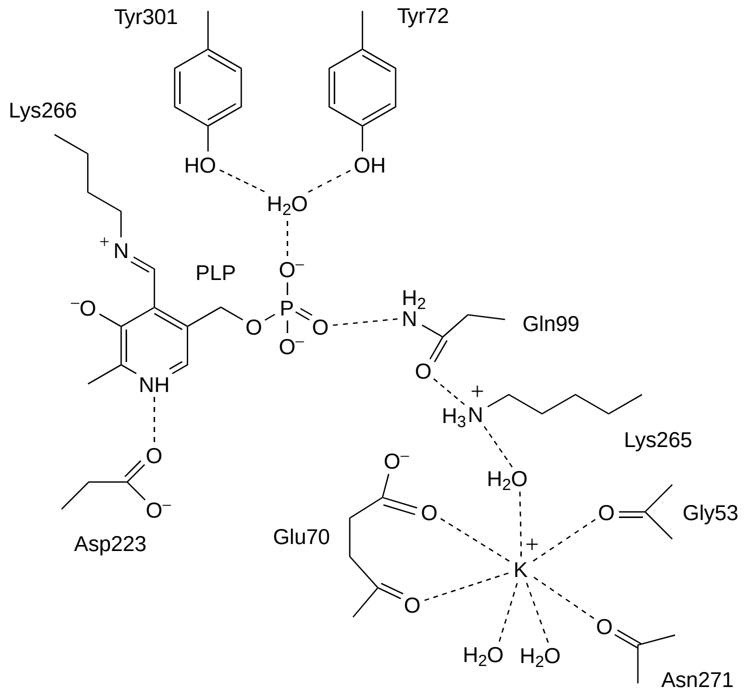

Figure 3 Diagram of the active site of tryptophanase[34] showing the large distance between the K^+ and the active site. The distance between K^+ and N1 of PLP is 15.5 Å

at the interface of two subunits.[34,35] The crystal structure at 2.1 Å resolution shows that the K^+ site is about 6 Å from the active site and 18 Å from the nearest pyridoxal 5′-phosphate (PLP, vitamin B_6) ring.[34] The K^+ is bound to the enzyme by backbone carbonyl oxygen atoms of Gly53, Glu70, and Asn71, a side-chain carboxylate group from the same Glu70 and three water molecules; Glu70 is in a different subunit from the other protein ligands. This is diagrammed in Figure 3. In this way, both the K^+ and the PLP contribute to the stability of the catalytic dimer. It appears that K^+ binding stabilizes the ground state of the quinonoidal form of the PLP-enzyme complex and lowers the activation energy for a subsequent α-proton abstracting step, that is, the conversion of an external aldimine Schiff base to the quinonoid form. By contrast, Na^+ does not behave in this way, which may explain why it is less efficient at activating. This is in line with spectroscopic evidence. A bound coenzyme gives a spectrum with peaks at 337 and 420 nm. In the presence of K^+, this spectrum changes with pH, but not in the presence of Na^+.[35] Tyrosine phenol-lyase cleaves L-tyrosine to give phenol, pyruvate, and an ammonium ion. This enzyme is like tryptophanase.[36] The metal ions add to subunit interactions and in the absence of metal the enzyme dissociates to monomers.

4.7 Tryptophan Synthase

Tryptophan synthase catalyzes the last two reactions in the biosynthesis of L-tryptophan. This enzyme needs a monovalent cation for activity. K^+ does not play a direct role in binding the substrate or cofactor but changes some side-chain orientations. The α-subunit cleaves 3-indole-D-glycerol 3′-phosphate to α-glycerolphosphate and indole. The β-subunit replaces the β-hydroxyl of L-serine by indole to form L-tryptophan. In the reaction, the α-subunit catalyzes the conversion of 1-(indol-3-yl)glycerol 3-phosphate to indole and glyceraldehyde 3-phosphate. The indole then migrates to the β-subunit where, with serine in the presence of pyridoxal 5′-phosphate, it is converted to tryptophan. The crystal structure of tryptophan synthase at 2.8 Å resolution showed that the active sites of the α- and β-subunits are about 25 Å apart.[37,38] The two sites are connected by a largely hydrophobic intramolecular tunnel with dimensions sufficiently large to accommodate up to four molecules of indole. It was found from further studies that the tunnel could be blocked by the side chain of Phe280. It appears that various monovalent cations cause movements of Phe280 out of the tunnel, implying that Phe280 can act as a gate to control passage through the tunnel.

4.8 Other Potassium-activated Enzymes

Many crystal structures of other potassium-activated enzymes have been reported. They generally require a divalent cation and are activated by a monovalent cation that also binds. Such enzymes include amylase,[39] which has a unique Ca–Na–Ca trinuclear center, *S*-adenosylmethionine synthetase,[40] *E. coli* methionine aminopeptidase[41] in which

the K^+ is 13 Å from a dinuclear metal center and rhodanese,[42] Class II fructose 1,6-bisphosphate aldolase,[43,44] ascorbate peroxidase that contains a K^+ cation that has a profound influence on the redox properties of the heme group,[45] and cytochrome $P450_{cam}$ that binds camphor more readily when K^+ is present, possibly due to stabilization of the environment of Tyr96.[46] In carbamoyl phosphate synthetase, which also requires K^+, Glu214 bridges the K^+ and ADP forming a 'K loop' that allows communication from K^+ to the active site via the carboxylate of this glutamic acid.[47] In the heat-shock protein Hsc70, two potassium ions are bound in the nucleotide-binding site.[48]

5 MAGNESIUM- AND CALCIUM-ACTIVATED ENZYMES

Activation by divalent cations is more difficult to assess because divalent cations are often integral parts of the enzyme mechanism. Some of the guidelines for determining whether a cation activates enzymes were given above. About 60–65% of total body magnesium is in bone and 27% in muscle. The remaining is in living cells and extracellular fluids. The insolubility of calcium phosphate has meant that calcium is unsuitable as an intracellular cation. This leaves magnesium as the major intracellular ion for the complexation of phosphate. Magnesium ions are used as cofactors in phosphate transfer, to carry out the transfer of substituted phosphoric acids. Examples are provided by kinases (that transfer phosphoryl groups between ATP and a metabolite), synthetases, and phosphatases. They also catalyze the transfer of acyl groups, hydration-dehydration or tautomeric reactions, carbonyl addition reactions, and dehydrogenases. Magnesium with its double positive charge neutralizes anionic centers in proteins, particularly phosphate and carboxylate groups. Magnesium ions are smaller than calcium ions and bind with a coordination number that is generally six, while the coordination number of calcium is seven or eight. Thus, Mg^{2+} can fit in Ca^{2+} holes, but the opposite is not true. Often calcium binds both oxygen atoms of a carboxylate group (bidentate binding), but when magnesium takes its place only one of the oxygen atoms is bound to the metal ion.

5.1 Magnesium

The features of magnesium ions that are of particular significance are their strong affinity for water and their rigid octahedral coordination sphere which suggest they may be used to deliberately prevent motion in certain regions of the enzyme system and also to orient functional groups as needed for catalysis.[49] Magnesium shields the negative charges of the phosphate groups because otherwise these charges would tend to repel the electron pairs of the attacking nucleophile, especially those with anionic character. DNA polymerase requires magnesium to provide the proper conformation of the arriving nucleotide triphosphate for incorporation into nascent DNA in a 5′ to 3′ direction. When magnesium is replaced by manganese, there is an increase in the speed of replication and a decrease in the precision of the operation. Thus, nature has opted for magnesium throughout nucleic acid enzymology to maximize fidelity at the expense of speed in transmitting the genetic code.

The function of magnesium in enzyme activity may either be to form a complex with the substrate, as in the magnesium-ATP complex formed in creatine kinase and phosphofructokinase, or to bind to the enzyme and either produce an allosteric activation or play a direct role in catalysis. If an enzyme is known to utilize a nucleotide as one of its substrates, it can be assumed that magnesium is also required for catalysis. The magnesium ion possibly acts as an electrostatic shield. The enzyme pyruvate kinase, described earlier, and shown in Figure 1, requires both magnesium and potassium ions for maximal activity.

5.2 Alkaline Phosphatase

One example of a magnesium-activated enzyme is *E. coli* alkaline phosphatase. This is a zinc-binding enzyme with a high pH optimum (hence the name) that catalyzes phosphoryl transfer to various alcohols. When a phosphomonoester binds to the active site, a serine hydroxyl group (Ser102) is phosphorylated and the product alcohol leaves. The enzyme binds one magnesium and two zinc ions per active site.[50] A crystal structure shows the phosphate group bound by arginine and the two zinc ions. The magnesium ion is bound to Asp51, Glu322, Thr155, and three water molecules. Both zinc ions bind to the phosphate group and one (Zn2) also binds to Asp51. Lys328 is constrained by Asp153, which binds to a magnesium-bound water molecule. The importance of Asp153 is evident. Replacement of this aspartate by histidine (Asp153His) is found to give an enzyme that binds three zinc ions, no magnesium.[51] This third site (Zn3) is tetrahedral rather than octahedral as found when magnesium is present. The result is that Zn3 is bound by Asp51, Glu322, Thr155, and His153 but the link of Asp51 to Zn2 is lost, as is the constraint of Lys328 by Asp153. Therefore Lys328 binds to the phosphate, and the hydroxyl group of Ser102 interacts with Zn2. This means that the all-important Ser102 has decreased activity as a nucleophile as a result of the mutation, and the resulting enzyme (Asp153His) is inactive. However, when excess magnesium is added it regains activity. In this example, the activating power of magnesium is evident.

5.3 Klenow Fragment of DNA Polymerase

In the Klenow fragment of DNA polymerase I (the 3′,5′-exonuclease), two metal ions are used.[52] One stabilizes the transient pentacovalent species and the leaving of a 3′ oxyanion (Mg^{2+}), and the other facilitates the formation of an attacking water molecule or hydroxyl group (Zn^{2+}).

5.4 Calcium (*See Calcium-binding Proteins*)

Ninety-nine percent of the calcium and 85% of the phosphorus in the body are found in bones, mostly a poorly crystalline hydroxyapatite $Ca_{10}(PO_4)_6(OH)_2$. In addition, calcium is involved in blood coagulation and is an intermediary factor between impulses and muscle contraction. Calcium has an activating effect on enzymes such as phosphorylase kinase and pyruvate dehydrogenase (lipoamide)-phosphatase.

In small organic structures, the coordination number of calcium varies from 6 to 10. The geometry of this coordination varies from octahedra (6) to pentagonal bipyramids (7) to square antiprisms (8), possibly with additional capping ligands (9 and 10). Two types of calcium-binding proteins have been identified. The first group contains enzymes stabilized by calcium ions that may even be used in catalysis. The second group contains proteins that bind calcium reversibly and modulate the action of other enzymes. The calcium-binding group in this case is generally a helix-loop-helix structure (referred to as the EF hand).[53] The motif can be thought of, in terms of a right hand, as an index finger representing the E-helix, a curved second finger, the loop, and a thumb the F-helix. Such EF hands have a well-conserved calcium-binding site. In each EF hand, there are seven oxygen atoms around the calcium ion with an octahedral arrangement and one carboxyl group contributing two oxygen atoms (bidentate).

6 SUMMARY

The significant theme in the action of cation-activated enzymes is the control that the cations have on the action of the enzyme. This subject needs more study with the hope that the information gained may help us understand how we can harness and control in more detail the action of certain enzymes. The role of potassium has been stressed here because so much recent structural work has clarified the binding sites and indicated possible modes of action. Overall, the action of such cations is due to their electric charge (which aids the chemistry of the mechanism), their size (which affects coordination geometry), and the geometry of their first coordination sphere (which affects their power to orient functional groups as required for catalysis). The borderline between those cation-binding enzymes that are activated by the cation and those that use the cation as an essential component of the reaction is not clear, especially when the ‘activating cation’ is divalent. Further structural and biochemical studies will clarify this subject.

1 INTRODUCTION

The class of chalcogenide compounds is large and its members contain combinations of various elements with the chalcogens, that is, sulfur, selenium, and tellurium. Oxygen is not included because it has a distinct and vast chemistry of its own and it must be dealt with separately. Solid-state chalcogenides generally refer to those compounds whose structure involves extended frameworks and it is to be distinguished from another class of chalcogenide compounds that involves discrete molecular species. This section aims to introduce the reader to solid-state chalcogenides with particular emphasis given to the developments of the last decade. It is not meant to be an exhaustive review article but an entry point to this area of inorganic chemistry. Therefore many interesting results will be left out. Several important review articles have appeared on the subject which, when taken collectively, capture most of the research activity of the last decade.[1–6]

There exist large structural and chemical differences between the class of oxides that is huge and the smaller class of chalcogenides. Why are oxides different from chalcogenides? Part of the answer lies in the ability of the oxide ion (O^{2-}) to adopt almost any M–O–M angle from very small (e.g. 80 deg) to 180 deg. In contrast, the chalcogenide ions (Q^{2-}) do not, and prefer a much smaller range of M–Q–M angles. This can be explained by the more extensive hybridization of s-p orbitals in S, Se, and Te relative to those of oxygen. In oxygen, s-p mixing does not occur readily because of the large energy gap between the two orbital levels. In the heavier congeners, the s-p levels come increasingly closer in energy to give rise to strong sp^3 hybridization and more rigid angular requirements.

As we move down group 16, the elements acquire an increasing tendency to catenate, that is, to form homoatomic bonds creating chains. This results not only in rings or chains in the several elemental forms known, but also in the polychalcogenide $Q_n{}^{2-}$ (Q = S, Se, Te; $n = 2-7$) ions that can exist in solution or in the solid-state.[7–9] The fascination of chemists with the chalcogen group has many reasons, not the least of which is the ability to form intriguing polyanions and polycations.

Sulfur and selenium have several allotropic forms with the rings of S_8 and Se_8 being the most known. Tellurium is polymeric with no known allotropes. The discovery of the cyclo-octatellurium ring (Te_8) in Cs_3Te_{22},[10] represented a landmark in chalcogen chemistry as it completed the chalcogen series S_8, Se_8, and Te_8. Indeed, Te_8 has the expected puckered ring structure. Although not a true allotrope, since it coexists with other components in Cs_3Te_{22}, Te_8 has been a missing species and had caused chemists to wonder about its stability.

Chalcogenides of the transition and main group metals can exhibit useful physical and chemical properties that are intellectually stimulating, scientifically interesting, and often useful for applications in a variety of technological fields. Some examples include optical information storage devices,[11] thermoelectric devices,[12–14] radiation detectors,[15] nonlinear optics,[16] thin film electronics,[17] solar energy conversion devices,[18] catalysis,[19] spintronics,[20] and even superconductivity.[21] Binary and ternary chalcogenides have been more extensively investigated than quaternary chalcogenides however the latter also exhibit interesting properties. Not surprisingly, therefore, during the last decade the chemistry of quaternary chalcogenides has witnessed the largest growth.[22] Indeed, we have seen an impressive expansion in solid-state chalcogenide chemistry with emphasis in materials with new compositions and structure types. In this regard, the emergence of novel synthetic methodologies such as flux and solventothermal techniques has played a major role. Unfortunately, the physical properties of many of these new chalcogenide materials have not yet been investigated.

In this article, we will present selected developments in chalcogenide solid-state chemistry of the past decade. We will begin from the simple binary systems and evolve towards more complex systems.

2 BINARY COMPOUNDS

The binary group of compounds can be divided into three major subgroups (a) alkali and alkaline earth metal chalco- and polychalcogenides, (b) valence-precise metal chalcogenides, and (c) metal-rich chalcogenides.

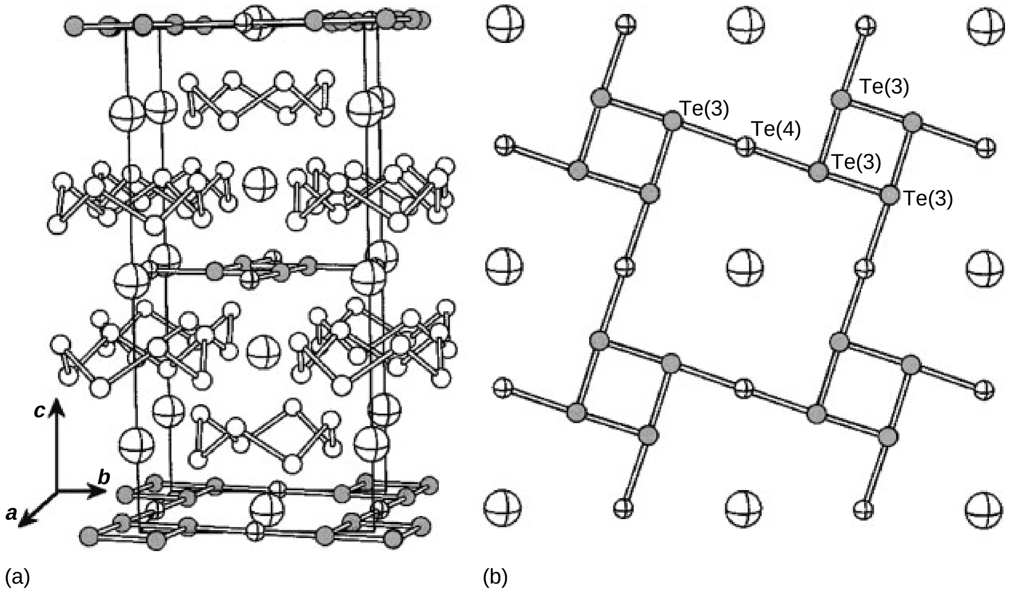

Figure 1 (a) Structure of Cs_3Te_{22} (b) The layer of $[Te_6]_n^{3-}$

2.1 Alkali and Alkaline Earth Metal Chalco- and Polychalcogenides A_xQ_y(A = Alkali Metal, Alkaline Earth Metal)

One of the most interesting binaries described is Cs_3Te_{22}, which was prepared solventothermally.[10,23] It contains the long time elusive Te_8 ring, which is trapped for the first time inside the crystal lattice. This has been the missing member of the well-known series of S_8 and Se_8 which in chemistry textbooks has been described as too unstable to exist. One way the Te_8 rings are stabilized in the structure is by acting as crown-ether type ligands on the Cs cations forming $(Te_8)_2Cs$ sandwiches. In addition to the Te_8 ring molecule, Cs_3Te_{22} contains the unusual infinite layer of $[Te_6]_n^{3-}$, a perfectly flat arrangement of Te atoms shown in Figure 1. The bond lengths in the flat layer range from 3.002(2) to 3.077(2) Å. The electronic structure of this network has been studied in detail.[24]

Along the same lines, the synthesis of Cs_2Te_{13} and Cs_4Te_{28}, tellurium-rich compounds[25] via a methanolothermal route is noteworthy. These systems are thought to be intermediates to Cs_3Te_{22}. The longest isolated tellurium anionic chain can be found in Cs_2Te_{13} (Figure 2). The bond lengths in the $[Te_{13}]^{2-}$ chain range from 2.755(2) to 2.910(2) Å and this is within the range of normal Te–Te bonds. The chains are connected in corrugated sheets via Te···Te interactions of 3.18 and 3.26 Å to form ladders of Te_4 rectangles and chair-shaped Te_6 rings.

Another interesting binary compound is $RbTe_6$, the structure of which has the slab of $[Te_6]^{1-}$ polyanions.[26] The layers contain fused Te_6 rings with a chair conformation, which are connected via four Te–Te bonds into a layer structure (Figure 3). A T-type geometry is adopted by the resulting $TeTe_3$ units.

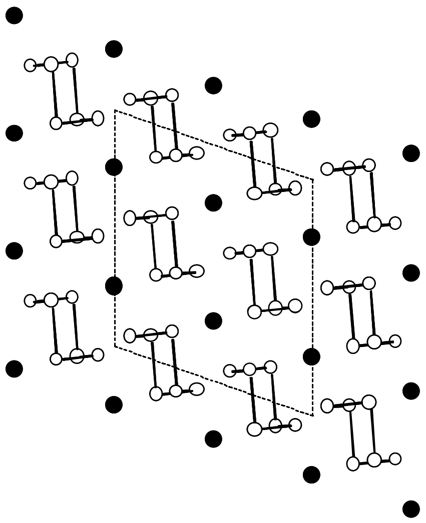

Figure 3 The structure of $RbTe_6$. The Te_6 rings are interacting via short Te–Te contacts to form a network

2.2 M_xQ_y (Valence-precise Metal Chalcogenides)

In this class of binary compounds, a new tetragonal form of boron sulfide B_2S_3 prepared by high-pressure synthesis is noteworthy. Remarkably, instead of a simple structure related to that of normal ambient pressure form of B_2S_3, it contains two kinds of supertetrahedra built up from 20 and 34 adamantane-type superclusters to form an elaborate three-dimensional framework (Figure 4).[27] These supertetrahedra are linked to each other in a unique way forming an interpenetrating zinc-blende-type structure. This compound is a wide band-gap semiconductor with an energy gap of 3.7 eV.

Another binary highlight is the $EuSe_2$ which was prepared in a Li_2Se_x flux.[28] $EuSe_2$ adopts the same structure as that of SrS_2 and $BaTe_2$ ($CuAl_2$ type) and has Eu^{2+} and $Se_2{}^{2-}$ ions. Looking down the *b*-axis (Figure 5), one can see the layers of Se stitched together by eight-coordinate Eu atoms. Looking down the *c*-axis in Figure 5, one can see rows of diselenide dumbbells. These rows are packed together in a staggered fashion and run parallel to the *c*-axis, separated by rows of Eu atoms. Each Eu atom is bonded to eight Se atoms in a square antiprismatic coordination. The diselenide dumbbell sits inside of a rectangular, parallelepiped pocket, shown in Figure 5. The structure of $EuSe_2$ is closely related to that of the ternary $KCeSe_4$, which is also tetragonal.[29] We can view the latter compound as deriving from $EuSe_2$ by substituting two Eu^{2+} ions with a K^+ and Ce^{3+} ion respectively. $EuSe_2$ is a semiconductor, with a well-defined energy gap, E_g, of 1.43 eV. It also behaves as a bulk antiferromagnet with a metamagnetic transition below 8 K.

2.3 M_xQ_y (Metal-rich Chalcogenides)

Metal-rich chalcogenides are those that contain enough metal atoms to form M–M bonds. These are regarded as reduced compounds with metals in very low oxidation states. Most of the metal-rich chalcogenide chemistry in the past decade had to do with early transition and rare earth element chemistry. Important in stabilizing these structures is an extensive array of M–M bonding distances. In general, it is not possible to predict the unusual compositions and structures of these compounds. Successful high temperature routes to metal-rich lanthanide chalcogenides have been developed, and for this the use of tantalum (or niobium) containers has made a great deal of difference. If glass or silica tubes are used to carry out these reactions the most common products are the REQ and RE_3Q_4 (RE = rare earth element) compounds. The metal-rich RE-Q systems are interesting species not only because of their novel compositions and structures, but also because of the localized 4f core electrons which can lead to novel electronic properties.

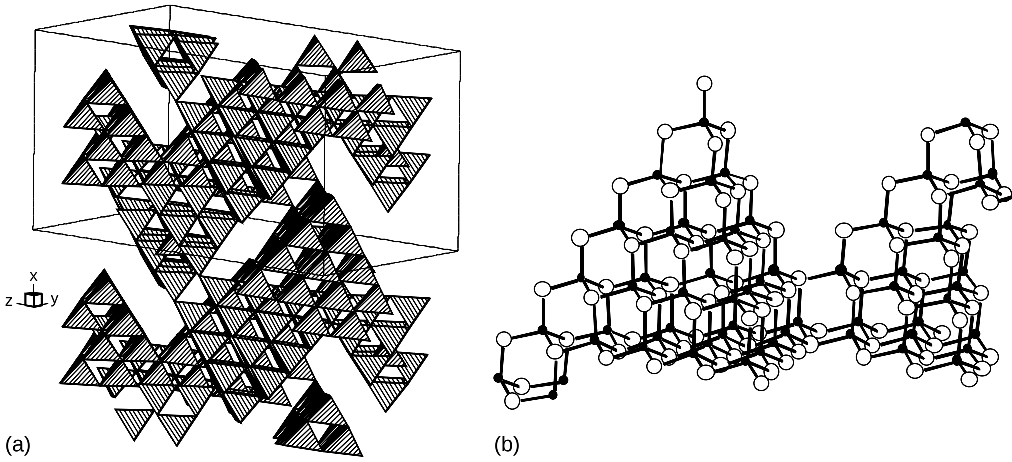

Figure 4 The structure of the high-pressure form of B_2S_3. (a) A polyhedral representation of the three-dimensional framework (b) an excised fragment from the structure showing the adamantane-type superclusters

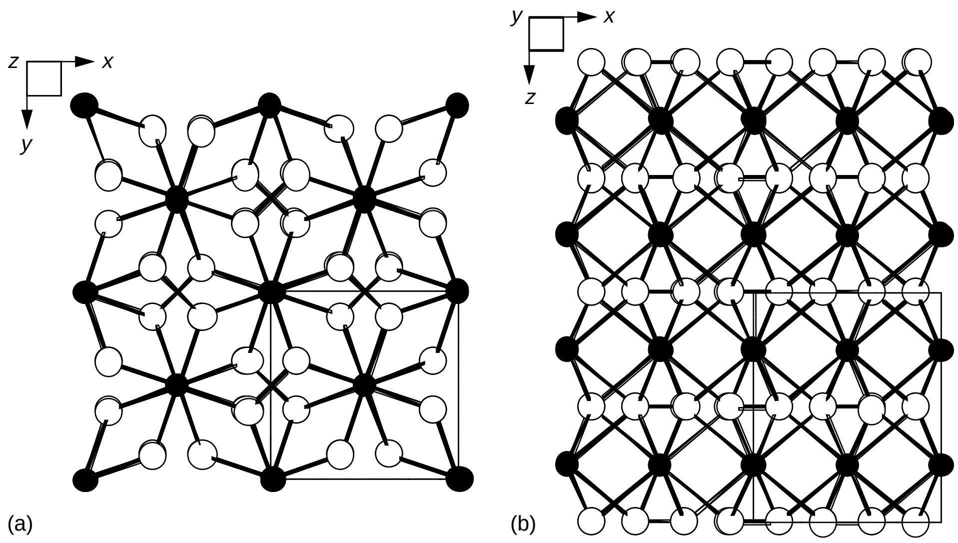

Figure 5 The structure of $EuSe_2$ viewed down (a) the *c*- and (b) the *b*-axis direction. Black atoms are Eu

There exists a remarkable range of compositions and structures, even among the M_2Q examples[30] (M = Sc, Ti, Zr, Hf, Nb, Ta; Q = S, Se, Te) and also rare earth analogs such as Dy_2Te. The building blocks observed in these structures are metal–metal bonded chains and sheets separated by Q^{2-} anions. It is an interesting example of a binary compound that shows condensed metal polyhedra in a metal-rich but in a relatively electron-poor environment. These compounds obtain their stability from a subtle synergism of metal–chalcogen and extended metal–metal bonding. Sc_2Te adopts a new structure-type with chains of condensed metal clusters.[31]

The structure of Sc_2Te contains two types of interconnected metal units separated by telluride in mono-, bi-, and tricapped trigonal prisms of metal: zigzag Sc4 chains and centrosymmetric 10-member condensed chains or ribbons that contain a spread of Sc–Sc distances (Figure 6). The more complex metal chain can be described geometrically starting with a pair of single chains of infinite trans-edge-sharing distorted octahedra that have been fused at Sc6-Sc6. As one moves from Sc to group 4 and lanthanide analogs, there are some appreciable differences because of significant changes in the metal's classical radius as well as orbital size and bond strength.

The electron-richer α-Ti_2Se[32] and Zr_2Te[33] also adopt the Sc_2Te-type structure, and increased bonding is evident in these phases. Since Zr and Sc have almost the same atomic radii, the contribution of crystal packing effects to bonding differences in Zr_2Te and Sc_2Te is small. So any differences in bonding can be attributed to other factors, such as the number of valence electrons. Theoretical studies of the bonding in Zr_2Te and Sc_2Te based on extended Hückel calculations indicate that M–Te bonding is comparable in the two compounds, whereas M–M bonding is reduced from a three-dimensional network in Zr_2Te to quasi-one-dimensional units in Sc_2Te. Despite the stability of the Sc_2Te structure-type with respect to variations in the valence electron concentration available for M–M bond formation and its adoption by Zr_2Te, it is interesting that the analogous Zr_2Se and Hf_2Te, adopt distinct types of structures.[34]

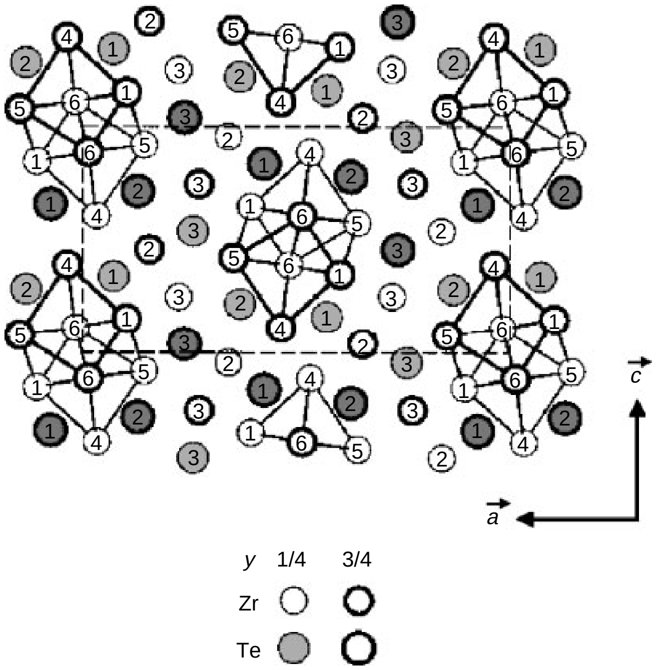

Figure 6 The structure of Sc_2Te. Some M–M bonds have been omitted for clarity

The early transition metals and rare earth elements exhibit a metal-rich chemistry that is often surprising in its structural and

physical aspects. The fertile nature of this area is illustrated by the discovery of several interesting binary compounds within the past decade. The factors controlling the structural anisotropy of a new class of tetragonal layered compounds that includes Ta_2Se, $Ta_{2-x}Nb_xS$, Hf_3Te_2, and the ternary ZrZTe (Z = Si, Ge, Sn) have been discussed.[35] Examples of reduced binary chalcogenides of the earlier transition metals include M_8Te_3 (M = Sc, Y),[36] Sc_9Te_2,[37] Ti_8Q_3 (Q = S, Se),[38] Lu_8Te,[39] Lu_7Te,[39] $Ti_{11}Se_4$,[40] Zr_3Te, Zr_5Te_6,[41] ZrTe,[42] Hf_2Te,[34] Hf_3Te_2,[43] $Nb_{21}S_8$,[44] Ta_2Se,[45] $Ta_{97}Te_{60}$,[46] $Ta_{181}Te_{112}$,[47] and Ti_9Se_2.[48] Of these, the phases Ti_9Se_2, $Ti_{11}Se_4$, Hf_3Te_2, Ta_2Se, and the tantalum tellurides account for new, previously unknown structure types. The more metal-rich chalcogenides generally contain more condensed metal substructures, often in the form of corrugated sheets composed of condensed octahedra that are separated by chalcogen atoms. Hf_3Te_2 and Ta_2Se represent layered materials with bcc-like metal stacks coated on both sides with chalcogen atoms. Lu_8Te and Lu_7Te represent an extreme example of a metal-rich phase which can be regarded as novel substitutional derivatives of lutetium metal. Another very metal-rich phase is Sc_9Te_2 which shows a two-dimensional distortion wave.

Differences in the cohesive energy between Nb and Ta give rise to the formation of a bundle of (Nb, Ta)-rich sulfides without counterparts in the corresponding binary M–S systems. The phase richest in metal of this class has been identified as $Nb_xTa_{7-x}S_2$.[49] $(Nb, Ta)_7S_2$ is an excellent example of a mixed niobium–tantalum-rich sulfide without counterpart in the adjoining binary systems. Its structure differs markedly from those of the known binary sulfides. $(Nb, Ta)_7S_2$ forms a structure of its own type comprising distorted M_{13} icosahedra. The structure of $(Nb, Ta)_7S_2$ is composed of six crystallographic inequivalent atoms: Ta(1), M(1)–M(4) with M representing Nb or Ta, and S(1). Ta(1), M(2) and M(4) lie in mirror planes at $y = 1/4$ and 3/4. The other atoms occupy general sites. Figure 7 shows a projection of the structure onto the *bc* plane. $Nb_xTa_{7-x}S_2$ forms a unique pentagonal antiprismatic columnar structure which – as opposed to the related structures of the Ta-rich sulfides – contains one additional metal site at which Nb accumulates. This facilitates an energetically favorable partial segregation of Nb outside the metallic columnar core.

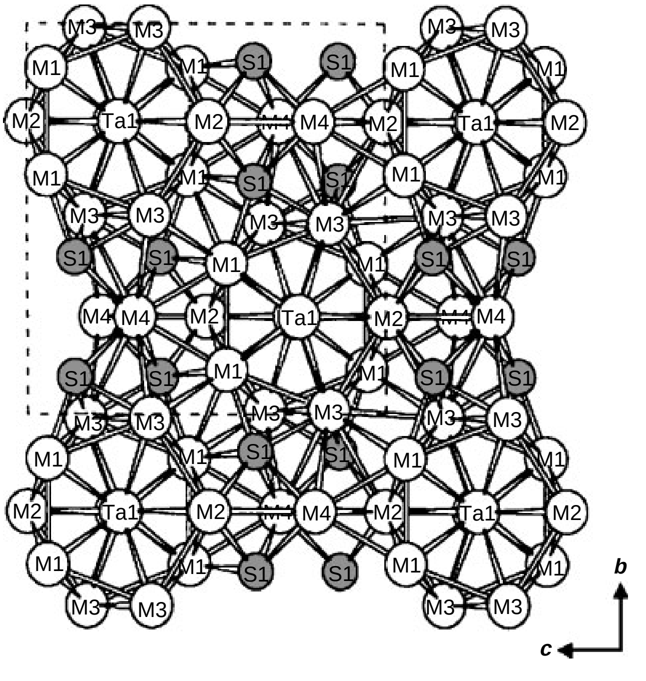

Figure 7 The structure of $Nb_{2.73}Ta_{4.23}S_2$ projected down the a-axis. (Reprinted from Ref. 49. © 2002, with permission from Elsevier)

The chemistry and metal–metal bonding is further enriched and enlarged by the addition of late transition metals that stabilize new metal frameworks (see below).

3 TERNARY COMPOUNDS

The ternary group of compounds can be divided into three major subgroups (a) alkali and alkaline earth metal chalco- and polychalcogenides, (b) valence-precise metal chalcogenides, and (c) metal-rich chalcogenides.

3.1 Compounds with Alkali and Alkaline Earth Metals

This subclass has seen rapid growth during the past decade. Compounds in this category can be conveniently viewed as pseudo-binary networks of metal chalcogenide anions which are charge-balanced with electropositive alkali or alkaline earth cations. The interactions between the electropositive cations and the $[M_xQ_y]^{n-}$ macro-anions are generally regarded to be electrostatic in nature. These compounds are normally prepared by direct combination reactions of simpler reagents, via the solventothermal method or by the polychalcogenide flux technique. The rationale behind the solventothermal method or alkali polychalcogenide flux technique has been explained in detail earlier.[4,5,50,51] Intercalation and ion-exchange chemistry as well as electrochemistry are also useful in preparing compounds at low temperatures that may not be accessible at higher temperatures.

Topotactic ion-exchange reactions can be used to prepare metastable materials. The use of alkali halides to form other alkali metal ternary chalcogenides has been used widely. The formation of other alkali topotactic derivatives from KBi_3S_5[52,53] is an example of such chemistry (equation 1).

$$KBi_3S_5 + x\text{s-AI} \longrightarrow ABi_3S_5 + KI \quad (1)$$
$$A = \text{alkali metal}$$

The KBi_3S_5 possesses an open framework composed of edge-sharing BiS_6 octahedra to form large parallel tunnels

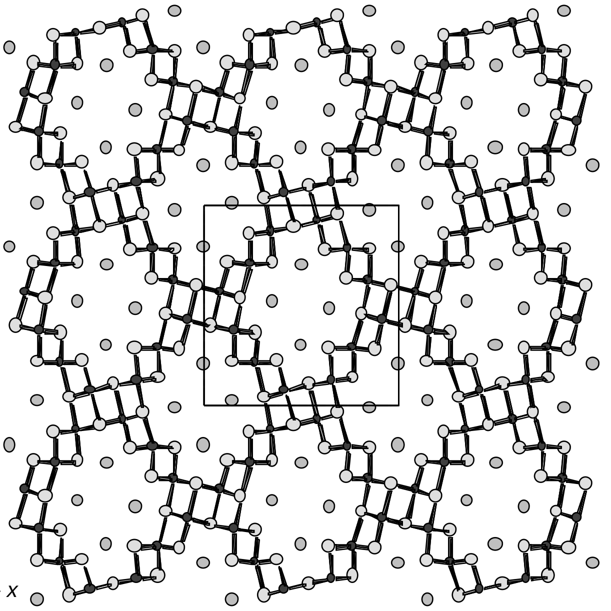

Figure 8 Structure of KBi_3S_5 with its large tunnels viewed down the large tunnels

which are occupied by K^+ ions fractionally distributed over several sites (Figure 8). The S···S distances across the channel range from 9.45–14.02 Å. The K^+ ions in KBi_3S_5 undergo one-dimensional diffusion along the large tunnels. As a result, KBi_3S_5 exhibits facile topotactic ion-exchange with various halides such as LiI, NaI, RbCl, and NH_4I. The resulting isostructural compounds, for example, $LiBi_3S_5$, $NaBi_3S_5$, and so on, cannot be prepared directly. This approach to new compositions though well-known has not been fully exploited. KBi_3S_5 is one of the early examples of a microporous, semiconducting nonoxidic framework. More information on ternary Bi compounds will be presented later.

The compounds $K_{1.10}Zr_2Se_6$, $Rb_{0.86}Zr_2Se_6$ and $Cs_{0.80}Zr_2Se_6$ were obtained by allowing mixtures of A_2Se (A = K, Rb, Cs), Zr and Se to react at 850 °C.[54] They have complex anionic layers $[Zr_2Se_6]^{x-}$ with intercalated alkali cations. The layers are built from $[ZrSe_3]$ trigonal prismatic columns, which are connected side by side by additional inter-column Zr–Se contacts, yielding an eightfold coordination for the Zr atoms. The structure is very similar to that of $ZrSe_3$ (Figure 9). In previous work in the 1970s and 1980s, $ZrSe_3$ was chemically and electrochemically intercalated with Li and Na but the structures of the products remained unknown owing to the absence of single crystals. The $A_xZr_2Se_6$ (A = K, Rb, Cs) compounds are bona-fide intercalation derivatives of $ZrSe_3$ and the fact that they were obtained in a single crystal form is significant. For the first time, the structural details of the intercalated forms are revealed and can now be compared to those of pristine $ZrSe_3$ and understood. For example, the Se–Se bond lengths are significantly altered, indicating a reduction of the Se–Se bond order owing to the electron transfer from the alkali metal.

In the early part of the periodic table, the infinite chain compounds $Cs_4Ti_3Se_{13}$, $Rb_4Ti_3S_{14}$, $Cs_4Ti_3S_{14}$, $Rb_4Hf_3S_{14}$, $Rb_4Zr_3Se_{14}$, $Cs_4Zr_3Se_{14}$, and $Cs_4Hf_3Se_{14}$ tend to be rather stable and are noteworthy.[55]

Interesting ternary chalcogenides have been prepared employing electrochemical methods via anodic dissolution of copper or silver electrodes at low temperatures.[56] For example, the series of $KCu_{7-x}S_4$ ($0 < x < 0.34$) was prepared in an ethylenediamine solution of polysulfide K_2S_x (x = 5, 6) electrolytes. Single crystal structure analysis confirmed the once ambiguous space group of these compounds and showed that the KCu_7S_4 phase which exhibits an unusual insulator-to-metal transition is non-stoichiometric.[57] The structure

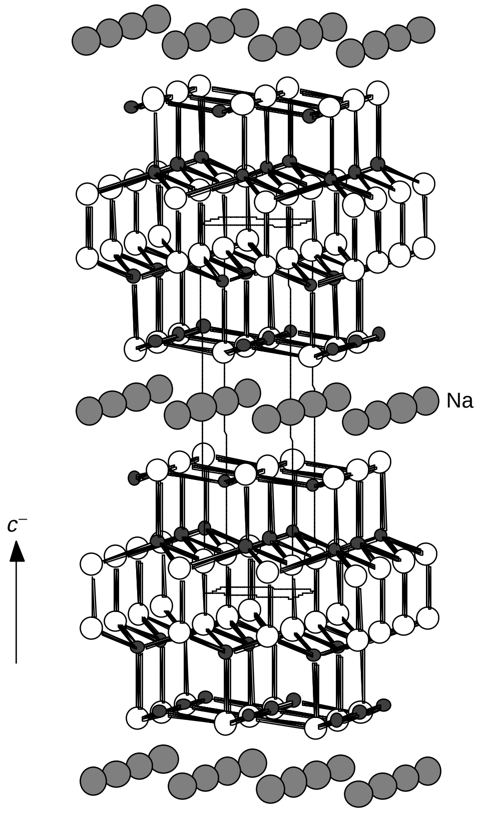

Figure 12 The layered structure of $NaCu_4S_4$. The S atoms are open circles. Cu atoms are small black circles

consists of quasi-one-dimensional Cu_4S_4 columns interlinked by tetrahedral copper chains (Figure 10). There are likely significant Cu–Cu interactions in the structure as several of the Cu–Cu distances are less than 2.8 Å. The $KCu_{7-x}S_4$ series exhibits complicated structure patterns with regard to the ordering of the Cu^+ cation along the tetrahedral chain. The nonstoichiometry and cation ordering are likely responsible for the anomalies observed in transport properties.

Crystals of $Ba_2Ag_8S_7$ were grown in a two-electrode cell from a BaS_3/ethylenediamine solution.[58] In the pseudo-one-dimensional structure columns of ${}^{1}_{\infty}[Ag_8S_7]$ are stacked head-to-tail in a stingray pattern to create voids where the barium atoms reside (Figure 11). The Ag atoms adopt both linear and trigonal planar coordination geometry. The isolation of this compound underscores the utility of the electrochemical method for controlled synthesis of reduced polychalcogenide phases.

$NaCu_4S_4$ was prepared in a polysulfide flux and has a two-dimensional Cu/S framework of trigonal symmetry.[59] Anionic $[Cu_4(S_2)(S)_2]^-$ layers, which contain both S_2^{2-} and S^{2-}, alternate with charge-compensating Na^+ ions. The structure of the $[Cu_4(S_2)(S)_2]^-$ slab is composed of a Cu_2S_2 layer of anti-GaS structure-type sandwiched between two BN-type CuS layers (see Figure 12). The connections are made via Cu–S bonds involving metal atoms from the anti-GaS type layer and sulfur atoms from the slightly puckered BN-type layers. The structure of $NaCu_4S_4$ is akin to that of CuS itself in that in the binary solid the anti-GaS type Cu_2S_2 layers alternate with the BN-type CuS layers forming an infinite stack along the *c*-axis. In $NaCu_4S_4$ every other anti-GaS layer is missing and replaced by a layer of Na atoms. The formal oxidation states of $NaCu_4S_4$ do not balance unless we invoke mixed valency. If all monosulfides and disulfides are considered as 2−, then the charges on the metal become $Na(Cu^{1+})_2(Cu^{2+})(S_2)S_2$. In general a Cu^{2+}/S^{2-} bonding combination is considered thermodynamically favorable and is spontaneously susceptible

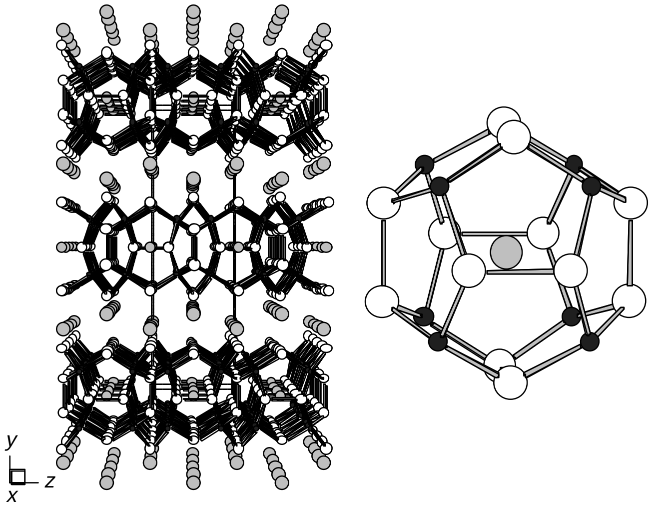

Figure 13 The layered structure of $A_2BaCu_8Te_{10}$. The $[Cu_8Te_{12}]$ pentagonal dodecahedral cage-cluster with Ba atoms inside. The Te atoms are open circles. Cu atoms are small black circles

to internal electron transfer giving Cu^{+}/S^{1-}. The S^{1-} species is considered a radical. Therefore, the metals should be taken as 1+ giving mixed valency at the sulfide side which manifests itself as holes in the sulfur-based valence band. As a result $NaCu_4S_4$ is p-type metallic.

The reactivity of copper in molten alkali polytelluride salts leads to a number of interesting compounds including $K_2Cu_5Te_5$,[60] $K_4Cu_8Te_{11}$,[61] $A_3Cu_8Te_{10}$,[62] $A_2BaCu_8Te_{10}$ (A = Rb, Cs) whose characteristic structural feature is the pentagonal dodecahedral $[Cu_8Te_{12}]$ cluster.[62] $A_3Cu_8Te_{10}$ and $A_2BaCu_8Te_{10}$ are isostructural and contain the same layered Cu/Te framework built from fused $[Cu_8Te_{12}]$ pentagonal dodecahedral cage-clusters (Figure 13). The quaternary phase derives from the ternary one by a substitution of a single A^+ ion for a Ba^{2+} ion. The structure is layered and consists of condensed pentagonal dodecahedral clusters sharing Te–Te edges. Each $Cu_8(Te_2)_6$ dodecahedral cluster endohedrally encapsulates an alkali or Ba^{2+} ion. The $Cu_8(Te_2)_6$ cluster is also the building block of $K_4Cu_8Te_{11}$ (Figure 14). This compound has a Cu/Te framework with large tunnels running parallel to *b*-axis, which are filled with K^+ ions. This framework is assembled from fused and linked $[Cu_8Te_{12}]$ clusters. $A_3Cu_8Te_{10}$ is mixed valence compound and exhibits metallic properties, whereas $K_4Cu_8Te_{11}$ and $A_2BaCu_8Te_{10}$ are narrow band-gap semiconductors.

The $K_2Cu_2Te_5$ forms under solventothermal conditions.[63] It contains a three-dimensional framework with the primary

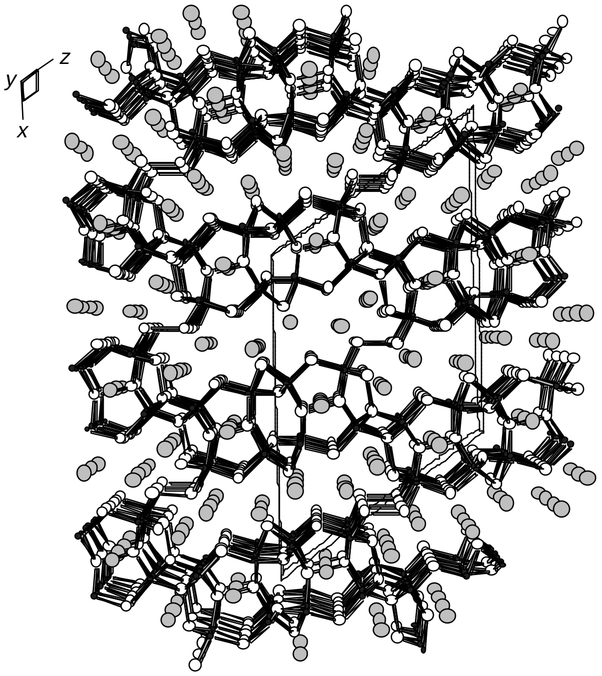

Figure 14 The tunnel framework structure of $K_4Cu_8Te_{11}$. The Te atoms are open circles. Cu atoms are small black circles

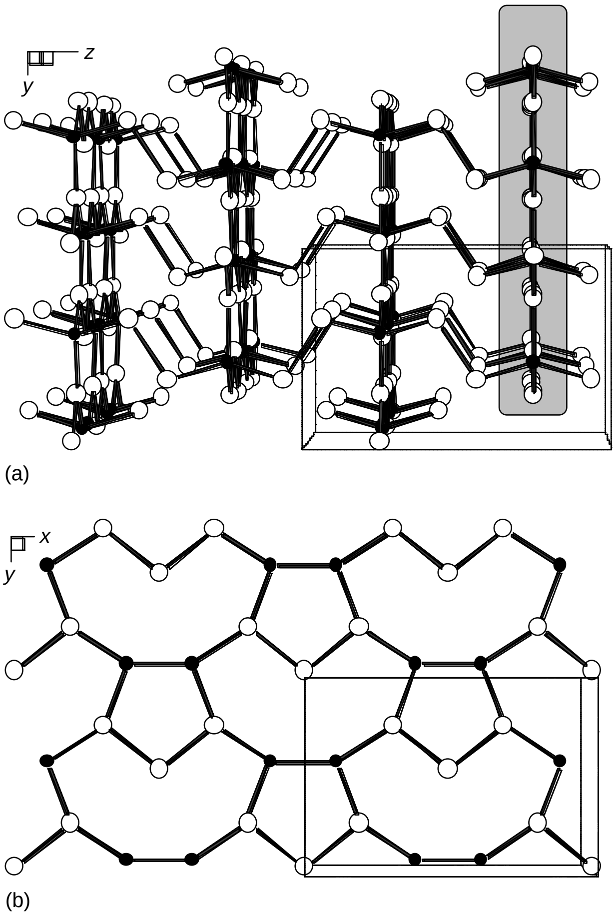

Figure 15 (a) The structure of $K_2Cu_2Te_5$ with the K atoms omitted. (b) The $Cu_2(Te_3)$ layers (indicated in the shaded boxed area in (a)) showing the linking modes of the Te_3^{2-} units. The Te atoms are open circles. Cu atoms are small black circles

building blocks being Te_2^{2-} and Te_3^{2-} fragments linking tetrahedral Cu^+ centers (Figure 15(a)). The framework can be viewed as $Cu_2(Te_3)$ layers that are linked by interlayer Te_2^{2-} units (Figure 15(b)). This generates small open channels that are occupied by the K^+ cations.

Systematic studies on selenoborates containing a B_{12} cluster entity and alkali metal cations led to the new crystalline phases $A_8[B_{12}(BSe_3)_6]$ (A = K, Rb, Cs)[64] and $Rb_4Hg_2[B_{12}(BSe_3)_6]$[65] which consist of a icosahedral B_{12} cluster completely saturated with trigonal-planar BSe_3 units and alkali metal counterions. These B-rich chalcogenoborates were prepared in a solid-state reaction from potassium selenide, amorphous boron, and selenium in evacuated carbon coated silica tubes at a temperature of 850 °C. The structure contains the first example of a B_{12} icosahedron completely saturated with chalcogen ligands (Figure 16). Six trigonal-planar selenoborate entities that function as bidentate ligands complete the B_{12} icosahedron to form a persubstituted closo-dodecaborate ion. The closo-cluster contains $2n + 2$ binding electrons for the B_{12} unit and therefore obeys Wade's rules for cluster compounds.

Other new compounds of boron with extended structures include $Rb_2B_2Se_7$, $Tl_2B_2Se_7$, $Cs_3B_3Se_{10}$, and $Tl_3B_3Se_{10}$, which contain infinite chains,[66] as well as BaB_2Se_6 and $Ba_2B_4Se_{13}$, which contain layers.[67]

From the reaction of Au with alkali metal polysulfide liquids, LiAuS and NaAuS were discovered.[68] Both compounds contain infinite one-dimensional $(AuS)_n{}^{n-}$ chains, featuring alternating sulfide anions and linear coordinated Au centers. In LiAuS, the chains are zigzag and fully extended and they pack in mutually perpendicular sets. In NaAuS, the same chains coil in an unusual fashion so that they become interwoven to form layers reminiscent of 'chicken-wire' (Figure 17). This novel coiling mode allows Au–Au contacts to form, which help to stabilize the structure.

The thioaurates $Rb_4Au_6S_5$ and $Cs_4Au_6S_5$ were prepared by allowing Rb_2S and Cs_2S, respectively, to react with

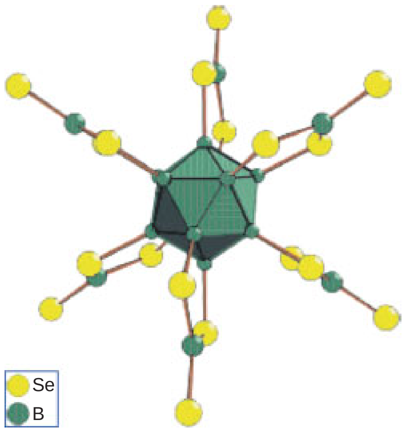

Figure 16 Structure of the $[B_{12}(BSe_3)_6]^{8-}$ ion in $Cs_8[B_{12}(BSe_3)_6]$

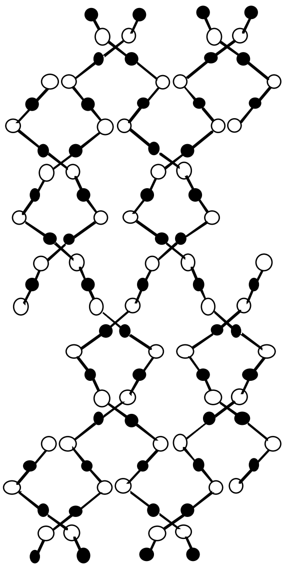

Figure 17 A section of a layer in the structure of NaAuS

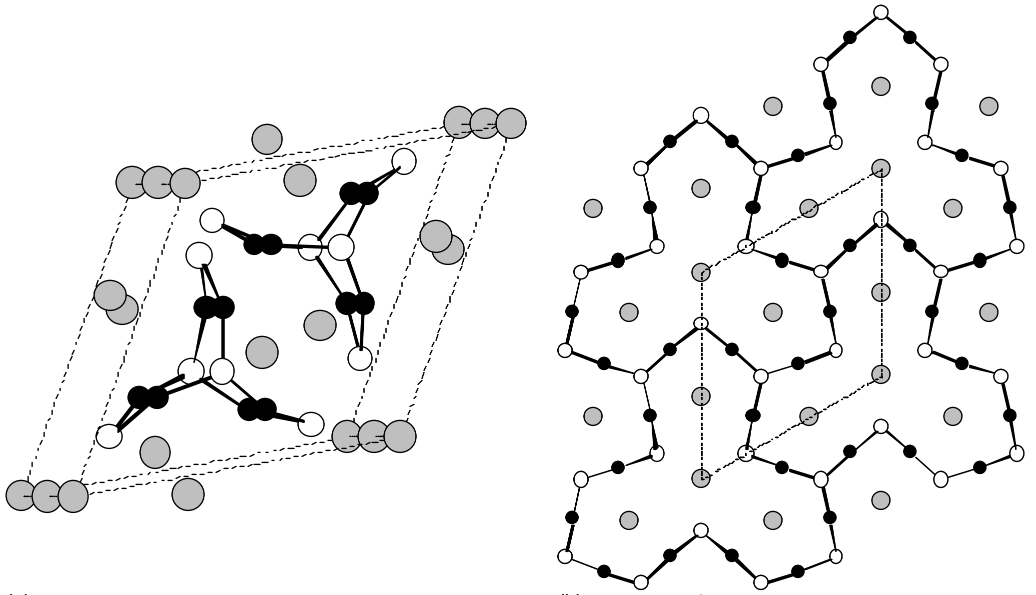
stoichiometric amounts of gold and sulfur at 500 °C.[69] Though both thioaurates are characterized by essentially linear chalcogen coordination of the Au atoms, the topology of the complex anions formed is entirely different (Figure 18). $Rb_4Au_6S_5$ contains discrete anionic clusters $[Au_6S_5]^{4-}$ of trigonal bipyramidal shape with μ_3-S on the apices and μ_2-S forming in the equatorial plane. The Au atoms in the cluster form a trigonal prism with the shortest Au–Au contacts of 3.163 Å. The Cs compound, however, possesses corrugated layers of $[Au_6S_5]^{4-}$, consisting of condensed $Au_{12}S_{12}$ rings with μ_3-S at the nodal positions.

Another interesting gold compound is $Cs_2Au_2Se_3$ which was obtained by allowing a stoichiometric mixture of Cs_2Se, Au, and Se to react at 670 K.[70] The characteristic structural feature of $Cs_2Au_2Se_3$ is the infinite helical anionic chains of $[AuSeAuSe_2]^{2-}$ (Figure 19). Au···Au contacts of 3.200 Å are formed within the chains. Other gold compounds worth mentioning here are $KAuS_5$, $KAuSe_5$, $CsAuSe_3$,[71] Na_5AuSe_{12},[72] and Li_3AuS_2.[73]

A fascinating set of compounds was generated by 'breaking up' the CdS (or CdSe, CdTe) lattice with A_2Q equivalents. The compounds $K_2Cd_2S_3$,[74] $A_2Cd_3Q_4$,[75,76] $Na_6Cd_7S_{10}$,[77] and $A_2Cd_3Te_4$[75,78] possess $[Cd_xQ_y]^{z-}$ networks that are low dimensional compared to that of diamond-like CdQ. The $K_2Cd_2S_3$ framework is assembled from $Cd_4S_6{}^{4-}$ clusters that are arranged in three dimensions to form K^+-filled channels running parallel to the crystallographic c-axis (Figure 20). $K_2Cd_2S_3$ is a semiconductor with a band gap of ~ 2.89 eV. The material photoluminesces at room temperature.

$Na_6Cd_7S_{10}$ has a three-dimensional framework in which Cd^{2+} tetrahedra are arranged to form four different channels running parallel to the crystallographic b-axis. Two types of channels, formed from the stacking of Cd_6S_6 and Cd_8S_8 rings,



(a) (b)

Figure 18 The structure of (a) $Rb_4Au_6S_5$ and (b) $Cs_4Au_6S_5$

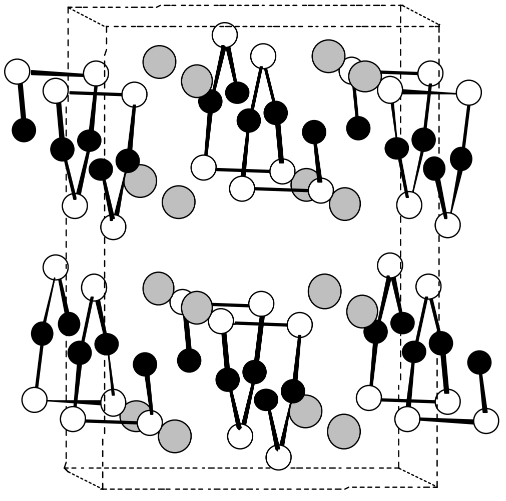


Figure 19 The structure of $Cs_2Au_2Se_3$

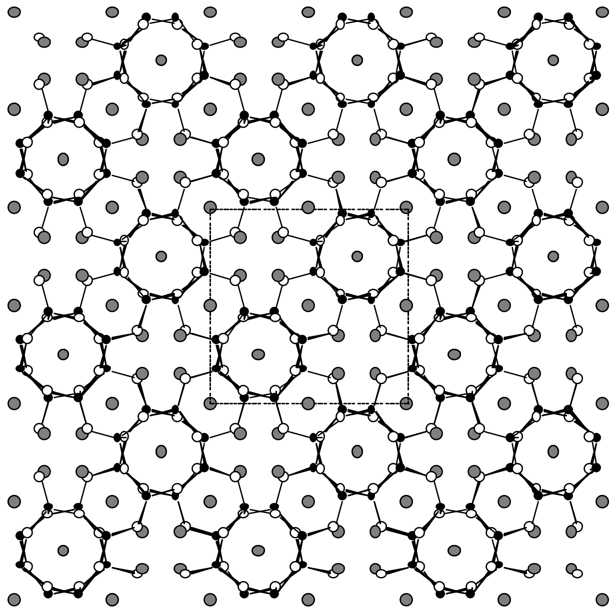

Figure 20 The framework structure of $K_2Cd_2S_3$

respectively, are filled with Na^+ cations, while two smaller channels (stacks of Cd_2S_2 and Cd_3S_3 rings) are devoid of Na^+ (Figure 21). $Na_6Cd_7S_{10}$ is a semiconductor with a room temperature band gap of 2.62 eV.

The isomorphous, layered $A_2Cd_3S_4$, $A_2Cd_3Se_4$,(A = K, Rb) and $K_2Cd_3Te_4$ feature $(Cd_3Q_4)_n{}^{2n-}$ layers separated with A^+ cations. The layers are composed of $(Cd_3Q_4)^{2-}$ units shaped as truncated cubes (Figure 22). The compounds are semiconductors with energy band gaps of 2.75, 2.92, 2.36, 2.37, and 2.26 eV respectively and also display strong photoluminescence. The structure and properties of these compounds have been compared with those of the three-dimensional binary parent phases CdS, CdSe, and CdTe, as well as those of the nanometer-sized CdQ clusters. A conceptual context has been presented to connect all these different ternary and binary compounds as shown in Figure 23:

A layered mercury telluride, $Rb_2Hg_3Te_4$, was discovered during an exploration of hydro(solvo)thermal synthesis of tellurides at temperatures somewhat above the boiling

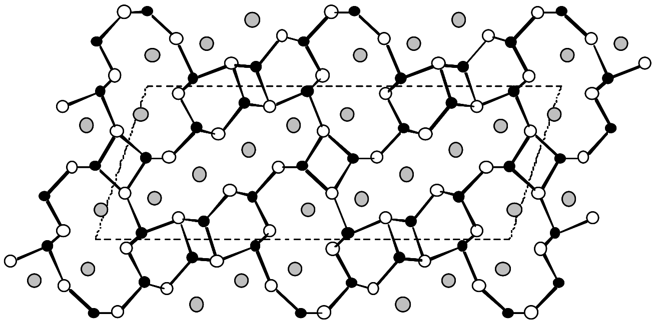

Figure 21 The structure of $Na_6Cd_7S_{10}$

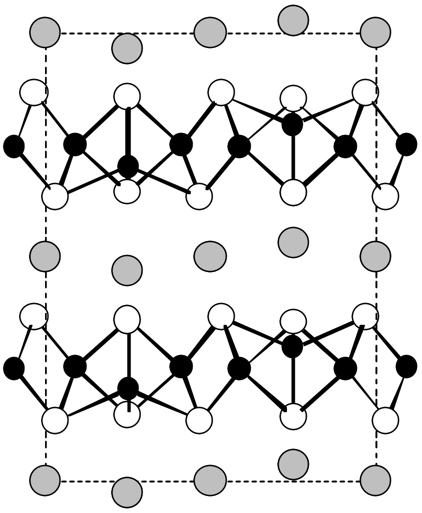

Figure 22 The structure of $A_2Cd_3Q_4$

point of ethylenediamine.[79] The structure contains slabs of $[Hg_3Te_4]^{2-}$ which are separated by the Rb^+ counterions (Figure 24). The interlayer Te–Te distances imply weak van der Waals interactions. The ${}^{2}_{\infty}[Hg_3Te_4{}^{2-}]$ layer is formed by interconnecting six- and eight-membered rings of alternating mercury and tellurium atoms, Hg_3Te_3, and Hg_4Te_4 (Figure 25). $Rb_2Hg_3Te_4$ is the first two-dimensional mercury telluride prepared by an unconventional low-temperature technique.

This stoichiometry ($A_2Hg_3Q_4$, where A = alkali metal, Q = S, Se) has several analogs. These are $K_2Hg_3S_4$,[80] $K_2Hg_3Se_4$,[80] $Cs_2Hg_3Se_4$,[4] and $Na_2Hg_3S_4$.[81] The first three are isostructural and contain chains of ${}^{1}_{\infty}[Hg_3Q_4{}^{2-}]$. They are closely related to that of the Te analog. The sulfide and selenide analogs are more one-dimensional in nature, whereas the bigger tellurium atoms reach to connect the chains forming slabs. $Na_2Hg_3S_4$ features highly corrugated layers based on 16-membered rings formed by alternating mercury and sulfur atoms.

The compounds AIn_3S_5 (A = Rb, Cs)[82] represent new ternary chalcogenides on the quasi binary section A_2S-In_2S_3 with the two binary phases in a molar ratio of 1:3. The indium atoms are coordinated by sulfur atoms with tetrahedral as well as octahedral arrangement, while the coordination numbers

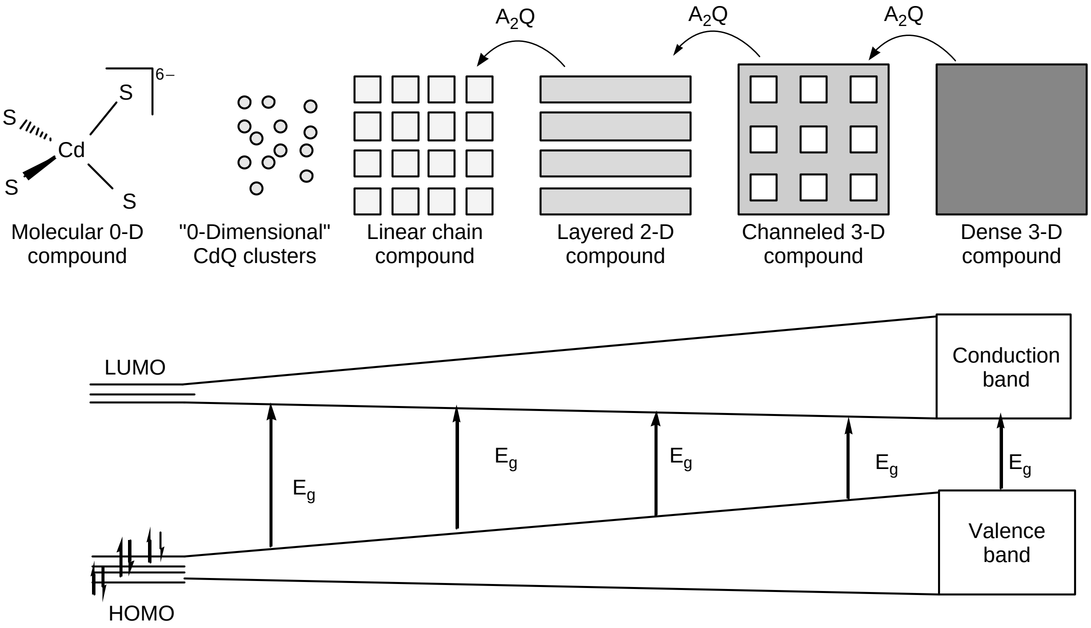

Figure 23 Structural evolution to lower dimensional structures in a A_2Q/MQ systems with increasing A_2Q/MQ ratio. The most dense and highest dimensionality exists in the MQ itself and the least in the compound that forms with the highest possible A_2Q/MQ ratio giving molecular $[MQ_n]^{z-}$ species

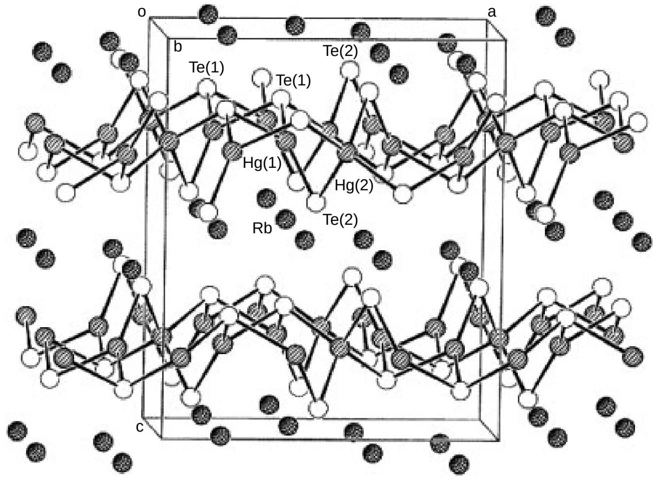

Figure 24 The layered structure of $Rb_2Hg_3Te_4$

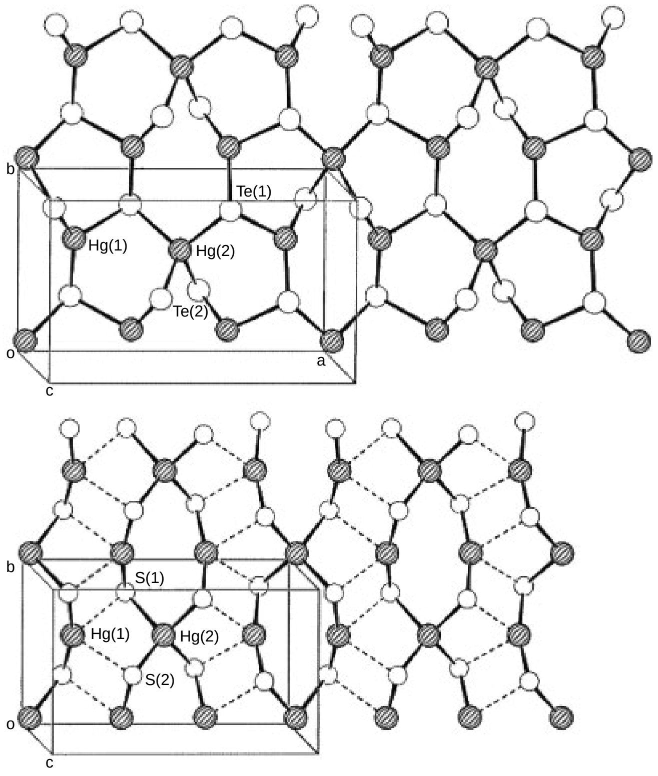

Figure 25 Comparison of the related structures of $Rb_2Hg_3Te_4$ and $K_2Hg_3Se_4$

of the two crystallographically independent A atoms are nine and ten (Figure 26). A special feature of these solids is the slightly distorted joint cubic close packed arrangement of the sulfur and alkali metal atoms.

Thallium is of comparable size and has the same charge as K^+ and Rb^+ and often behaves like an alkali metal.

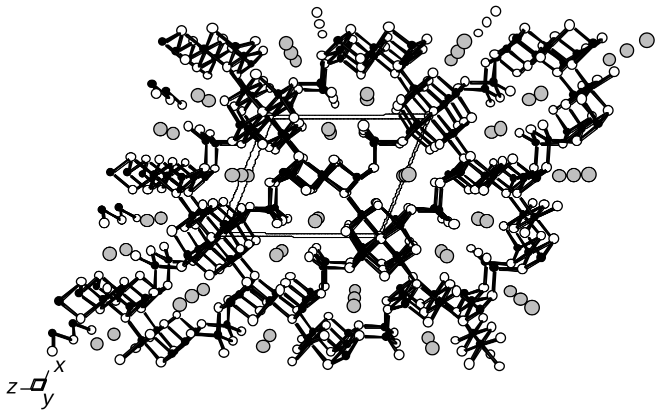

Figure 26 The structure of AIn_3S_5 (A = Rb, Cs)

New phases with indium have been reported such as $TlIn_5S_8$, $TlIn_3S_5$, $TlInS_2$, Tl_3InS_3, $TlIn_5S_6$, and $Tl_3In_5S_8$.[83] All compounds contain Tl^+ ions in a characteristic 'lone pair coordination' of S^{2-} ions. In atoms, however, they occur with the oxidation numbers +2 (formal In dumbbells with covalent In–In bonding) and +3 (with In^{3+} in tetrahedral and octahedral coordination of S^{2-}). Chemical preparation, crystal chemistry, and general properties of the ternary solids have been described.

Crystalline semiconducting sulfide and selenide zeolite analogs were synthesized that possess four-connected, three-dimensional tetrahedral networks built from tetravalent ($M^{4+} = Ge^{4+}$ or Sn^{4+}) and trivalent ($M^{3+} = Ga^{3+}$ or In^{3+}) cations.[84] These followed the reports of ternary In/S open framework materials whose anionic part was charge-balanced with various organic cations.[85] Also hydrothermal conditions give a series of compounds with the framework of $(M_4In_{16}S_{33})^{10-}$ (M = Mn, Co, Zn, Cd) which contain supertetrahedral clusters.[86] These materials are microporous and contain so-called supertetrahedra as their building blocks. These materials exhibit framework topologies with pore sizes ranging from 12 to 24 tetrahedral atoms, high surface area, high framework charge density and ion-exchange capacity, and tunable electronic and optical properties.

An interesting series of three-dimensional sulfides and selenides containing highly mobile alkali metal cations as charge-balancing extra-framework cations has been described.[87] Such crystalline inorganic chalcogenides integrate zeolite-like architecture with high anionic framework polarizability and high concentrations of mobile cations. Such structural features are particularly desirable for the development of fast-ion conductors. These materials demonstrate high ionic conductivity (up to 1.8×10^{-2} S cm^{-1}) at room temperature and moderate to high humidity. To make very open tetrahedral chalcogenido materials, three conditions seem to be required: (i) the building units should be supertetrahedra, (ii) the nets should have large cavities even in their contracted forms, and (iii) the nets should not interpenetrate.

A fascinating ternary compound is $Cs_2Sn_3S_7 \cdot 1/2S_8$, which was synthesized by reacting Sn with a Cs_2S_x flux at temperatures from 400–500 °C.[88] $Cs_2Sn_3S_7$ $1/2S_8$ encapsulates S_8 molecules in much the same way Cs_3Te_{22} encapsulates Te_8 molecules. The structure has an extended framework of $[Sn_3S_7]^{2-}$ anionic layers which possess large open rings (Figure 27). As these layers stack along the c direction, the large open rings are aligned forming channels. Cs^+ cations are located between the layers and S_8 molecules are found to occupy the space within the channels and also interacting with the Cs^+ cations. The $[Sn_3S_7]^{2-}$ layer has been crystallized with a number of other counterions but none of these analogs encapsulates sulfur or other neutral molecules.[89,90] In addition, several selenium analogs are also known.[91]

An interesting example of a compound is Cs_2SnTe_4 prepared by the methanolothermal reaction of Cs_2CO_3 with Sn and Te at 190 °C,[92] The crystal structure contains chain anions $[SnTe_4]^{2-}$ in which individual $SnTe_4$ tetrahedra are linked via Te–Te bonds of length 2.814(3) Å. Weak Te···Te secondary bonds of length 3.631(3)–3.663(3) Å connect neighboring chains into a framework structure. Nine Te atoms from three chain anions participate in the coordination sphere of the cesium cation. Apparently, the highly basic environment created by the presence of $[CO_3]^{2-}$ ions resulted in excess polytelluride ions most likely via a disproportionation reaction of elemental Te.

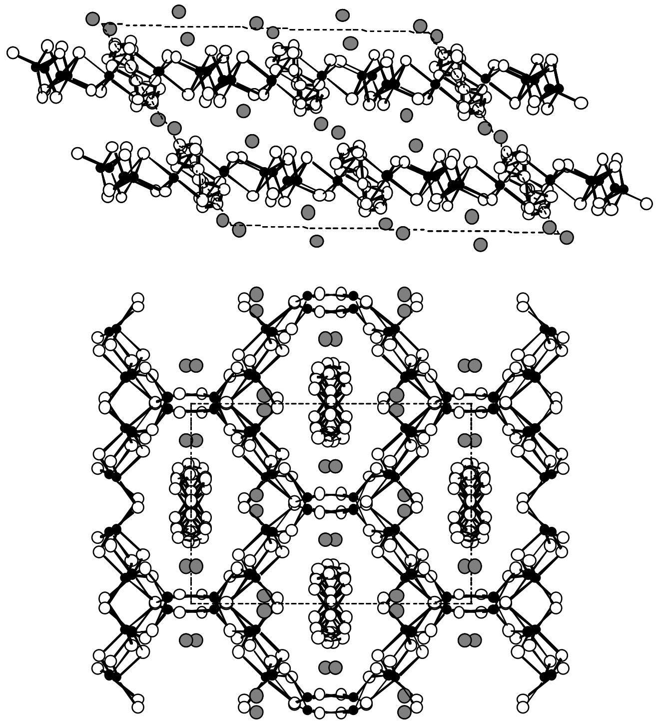

Figure 27 The structure of $Cs_2Sn_3S_7$ $1/2S_8$

Bismuth chalcogenide compounds have been investigated extensively because of their relevance as thermoelectric materials. As a result a large variety of them was discovered and shown to posses a fascinating array of structural arrangements. Some interesting phases are KBi_3S_5, $RbBi_3Se_5$,[93] $KBi_{6.33}S_{10}$,[94] $K_2Bi_8Q_{13}$ ($Q = S$, Se)[95] and $Cs_3Bi_7Se_{12}$.[96] These compounds belong to the general family of compounds $(A_2Q)_n(Bi_2Q_3)_m$ (A = alkali metal; Q = S, Se). Structurally, they can be thought of as an intimate composite of two different structure types interconnected to form a 3D network. They have three-dimensional structures made up of modular fragments that connect to form tunnels filled with K^+ cations.

The $[Bi_{6.33}S_{10}]^-$ framework is made of edge-sharing BiS_6 octahedra in a structure that is very similar to that of the mineral cosalite ($Pb_2Bi_2S_5$) (Figure 28). A key feature of this and other structures of this type is the occurrence of mixed occupancy sites between K and Bi in the structures. The mixed occupancy between nonisoelectronic elements can influence the electrical properties of these materials. These sites tend to be the high coordination sites (coordination number >6). The structure of $K_2Bi_8S_{13}$ is a three-dimensional assembly made up of Bi_2Te_3-, NaCl-, and CdI_2-type infinite rod shaped blocks (Figure 29(a)).

$K_2Bi_8Se_{13}$ comes in two modifications α- and β- in two structure types and represents an example where similar building blocks combine to give compounds with the same stoichiometry but different architecture.[97] α-$K_2Bi_8Se_{13}$ consists of Bi_2Te_3-, CdI_2-, and Sb_2Se_3-type rod fragments. β-$K_2Bi_8Se_{13}$ is isostructural to $K_2Bi_8S_{13}$. Overall, the structure of β-$K_2Bi_8Se_{13}$ is slightly denser, because in the latter 25% of the Bi atoms are found in a trigonal pyramidal geometry, while in the former all Bi atoms are in an octahedral or higher coordination geometry (see Figure 29(b)). Other related compounds include, $K_{2.5}Bi_{8.5}Se_{14}$, $Rb_2Bi_8Se_{13}$,[98] $K_{1+x}M_{4-2x}M'_{7+x}Se_{15}$ (A = K, Rb; M = Pb, Sn; M′ = Bi, Sb),[99] and so on.[100]

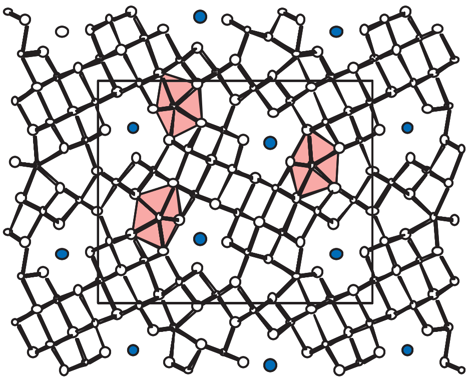

Figure 28 The structure of $KBi_{6.33}S_{10}$ (cosalite type). The shaded areas are the site of extensive K/Bi mixed occupancy

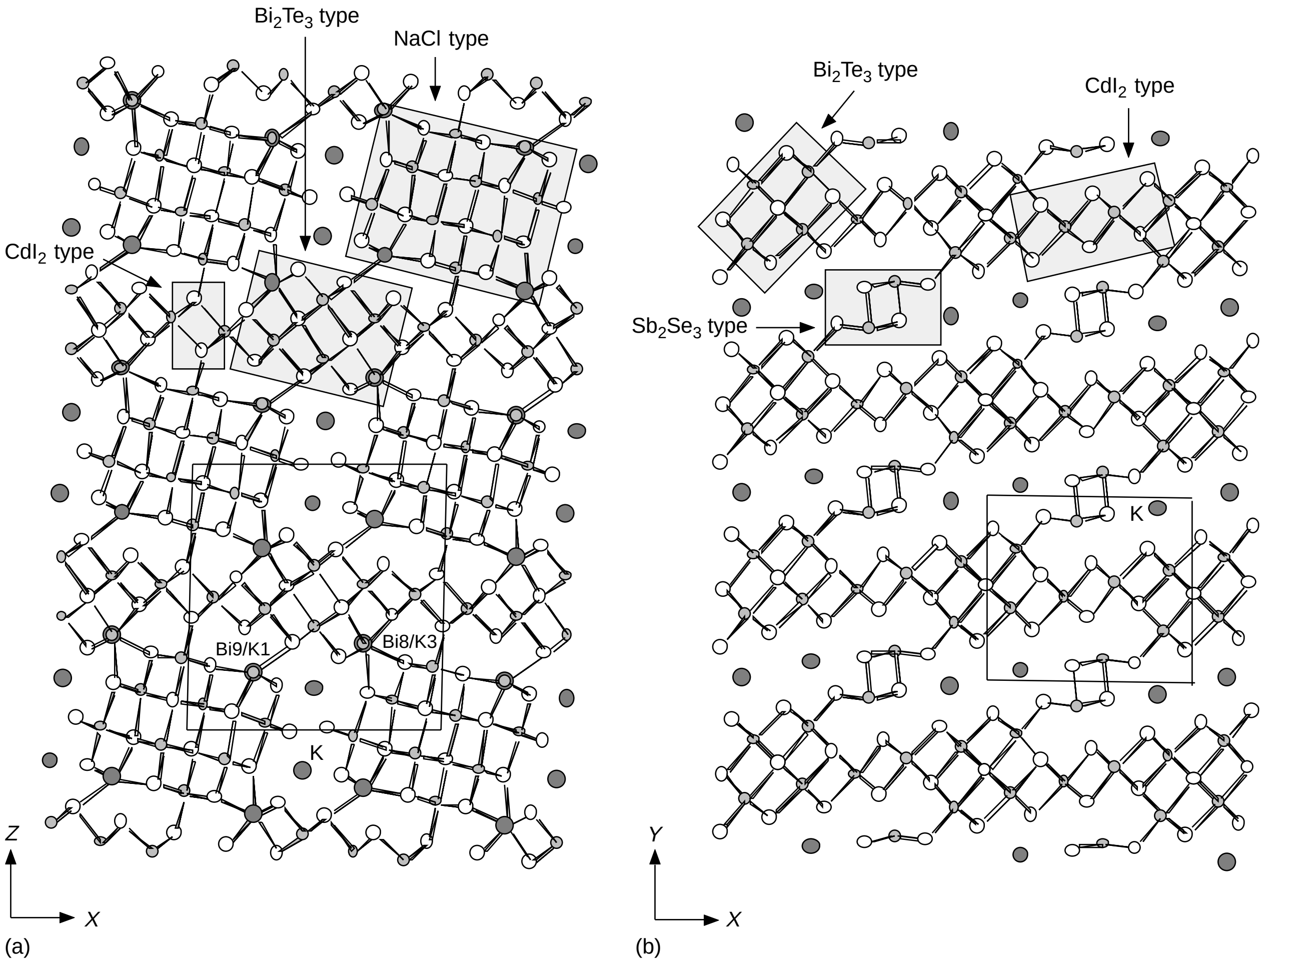

Figure 29 (a) The structure of β-$K_2Bi_8Se_{13}$. (b) The structure of α-$K_2Bi_8Se_{13}$. The modular fragments of the structure are related to the Bi_2Te_3 and CdI_2 structures are shown

$Cs_3Bi_7Se_{12}$ is a fascinating example of a layered compound which undergoes stepwise redox-induced oxidative coupling of its layers to convert to a three-dimensional structure. It is capable of two successive, single crystal to single crystal oxidative transformations. These processes convert the original 2D framework to another 2D′ framework and finally to a 3D framework. Well-defined solid-state processes of this type, besides being spectacular, are of fundamental importance in chemistry because they could provide basic systems for mechanistic studies. $Cs_3Bi_7Se_{12}$ has a layered structure made of Bi_2Te_3-type blocks (Figure 30(a)). A key characteristic of the structure is that adjacent slabs come in close, nonbonding contact by rows of Se(4) atoms. $Cs_3Bi_7Se_{12}$ can be oxidized topotactically to give $Cs_2Bi_7Se_{12}$ (Figure 30(b)). Remarkably, $Cs_2Bi_7Se_{12}$ also oxidizes topotactically to give $CsBi_7Se_{12}$ (Figure 30(c)). The structure has essentially the same $[Bi_7Se_{12}]^{3-}$ framework only now the original layers are all linked with a new set of Se(4)-Se(4) bonds forming a truly 3D framework. The $Se_2{}^{2-}$ groups act as the pillars between the original layers. $CsBi_7Se_{12}$ contains only 1/3 of the original Cs atoms present in Cs_3Bi_7 Se_{12} and because of all the void space now created they show a rather diffuse character (i.e. high temperature factors).

A rather unusual compound is $BaBiTe_3$, which is in fact a polytelluride (i.e. contains Te−Te bonds).[101] Its structure is layered with $[BiTe_3]^{2-}$ slabs alternating with Ba cations (Figure 31). The presence of Te–Te bonds form zigzag Te chains arranged in ribbons. The flat Te ribbons alternate between NaCl-type Bi–Te blocks.

Finally, the layered anisotropic phase $CsBi_4Te_6$ has been of interest because of its enhanced thermoelectric properties. Its structure is composed of anionic $[Bi_4Te_6]$ layers alternating with layers of Cs^+ ions (see Figure 32).[102–104] The average oxidation state of Bi is less than three with some of the Bi atoms forming Bi–Bi bonds. The presence of such bonds is very unusual in bismuth chalcogenide chemistry and it is not clear at the moment whether they play a role in the enhanced thermoelectric properties of the material. The Bi coordination geometry is octahedral. This material has strong anisotropic electrical transport and thermal transport properties.

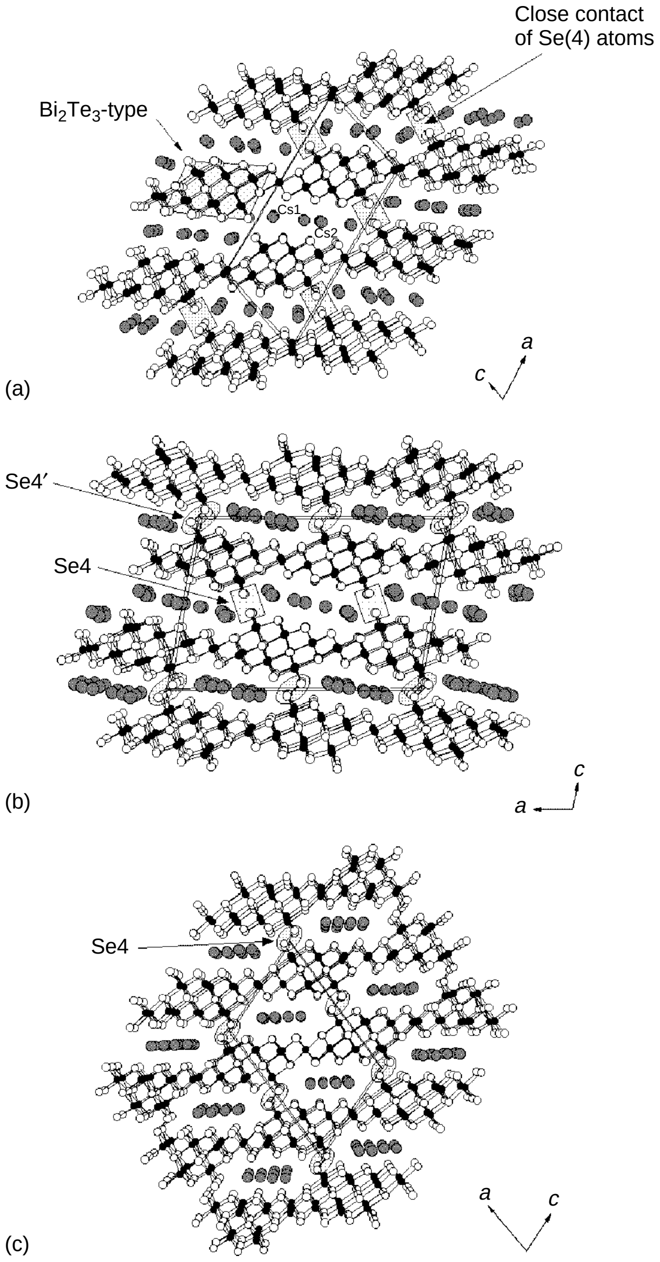

Figure 30 Projection down the b-axis of the structure of (a) $Cs_3Bi_7Se_{12}$, (b) $Cs_2Bi_7Se_{12}$, (c) $CsBi_7Se_{12}$. The square-like shaded areas indicate the Se(4)-Se(4) contacts while the oval ones the Se(4)′-Se(4)′ bonds in $Cs_2Bi_7Se_{12}$ and the Se(4)-Se(4) bonds in $CsBi_7Se_{12}$

A large number of ternary systems have been prepared via solventothermal techniques. Hydrothermal and in general solventothermal synthesis has played a major role in expanding the scope of solid-state chemistry of a large number of compound classes including the chalcogenides. Some of the most interesting structural motifs and compositions in chalcogenides have formed under solventothermal conditions. Solventothermal synthesis involves reactions in a closed container with solvent added and the temperature taken above the boiling point of the solvent. The temperature need not be near the supercritical point. Even at a few degrees above boiling, the solubility, mobility, and reactivity of species changes substantially and promotes reactions that may not otherwise proceed. This leads to stabilization of a variety of novel materials. Under these relatively mild conditions intact molecular building blocks such as rings and chains can self-organize to a fascinating variety of chalcogeno-anions, whose dimensionality can be influenced by the choice of suitable structure-directing agents such as alkali metal or organic cations.

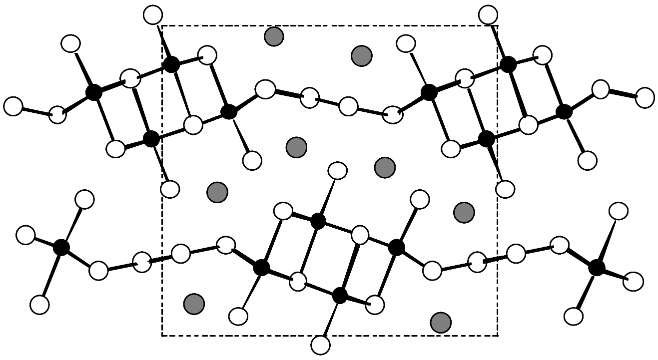

Figure 31 The layered structure of $BaBiTe_3$. Te atoms are in open circles

A novel layered Rb–Pd polyselenide has been synthesized by methanothermal reaction of Pd^{2+} with $Se_x{}^{2-}$ (from $Se^{2-}+$ Se) in the presence of Rb_2CO_3. $Rb_2[Pd(Se_4)_2]\cdot Se_8$ reveals a unique structure with infinite $[Pd(Se_4)_2]^{2-}$ sheet polyanions acting as a host for neutral Se_8 rings. The black shiny rectangular crystals of $Rb_2[Pd(Se_4)_2]\cdot Se_8$ are insoluble in H_2O and common organic solvents. The $[Pd(Se_4)_2]^{2-}$ sheet anion contains Pd^{2+} ions with a distorted square planar coordination geometry to four terminal Se atoms of $Se_4{}^{2-}$ chains. The cocrystallized neutral Se_8 rings have a crown-like conformation as known from the elemental Se_8 forms (Figure 33). Through coordination to Rb^+ ions, they build $[Rb(Se_8)^+]_n$ 'cationic chains' running in the c direction.

3.2 Valence-precise Metal Chalcogenides. Ternary Phases M/M/Q

This group of ternary chalcogenides contains metals other than from group 1 and 2. It is also a large group and only a small fraction will be highlighted. A fascinating set of compounds worth mentioning here is the family $Bi_2M_4Q_8$ (M = Al, Ga; Q = S, Se).[105] Although this set might also belong to the metal-rich chalcogenide section we chose to place it here for convenience. They possess a tetragonal structure shown in Figure 34 with the rare Bi–Bi dimeric unit (Bi–Bi 3.142 Å) which was also found in $CsBi_4Te_6$ described above. The structure is tetragonal and related to the TlSe type

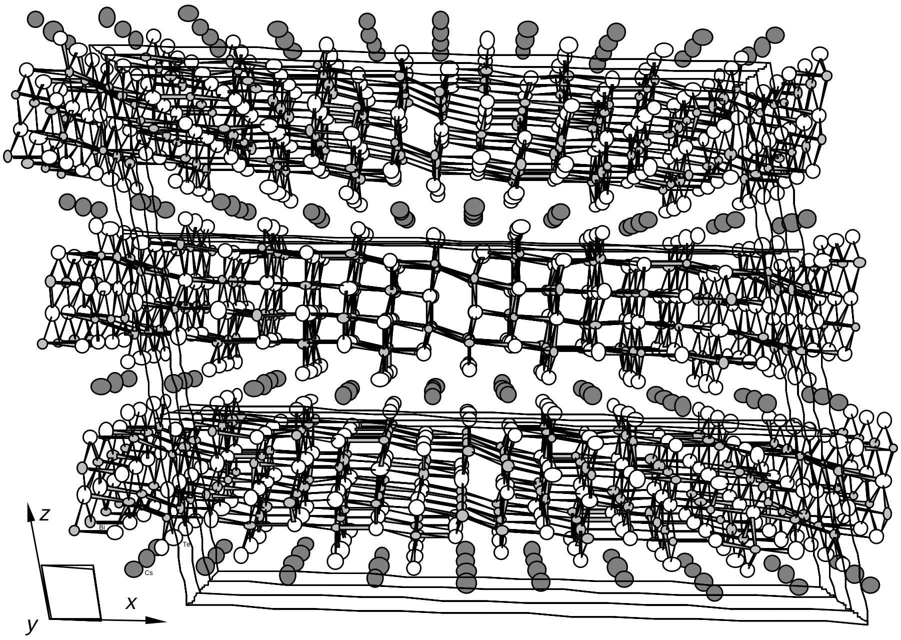

Figure 32 The layered structure of $CsBi_4Te_6$

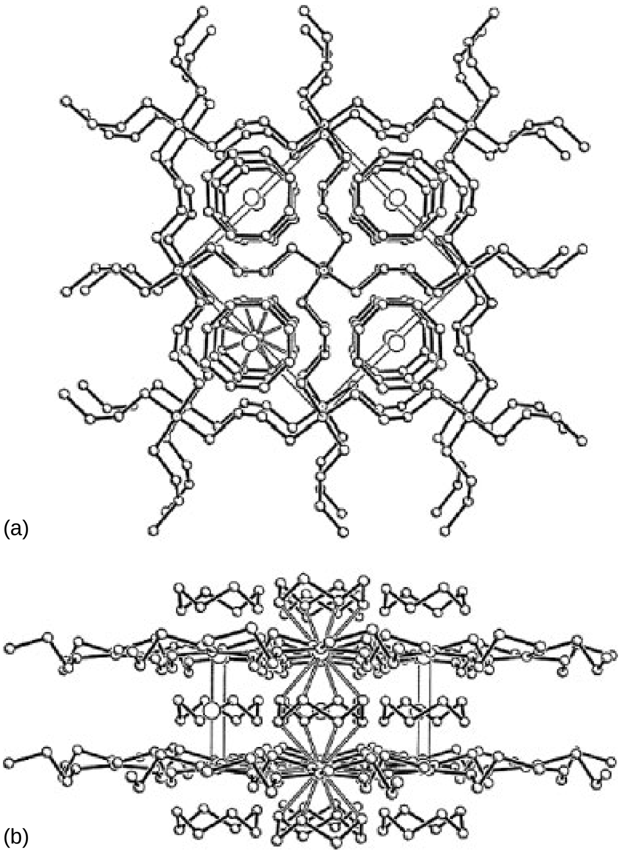

Figure 33 The structure of $Rb_2[Pd(Se_4)_2]{\cdot}Se_8$ viewed down the (a) [001] and (b) [010] directions. The $[Rb(Se_8)^+]_n$ chains pass through large rectangular rings of the 2D $[Pd(Se_4)_2]^{2-}$ sheet and run along the *c*-axis

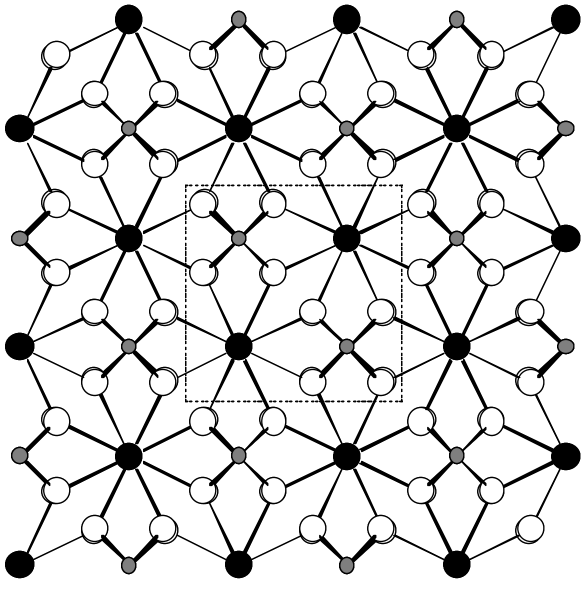

Figure 34 The tetragonal structure of $Bi_2M_4Q_8$ (M = Al, Ga; Q = S, Se) viewed down the *c*-axis

with the Bi–Bi dimers running parallel to the *c*-axis inside infinite columns made of stacked square antiprisms (sap) of chalcogen atoms. The group 13 atoms Al (or Ga) occupy tetrahedral sites in the structure. The relationship to TlSe is as follows: TlSe = $Tl^{sap}{}_4Tl^{tet}{}_4Se_8$, (two type of thallium atoms are square antiprismatic and tetrahedral). In this formulation the $Bi_2M_4Q_8$ can be written as $(Bi_{2\square 2})^{sap}Al^{tet}{}_4Q_8$. These compounds are semiconductors with an electrical conductivity varying depending primarily on Q.

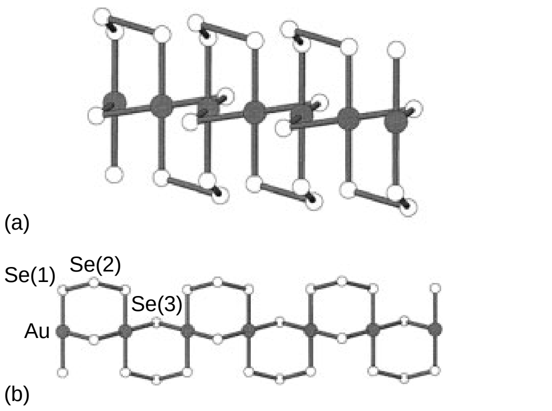

Figure 36 Two side views of the hypothetical $[Au(Se_3)Se]_n{}^{n-}$ chain running parallel to the *b*-axis with atom labeling scheme

An interesting ternary polychalcogenide phase is $AuCuSe_4$, which possesses a unique three-dimensional covalent framework (see Figure 35).[106] As revealed by the local metal coordination, this is formally a Au^{3+}/Cu^{+} compound with $Se_3{}^{2-}$ and Se^{2-} fragments. The structure can be regarded as made from one-dimensional $[Au(Se_3)Se]_n{}^{n-}$ chains linked by Cu^{+} atoms. Two views of the $[Au(Se_3)Se]_n{}^{n-}$ chain are shown in Figure 36. The structure is clearly anisotropic. Two views of the $[Au(Se_3)Se]_n{}^{n-}$ chain are shown in Figure 36. In this chain, the $Se_3{}^{2-}$ ligands bridge the Au atoms via their terminal Se(1), which spans the Au–Au distance of 3.7234(7) Å. The square planar coordination of Au atoms is completed by the bridging, Se(3). The chains are centrosymmetric and run parallel to the crystallographic *b*-axis.

$AuCrS_2$ was prepared from a mixture of Au, Cr, and S powder.[107] $AuCrS_2$ is a layered compound composed of CdI_2 -type layers and Au ions which reside in the interlayer regions. The Au atoms are linearly coordinated with two sulfide atoms, one from each $[CrS_2]^{1-}$ layer, thus acting as linking points between layers (Figure 37). This motif is very similar to that found in the $CuGaO_2$ structure-type and a related structure was determined for Ag_xMoS_2.[108] The magnetic susceptibility of $AuCrS_2$ follows the Curie–Weiss law above 150 K, and it becomes antiferromagnetic with Neel temperature at 55 K.

The $MREQ_2$ phases include $CuRES_2$, (RE = La, Nd, Sm, Gd, Dy, Ho, Yb, Lu, Y).[109–112] The structure of $CuLaS_2$ is made of a three-dimensional framework of $[LaS_2]^{-}$ with Cu^{+} ions occupying tetrahedral sites in it (Figure 38). Alternatively, it can be described as comprising of layers of $[CuS_2]^{3-}$ linked by La^{3+} atoms. The coordination environment of the RE atoms is monocapped trigonal prismatic. These compounds are p-type semiconductors with wide band gaps. The $YCuS_2$ also forms but its structure is different. It too is made of a three-dimensional framework of $[YS_2]^{-}$ with Cu^{+} ions occupying tetrahedral sites in it. The CuS_4 tetrahedra form chains along the *c*-axis and these chains fill the tunnels in the $[YS_2]^{-}$ framework. The coordination environment of the Y atoms is octahedral (Figure 39).

When the coinage metal is silver the compounds $REAgS_2$ (RE = Sm, Gd-Yb, Y),[113] $REAgSe_2$ (all RE except Pm and Eu), and $REAgTe_2$ (RE = Gd, Dy-Er, Y) have been described. $ErAgSe_2$ and $REAgS_2$ (RE = Gd, Ho, Yb)[114] have been studied by single crystal X-ray diffraction methods. $ErAgSe_2$ has a low and a high temperature form. The high temperature form adopts the NaCl structure with Ag and Er randomly distributed over the cation sites, whereas the low-temperature version has an orthorhombic distorted NaCl structure with ordered Er and Ag atoms (Figure 40). Both Ag and Er atoms have octahedral coordination. The structure of the $REAgS_2$ (RE = Gd, Ho) is a superstructure of the RES (NaCl) type with one-half of the RE cations replaced with Ag. The Ag atom is in a severely distorted octahedral environment with two short, three intermediate, and one long Ag–S bond.

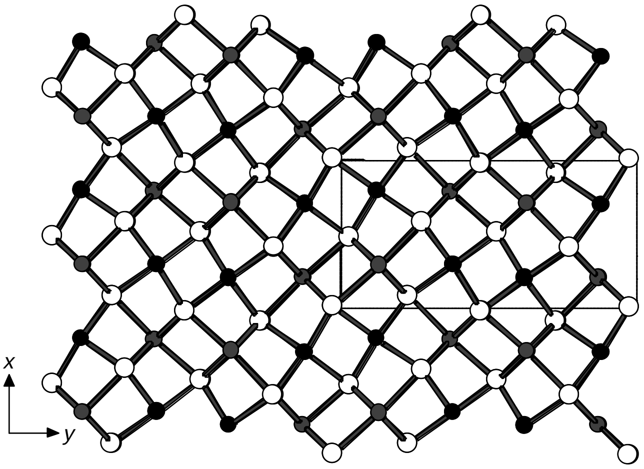

Figure 40 View of the structure of $ErAgSe_2$ along the *c*-axis

The combination of the soft transition metals such as Cu with hard lanthanide elements can give rise to interesting compounds as, for example, $CuSm_3Se_6$. The crystal structure of $CuSm_3Se_4[Se_2]$ contains both mono- (Se^{2-}) and diselenide anions ($[Se_2]^{2-}$) (Figure 41).[115] The latter are surrounded by six Sm^{3+} cations. If the diselenide units serve as one fragment, they form irregular $\{[Se_2]Sm_6\}^{16+}$ octahedra, which produce chains running along [010]. Together with $[SeSm_4]^{10+}$ tetrahedra, they build up a two-dimensional layer parallel to (001) according to $^2_\infty\{(Sm_3Se[Se_2])^{5+}\}$. Vertex-, edge-, and face-shared $[CuSe_4]^{7-}$ tetrahedra compose chains running along [010] as well. A three-dimensional network is created by stacking $\{(Sm_3Se[Se_2])^{5+}\}$ layers and $\{(CuSe_3)^{5-}\}$ chains parallel to (001) (Figure 42).

3.3 Metal-rich Chalcogenides

Similar to the metal-rich binary chalcogenides ternary metal-rich systems are also of growing interest. It has been demonstrated that strong early-late transition metal intermetallic bonding in combination with late transition metals can lead to an expanding class of compounds that includes members such as Hf_8MTe_6 (M = Mn, Fe, Co, Ni, Ru),[116] Hf_5MTe_3 (M = Fe, Co),[117] Nb_4MTe_4 (M = Al, Si, Cr–Ni),[118] Zr_6MTe_2 (M = Mn, Fe, Co, Ni, Ru, Pt),[119] Dy_6MTe_2 (M = Fe, Co, Ni),[120] $Sc_{14}M_3Te_8$ (M = Ru, Os),[121] $Ta_{1.09}Fe_{2.39}Te_4$,[122] $Ta_2M_3Q_5$ (M = Ni, Pd; Q = Se, Te)[123–125] and $Er_7Ni_2Te_2$.[126] Many of these compounds are known to crystallize in the ordered variant of the Fe_2P structure-type known as the Zr_6CoAl_2 type.[127] Here, the unit cell of Fe_2P

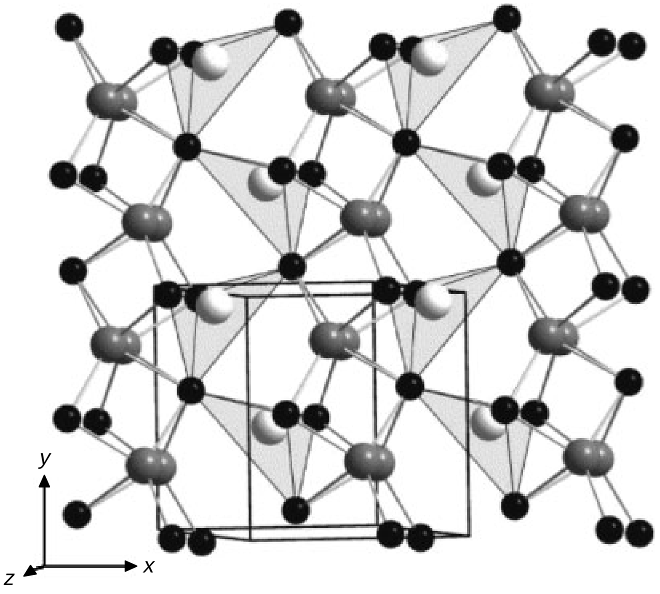

Figure 41 The structure of $CuSm_3Se_6$. Sm^{3+}: black, Se^{2-}: white, $[Se_2]^{2-}$: gray; $\{[Se_2]Sm_6\}^{16+}$ octahedra are marked by bonds, whereas the $[SeSm_4]^{10+}$ tetrahedra appear as closed polyhedra

is tripled, with the early transition metal on the iron positions and the late transition metal and main group element ordered between the two independent phosphorus sites.

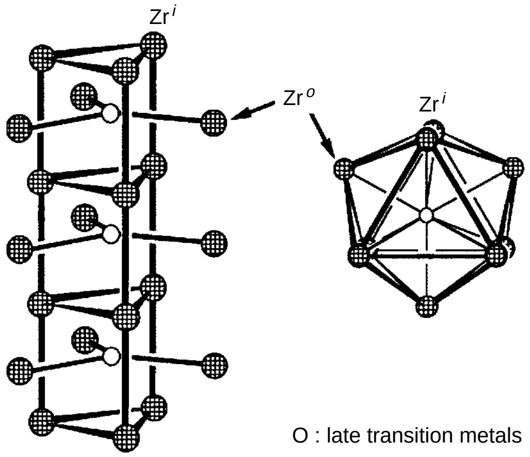

Figure 43 The infinite trigonal prismatic column found in metal-rich chalcogenides with the Zr_6CoAl_2-structure type

A structural motif in the chemistry of more metal-rich compounds is the M-centered tricapped trigonal prismatic column (M-centered tetrakaidecahedron) shown in Figure 43. In this structural building block, late transition metals (M) are surrounded by nine early transition metals (Nb, Ta, Hf) that serve as vertices of the surrounding tetrakaidecahedron. Such tricapped trigonal prisms are observed in Hf_8MTe_6 (M = Fe, Co, Ni) and Hf_5MTe_3 (M = Fe, Co, Ni). Similarly, chains of condensed, M-centered square antiprisms are found in Ta_4MTe_4 and Nb_4MTe_4 (M = Al, Si, Cr–Ni). As with the metal-rich binaries bonding in these extended metal-linked networks is often discussed with particular emphasis on localized bonding descriptions for metal–metal bonds. Such descriptions give a reasonable understanding of otherwise anomalous properties and help unify the boundary between ''metallic'' and ''covalent'' bonding concepts.

The Sc_6MTe_2 and Zr_6MTe_2 (M = Mn, Fe, Co, Ni) belong to the Zr_6CoAl_2-structure type (Figure 44). The late transition metals Mn–Ni center the tricapped trigonal prisms of Zr that stack and share faces along the *c*-axis to form linear chains. The tricapped trigonal prismatic chains are interconnected via Zr–Zr bonds. The condensation of Zr_9Fe polyhedra is achieved by sharing of triangular Zr_3 faces.

Interestingly, the smaller sized sulfide and selenide, analogs of the Zr_6MQ_2 composition have different structures than the telluride one (Figure 45). The larger Te atoms naturally adopt a higher coordination number (nine-coordinate in this compound), and the wide open channels in the Zr_6FeTe_2 structure are the result. In $Zr_6Fe_{1-x}Q_{2+x}$, the structure rearranges to offer smaller seven- and eight-coordinate chalcogen sites, while retaining characteristic chains. In accordance with the closer Fe–Q size match for Q = S, Se is the fact that Zr_6FeTe_2 is stoichiometric whereas the $Zr_6Fe_{1-x}Q_{2+x}$ phases exhibit noticeable phase width. Unlike the regular Zr tetrakaidecahedra in Zr_6FeTe_2, those in both $Zr_6Fe_{0.6}Se_{2.4}$ and $Zr_6Fe_{0.57}S_{2.43}$ are appreciably distorted.

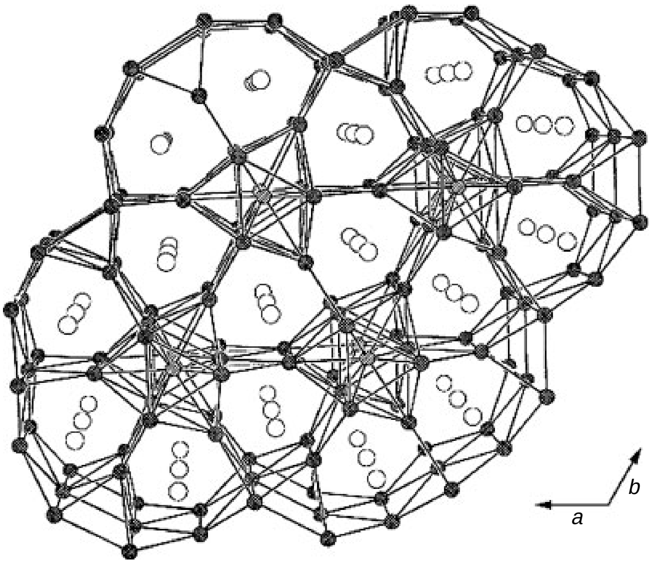

Figure 44 Approximate (001) projection of the Zr_6FeTe_2 structures. The zirconium, iron, and tellurium atoms are shown as cross-hatched, hatched, and open circles, respectively. Bonds shown indicate the Zr–Zr and Zr–Fe contacts

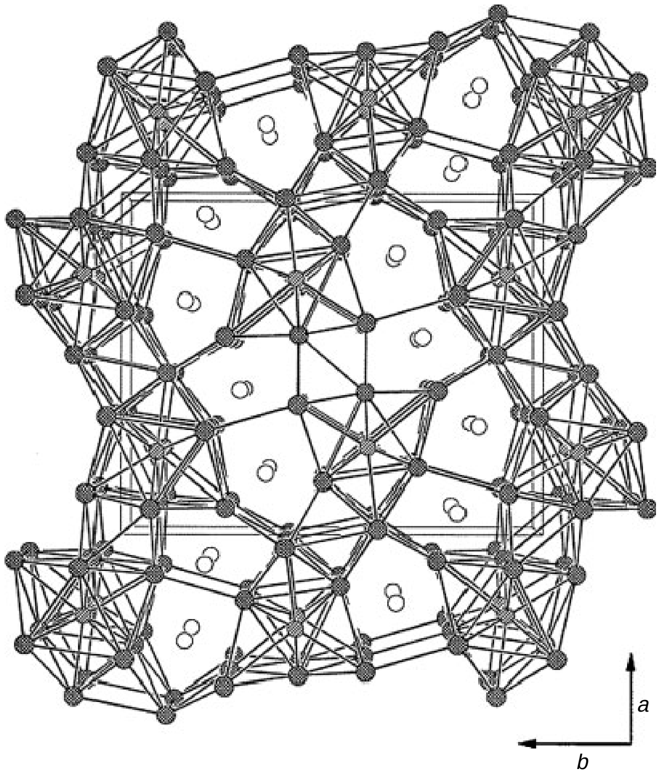

Figure 45 Projection of the $Zr_6Fe_{1-x}Q_{2+x}$ (Q = S, Se) structures down the [001] direction. Zirconium, iron, and chalcogen atoms are shown as cross-hatched, hatched, and open circles, respectively. Bonds shown indicate the Zr–Zr and Zr–Fe contacts

The compounds Sc_6AgTe_2, $Sc_6Cu_{0.80}Te_{2.20}$ and Sc_6CdTe_2, have similar stoichiometry to those described above but possess a different structural motif,[128] that is, isotypic with Sc_6PdTe_2. The structure can be viewed as heterometal sheets lying parallel to the *b*-*c* planes that are separated by isolated tellurium atoms. These sheets can also be viewed as a polymerization of two different types of metal chains in Sc_2Te (blades and zigzag chains) by heterometal (M) replacements of some intervening tellurium atoms, The new Sc_6CuTe_2 and Sc_6AgTe_2 are isostructural with Sc_6PdTe_2. The Sc_6AgTe_2 structure viewed along the short *b*-axis is given in Figure 46. The structure can be described as the result of a polymerization of two kinds of scandium metal chains, which were formerly described in Sc_2Te (see above) as separate double octahedral chains or blades (blue) and zigzag chains (black), via displacement of the Te1 atom by a strongly bonding heterometal Ag, and so on. The resulting condensed heterometal sheets are separated by isolated Te atoms (red) along the *a*-axis.

$Er_7Ni_2Te_2$ is the most metal-rich of the ternary rare earth chalcogenides. The structure is shown in Figure 47. The basic structural unit is a distorted, Ni-centered, tricapped trigonal prism of Er that is fused with similar prisms by sharing the Er_3 triangular bases to form an infinite $^1_\infty[(Er_3Er_{3/2}Er_{3/2})Ni]$ chain that propagates along the *b*-axis. These infinite chains are condensed to form corrugated layers across the *bc* plane by sharing Er zigzag chains, which are composed of capping

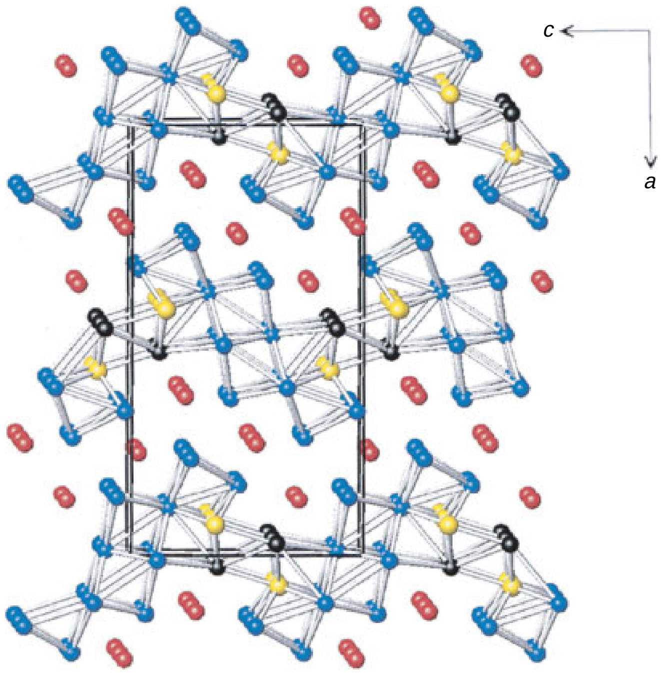

Figure 46 Unit cell of Sc_6AgTe_2. The blue atoms are Sc in the blade unit, the dark atoms are Sc4 that form the zigzag chains, the yellow atoms are silver, and red atoms are tellurium. The structure is infinite along the view direction

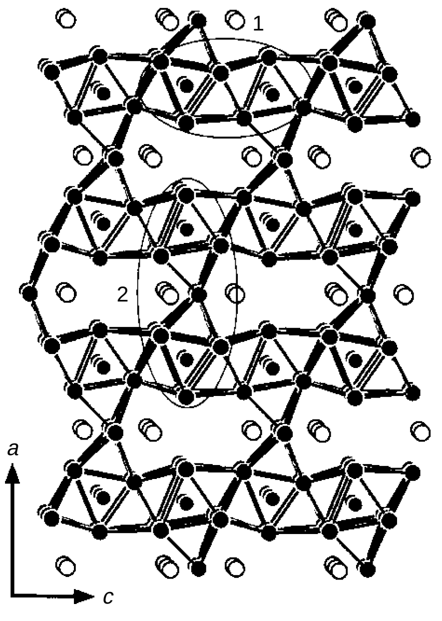

Figure 47 The $Er_7Ni_2Te_2$ structure. Er and Ni atoms are shown as dark circles with and without bonds, respectively. Te atoms are open circles. Er–Te and Er–Ni bonds are not shown for clarity. Circled regions 1 and 2 are depicted below

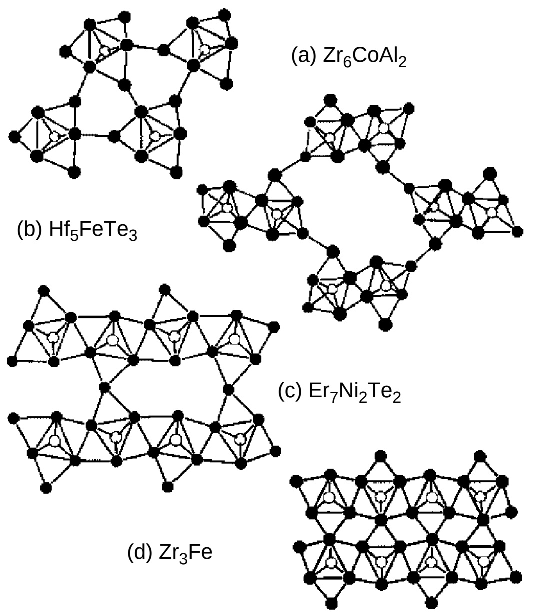

Figure 48 Arrangements of trigonal prismatic building blocks into (a) single chains in the Zr_6CoAl_2 structure, (b) double chains in the Hf_5FeTe_3 structure, (c) layers in the $Er_7Ni_2Te_2$ structure, and (d) a 3-D network in the Zr_3Fe structure. Early transition metals are shown as larger circles, and late transition metals are smaller. Some metal–metal bonds are omitted for clarity

Er atoms on one TTP and inner Er on the adjacent TTP (see region 1 in Figure 47). Finally, vertex condensation forms links between individual layers that result in the overall structure (see region 2 in Figure 47). Tellurium atoms reside between the metal–metal bonded layers, on *bc*-planes.

There is a structural relationship between $Er_7Ni_2Te_2$ and three other structures: Zr_6CoAl_2-type (e.g. Zr_6MTe_2, Sc_6MTe_2, Gd_6MTe_2), Hf_5FeTe_3, and Zr_3Fe. All can be constructed using centered transition metal trigonal prisms as fundamental building blocks, but with different condensation schemes (Figure 48). In the Zr_6CoAl_2-type structure, bonding between the capping and apical atoms of adjacent trigonal prisms interconnects single trigonal prismatic columns. In Hf_5FeTe_3, double chains are formed by edge condensation of single chains, and the double chains are then stitched together into a 3D network by forming longer bonds between the capping atoms not involved in condensation. Formation of condensed intermetallic layers becomes characteristic in the $Er_7Ni_2Te_2$ structure. Successive layers are shifted relative to one another along the *c* direction and are linked together by sharing capping atoms such that Te atoms are accommodated at two chemically inequivalent sites between the layers. A similar but more symmetrical layer architecture exists in Zr_3Fe, which in turn is a hexagonal-close-packing example in metals. Adjacent layers in the Zr_3Fe structure stack vertically, sharing one Zr atom in every trigonal prismatic unit. This 3D network is even more condensed owing to the formation of extensive Zr–Zr bonds between the layers (Figure 48(d)).

The $Sc_{14}M_3Te_8$ (M = Ru, Os) phases represent yet another structure-type among metal-rich ternary chalcogenides. In this motif, scandium atoms define infinite chains of alternate trans-face-sharing cubes and pairs of square antiprisms in which each polyhedron is also centered by an M atom (M = Ru, Os). These chains are further linked into a three-dimensional (3D) structure by $Sc(Te_2Te_{4/2})$ octahedra through strong Sc–Te interactions. A projection of the $Sc_{14}Ru_3Te_8$ structure is shown in Figure 49. Scandium metal plays two roles: one as Sc_3 in chains of individual octahedral complexes $[Sc(Te_2Te_{4/2})]$ centered at $^1/_2, 0, z$, and so on. The second role is seen in a side view in Figure 50 where Sc atoms define infinite columns of confacial clusters, each centered by a Ru or Os atom. In these columns, are found square antiprismatic units that share faces. Each metal unit is connected to four Te-rich bridging chains built of $Sc(3)Te_6$ octahedra to complete the 3D structure. The Te atoms have trigonal prismatic and pentagonal bipyramidal configurations, respectively. Physical property measurements show that $Sc_{14}Ru_3Te_8$ is metallic and Pauli-paramagnetic, consistent with the results of extended Hückel band structure calculations. The Sc–M and Sc–Te interactions are major.

The presence of early transition metals or rare earth elements is not necessary for the stabilization of metal-rich compounds. This is shown by the metal-rich nickel–tin sulfides Ni_6SnS_2 and $Ni_9Sn_2S_2$, which were found during investigations of phase relations in the ternary Ni–Sn–S

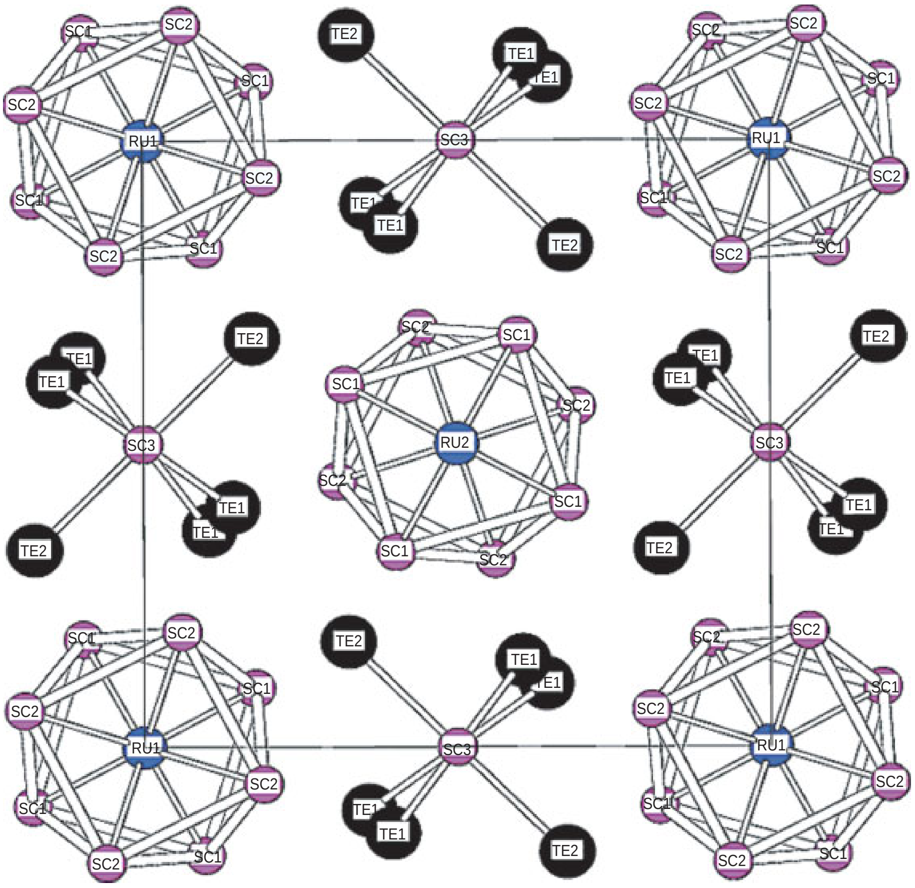

Figure 49 Projection of the unit cell of $Sc_{13.2}Ru_3Te_8$. The confacial Sc-based cubes and antiprisms centered by Ru are clearly seen. Sc3 atoms center infinite chains of edge-sharing $\{ScTe_6\}_n$ octahedra

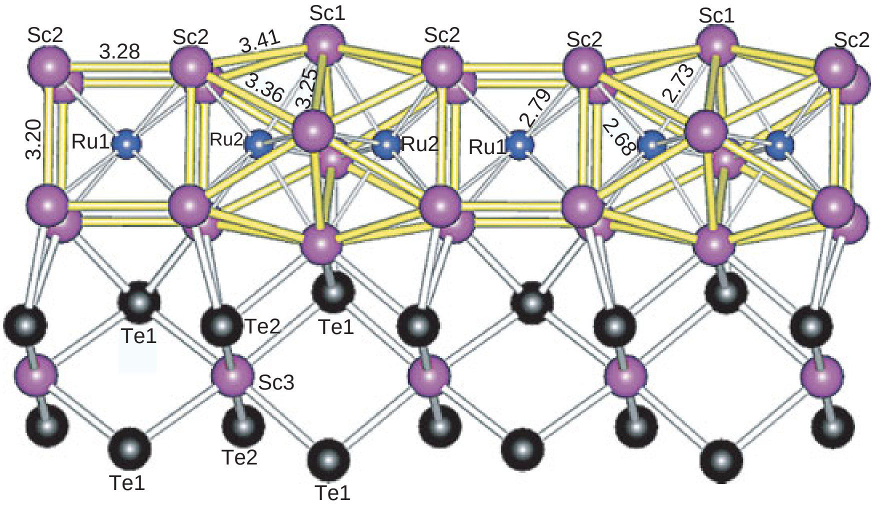

Figure 50 Segment of condensed $\{Sc_4Ru\}_n$ infinite chain of trans-face-sharing cubic (Sc1) and square antiprismatic (Sc1 and Sc2) polyhedra centered by Ru1 and Ru2, respectively. Distances are in Å

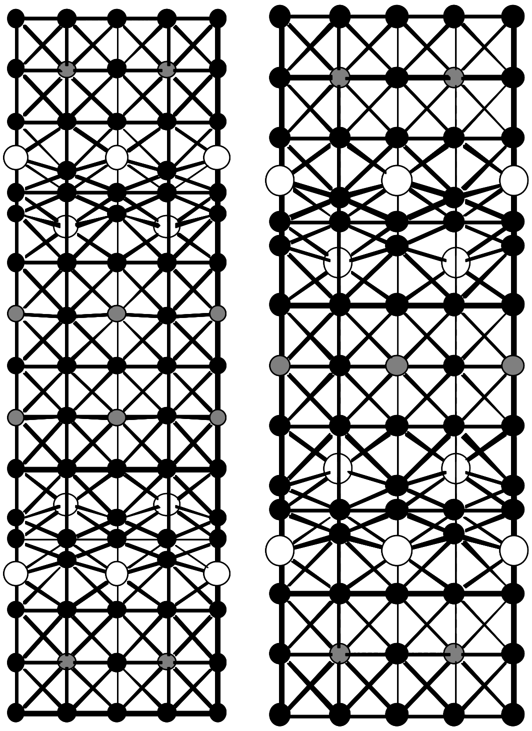

Figure 51 The structures of Ni_6SnS_2 and $Ni_9Sn_2S_2$

system at 540 °C.[129] Their crystal structures are tetragonal and represent a new structure-type that can be considered as assembled from bimetallic nickel–tin and nickel–sulfide slabs alternating along the crystallographic c-axis (Figure 51). Band structure calculations showed the bonding within the bimetallic slabs to have a delocalized, multicenter nature, typical for metallic systems, yet the bonding between nickel and sulfur is predominantly classical.

3.4 Misfit Compounds

A peculiar class is that of misfit layer compounds that can be viewed as stage composites of the type $[(MQ)_m]_{1+x}(TQ_2)_n$. The MQ part is an approximate tetragonal layer often called the Q-sublattice (not to be confused with the chalcogen atoms) and the TQ_2 sublattice is a hexagonal layer called the H-part. They are called misfit because the periodicities of the MQ and TQ_2 parts do not match exactly. That is, compounds are characterized by their incommensurate structures built from an alternate stacking of two different layered entities (sublattices Q and H), giving them a composite character (i.e. intergrowth compounds). Members of this class have been reported for T = Ti, Nb, or Ta and M = Sn, Pb, Sb, Bi, or rare earth elements. For example, the structure of $(LaSe)_{1.14}(NbSe_2)_2$ or '$LaNb_2Se_5$' contains double 2H-$NbSe_2$ slabs separated by rock salt LaSe layers as shown in Figure 52. The compound $(PbS)_{1.14}(NbS_2)_2$ is polytropic adopting orthorhombic and monoclinic modifications.

Incommensurability comes from the mismatch between periodicities of the two entities, along one direction. Their general formulation is defined and now well admitted as $[(MQ)_m]_{1+x}(TQ_2)_n$, with $m = 1$, 1.5, 2 and $n = 1$, 2, 3, the $1 + x$ value being related to the incommensurability. Such a formulation clearly indicates the composite nature of the compounds, with (MQ) and (TQ_2) sublattices that are of rock salt type structure for (MQ) (double-layer-thick for $m = 1$, or three-layer-thick for $m = 1.5$) and of CdI_2 type structure for (TQ_2) (T = Ti, V, Cr, i.e. an octahedral coordination) or NbS_2 (T = Nb, Ta, i.e. a trigonal prismatic coordination)

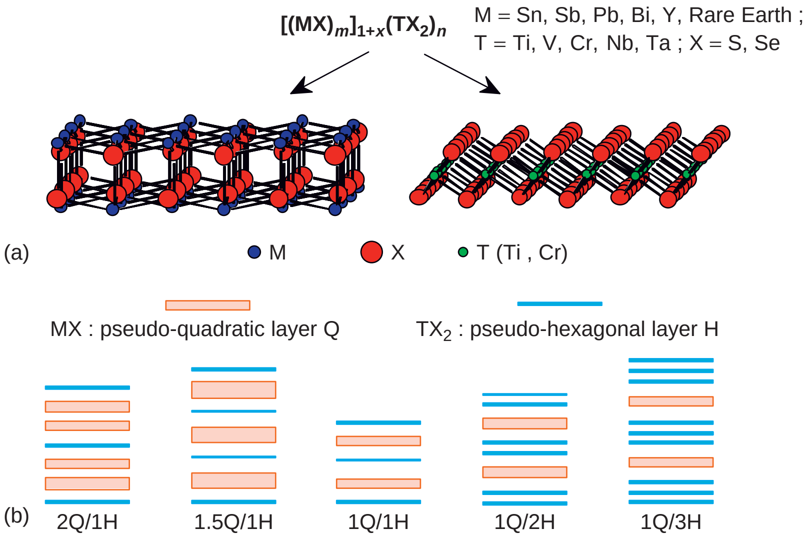

Figure 52 (a) The MQ and TQ_2 parts of a misfit layer compound. (b) Different stacking motifs between the so-called quadratic and hexagonal slabs

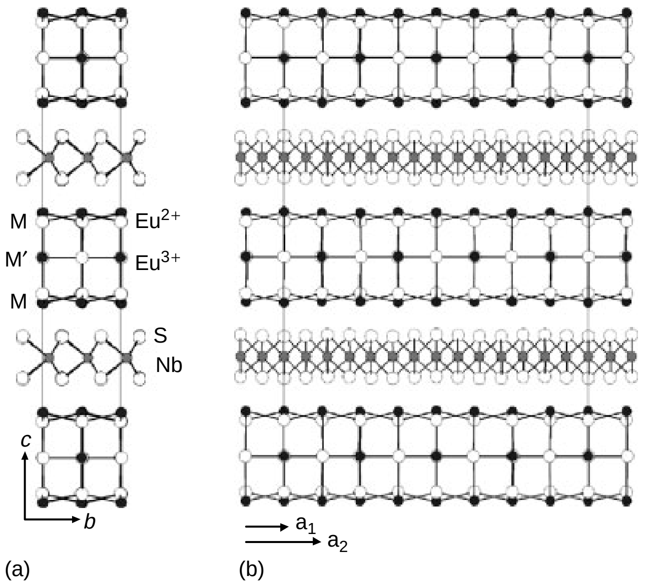

Figure 53 Projection of the structure of $[(EuS)_{1.5}]_{1.15}NbS_2$ (a) onto the (b, c) plane and (b) onto the (a, c) plane. This drawing was done for the commensurate approximation of 4/7

(Figure 53(a)). Abbreviated labeling 'Q' for MQ (= pseudo quadratic symmetry) and 'H' for TQ_2 (= pseudo Hexagonal symmetry) is typically used in this class. According to the combination of m and n values, one gets a variety of alternating sequences that are shown in Figure 53(b), with some respective referenced compounds.[130,131]

The $[(MQ)]_{1+x}(TQ_2)_2$ family has $n = 2$ and features a van der Waals gap between the two adjacent (TQ_2) slabs. Because the van der Waals gaps between the double MS_2 slabs are empty, the compounds can be exfoliated and intercalated in analogy to the parent MS_2 compounds. The octahedral holes in the van der Waals gap of monoclinic $(PbS)_{1.14}(NbS_2)_2$ are partially occupied by additional Nb. Thus, for the parent binary TQ_2 compounds tetrahedral and/or octahedral vacant sites within the gap are available for metal intercalation (donor species) as for instance, alkali metals[132] or transition metals such as Mn, Fe, Co.[133] One could also say that the [MQ] slab is, in itself, an intercalated entity (donor species) between two TQ_2 slabs. The crystal chemistry of the ternary misfit chalcogenides is similar to that of their parent binary chalcogenides, and this is reinforced by the phenomenon of polytypism which is occurring for both families.[134,135] Examples of Q-multilayered derivatives where $m = 2$, is $[(\{Pb_{1-x}Sb_x\}S)_2]_{1.14}(NbS_2)$ with $x \approx 0.2$.[136]

The issue of stability of these phases was not answered in the early studies. Only after a large number of misfit compounds was synthesized and studied did it become apparent that the key factor for the stability of these phases is a mechanism of charge transfer between the Q and H sublattices. The Q-part plays the role of electron donor and the H-part that of acceptor.[137,138] This hypothesis was of course envisioned, since the beginning, when a trivalent M metal was present (e.g. the rare earth elements), just considering the Q-part as $M^{3+} + Q^{2-} \rightarrow 1e^-$ to be transferred to the H-part. But the situation with a divalent M metal atom (e.g. Pb, Sn) has been 'resolved' later, after very precise chemical analyses were performed. It was found that a partial substitution of M^{2+} by T^{4+} took place in the Q-part, giving an excess of positive charges that must be equilibrated within the H-part as a reduction from T^{4+} to T^{3+}.[139] The analysis also indicated the presence of M-vacancies within the Q-part, specifically when $T = V$, Cr; this was illustrated for $[Gd_{1.16}\square_{0.11}S_{1.27}](CrS_2)$.[140] Thus, including the vacancies (□) in the composition leads to an almost exact charge equilibrium: the electronic transfer from the [GdS] to the $[CrS_2]$ slab is such that no excess electrons exist, and then the +3 oxidation state for Cr is stabilized.

Special attention has to be given to the case of 1.5-Q type misfit phases. For these phases, the Q-part is three-layer-thick, which implies two different coordination polyhedrons around the M/M′ metal atoms (Figure 53). Within the central layer, the M′ atom is octahedrally coordinated with X atoms, while the two external layers are concerned with M atoms surrounded by five X atoms within the Q-part and, in addition, two or three X atoms from the H-part. An example of this is provided with $[(EuS)_{1.5}]_{1.15}(NbS_2)$. It has to be noted that the charge transfer is established by the presence of Eu^{3+} (M′-site) while Eu^{2+} cations are attached to the external M-sites (see Figure 53). The mixed valence state for Eu was confirmed by Mössbauer spectroscopy.[141] Another example can be given with the Pb^{2+}/Fe^{3+} couple, that is, with $M \neq M'$. The 'classical type m = 1' for the Eu-derivative, $(EuS)_{1.173}(NbS_2)$, has been recently characterized; a mixed valence state for Eu, that is, Eu^{2+}/Eu^{3+} with a ratio close to 40/60, was demonstrated. However, in this compound, Eu^{2+} and Eu^{3+} ions occupy the same crystallographic site.[142]

Owing to the marked lamellar character of these phases, their physical properties are very anisotropic, and this anisotropy can be tuned by varying the mQ/nH ratio. It can be roughly said that transport properties are attributed to the H-part, while magnetic properties are related to the Q-part (when M = rare earth except La), or the H-part when T = Cr, or both parts together. About transport properties, an insulating behavior is found if T = Cr, or a semiconducting one with T = V[143] or a metallic one when T = Ti, Nb, or Ta.[144] A superconducting state was reported for the $[PbSe]_{1.14}(NbSe_2)_n$ series with $n = 1$, 2, 3.[145] A superconducting transition at a temperature as high as 5.3 K was observed for $[LaSe]_{1.14}(NbSe_2)_2$.[146] A complex behavior for electrical and/or magnetic properties is often present in relation with the modulated nature of both sublattices, which modulation results from the mutual interaction between sublattices. It is important to elucidate the details of the structures of these unusual compounds using sophisticated crystallographic methods such as the superspace approach.[147,148]

4 QUATERNARY COMPOUNDS

The number of quaternary phases has expanded dramatically in the past decade as interest in structural and compositional diversity in chalcogenides has increased. The majority of compounds has included alkali metal and alkaline earth metals which are in general associated with a ternary $[M_xM'_yQ_z]^{n-}$ covalently bonded framework. The selection of M and M′ is often a lanthanide/transition metal pair or a transition/main-group element pair. In the latter case, many of the compounds can also be conveniently considered as salts of various chalcometallate anions (e.g. $[PQ_4]^{3-}$, $[SnQ_4]^{4-}$ etc.) with different metals. As in the case of the ternary phases, the quaternary compounds also are generally prepared by direct combination reactions of simpler reagents or via solventothermal and polychalcogenide flux methodologies.

4.1 Alkali Metal Containing Quaternary Compounds

One permutation that has proven productive is the combination of lanthanides with late transition metals. From the reaction of the elemental copper and either lanthanides or actinides in molten alkali metal/polychalcogenide salts, several new quaternary phases have been discovered. Specifically, these phases are $ACuRE_2Q_6$ (where A = K, M = La, Q = S; A = Cs, M = Ce, Q = S; or A = K, M = Ce, Q = Se),[149,150] $ACuREQ_3$ (where A = Cs, RE = lanthanide or actinide, Q = S, Se)[151] and the structurally related $BaREMQ_3$ (RE = rare earth, M = coinage metal, Q = Se or Te),[152] ARE_2CuQ_4 (Q = S, Se),[153] $ARE_2Cu_3Q_5$, $ARE_2Ag_3Q_5$,[154] and $KCuCeTe_4$.[155] Other notable quaternary phases include $Rb_2Gd_4Cu_4S_9$, $Ba_4RE_2Cd_3S_{10}$ (RE = Sm, Gd, Tb),[156] $K_2Ag_3CeTe_4$,[157] $A_3RE_4Cu_5Te_{10}$ (A = alkali; RE = Sm, Gd, Er, Nd, Gd),[158] $CsGdZnSe_3$, and $BaGdCuSe_3$,[159] $Rb_2Cu_3CeTe_5$.[160] The class of rare earth transition metal chalcogenides has been recently reviewed.[2] In addition, the subclass of quaternary compounds with rareearth transition metal chalcogenides featuring square Te-based nets has also been reviewed.[161] Examples of square net compounds are $KCuCeTe_4$, $K_{2.5}Ag_{4.5}Ce_2Te_9$, and $KCuEuTe_2$; Section 4.2.

In $ACuM_2Q_6$, the lanthanides bond to a mixture of mono- and disulfides in a bicapped trigonal prismatic geometry; these polyhedra subsequently connect in two dimensions, forming layers equivalent to those seen in the $ZrSe_3$ structure-type with Cu^+ atoms residing in tetrahedral sites within the layers and alkali cations in the interlayer gallery.[162] A view of the structure of the orthorhombic compounds is given in Figure 54. The rare earth atoms are coordinated by a bicapped trigonal prism of Q atoms made of two $(Q_2)^{2-}$ units forming the short sides of the prism and four Q^{2-} ions at the apex and capping positions.

The compounds of the formula $ACuMQ_3$ also possess a layered structure.[149] Here the $[MQ_6]$ octahedral units form corrugated, two-dimensional sheets via edge-sharing in the first dimension and corner-sharing in the second. Cu cations are coordinated to tetrahedral sites in the folds of the corrugations, and alkali cations are again in the intergallery region. In the structure of the $ACuMQ_3$ phases, the f-block metal is coordinated to an octahedron of monochalcogenides. These $[MQ_6]$ units share edges with each other, forming one-dimensional chains parallel to the *a*-axis. These chains of octahedra are further connected through corner-sharing into a corrugated two-dimensional sheet (see Figure 55). The overall anionic network remains layered as the Cu^+ cations occupy tetrahedral sites in the folds of the layers of octahedra and so provide no extra dimensionality to the framework. The alkali metal cations reside within the interlayer galleries. If the Cu^+ were to be ignored, the remaining atoms would possess the anti-Pd_3Te_2 structure-type in which the Te atoms occupy both the octahedral sites and the interlayer gallery positions.

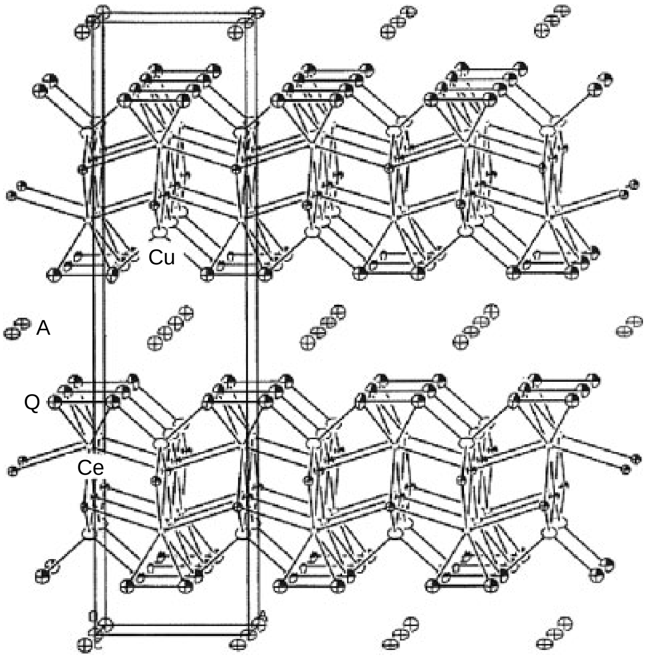

Figure 54 Extended structure of the orthorhombic form of $ACuCe_2Q_6$ as seen down the *a*-axis (circles with nonshaded octants, A; large open circles, Cu; small open circles, Ce; circles with shaded octants, Q)

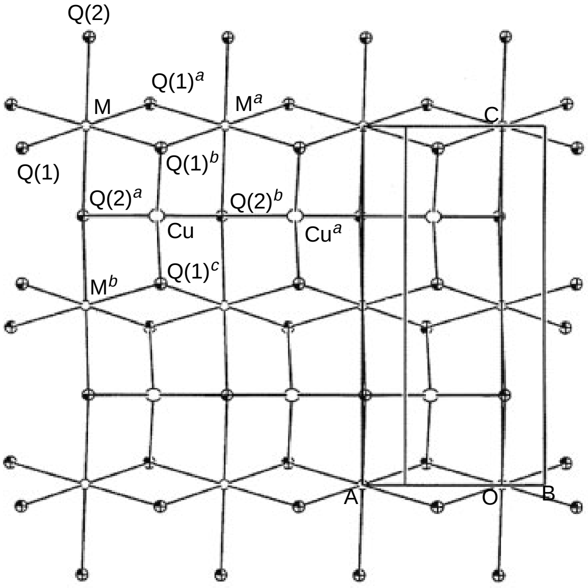
The group of $ACuMQ_3$ compounds are members of a larger family that includes other members such as $CsCeCuS_3$, $CsGdZnSe_3$, $BaRECuQ_3$,[152] $BaREAgQ_3$.[163]

The ARE_2CuQ_4 family includes KGd_2CuS_4, $RbNd_2CuS_4$, $RbSm_2CuS_4$, $RbSm_2CuSe_4$, $RbGd_2CuSe_4$, $RbDy_2CuSe_4$, $CsLa_2CuSe_4$, and $CsSm_2CuSe_4$.[164] This structure-type has a three-dimensional tunnel framework (see Figure 56). The tunnels are 10-membered pentagonal rings that are large enough in cross section to accommodate a single eight-coordinate A atom. The three-dimensional anionic framework is built from REQ_6 octahedra and CuQ_4 tetrahedra. The RE/Q fragments in these compounds consist of distorted



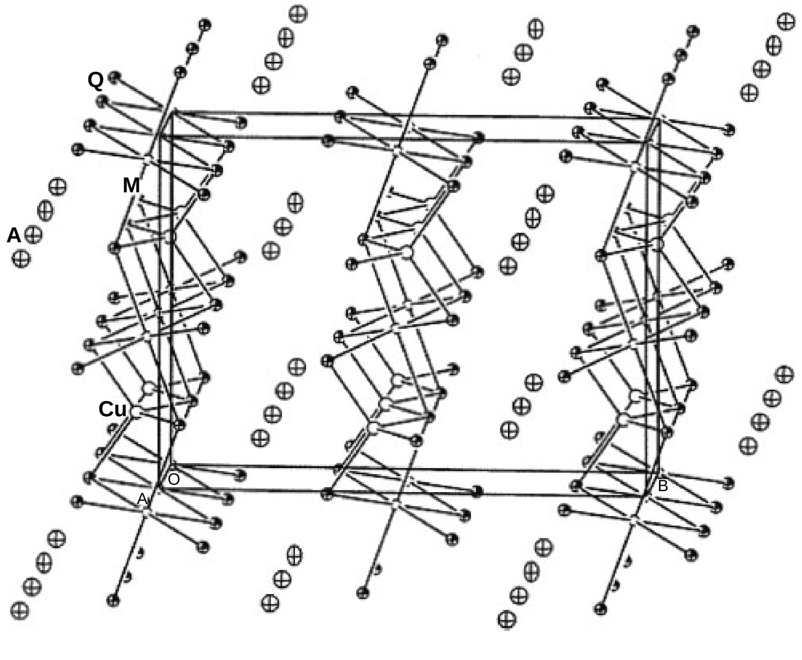


Figure 55 (a) View perpendicular to a single anionic layer of the $ACuMQ_3$ structure-type. (b) The $ACuMQ_3$ structure-type (A = Cs, M = Ce, Q = S; or A = K, M = U, Q = Se) as seen down the a-axis, parallel to the anionic layers (circles with nonshaded octants, A; large open circles, Cu; small open circles, M; circles with shaded octants, Q)

$^2_\infty[RE_2Q_5{}^{4-}]$ layers that are built from the REQ_6 octahedra sharing edges parallel to the a-axis to form chains. The chains are connected through vertex-sharing of Q atoms to form layers. The $^2_\infty[RE_2Q_5{}^{4-}]$ layers are connected by the octahedra in one layer sharing edges with octahedra in adjacent layers to form the three-dimensional framework.

The $ARE_2Cu_3Q_5$ and $ARE_2Ag_3Q_5$, compounds include $RbEr_2Cu_3S_5$,[153] $CsGd_2Ag_3Se_5$,[153] $CsTb_2Ag_3Se_5$,[153] and $RbSm_2Ag_3Se_5$.[154] The phases adopt a three-dimensional tunnel structure (Figure 57). The tunnels are 10-membered pentagonal rings consisting of six Cu–Q bonds and four RE-Q bonds that are large enough in cross section to accommodate a single eight-coordinate A atom. These AQ_8 polyhedra share triangular faces along the a-axis. The three-dimensional anionic framework is built from REQ_6 octahedra and CuQ_4 tetrahedra. The RE/Q fragments in these compounds consist of distorted $^2_\infty[RE_2Q_5{}^{4-}]$ layers that are built from the REQ_6 octahedra sharing edges parallel to the a-axis to form chains. The chains connect through vertex-sharing of Q atoms to form layers. The MQ_4 tetrahedra share vertices and edges

to form two-dimensional layers that connect to form the tunnel structure.

Some of the telluride compounds, such as $KCuCeTe_4$, $K_{2.5}Ag_{4.5}Ce_2Te_9$, $KCuEuTe_2$, and $Na_{0.2}Ag_{2.8}EuTe_2$, contain the interesting structural feature that is defined by a square net of Te atoms. This net is a monoatomic layer of Te atoms with equal Te–Te bond distances in the squares of ~3.1 Å. These distances are both curious and unusual in that they do not represent normal bonds. In addition, formal integer oxidation states cannot be assigned to these Te atoms and thus these compounds are considered 'nonclassical'. The chemical, physical, and electronic properties of these compounds are largely decided by these square nets, and by their interaction with the remaining part of the structure. It can be a challenge to understand the properties of these compounds because the observed crystal structures are not consistent with the measured properties. The equality of Te–Te distance of ~3.1 Å in the square net is at first intriguing but a more careful look in the diffraction properties of these materials reveals that there are extensive modulations in these nets that they are easy to miss. Both electron diffraction and X-ray diffraction experiments show the extent of these modulations (superstructures exist in the nets) and indicate that the square nets of Te atoms are actually distorted and the observation of the 'novel' distances of ~3.1 Å are an artifact of averaging. Some of these distortions have been elucidated. This class of rare earth chalcogenide compounds has been described in a recent review.[161]

One case in point is that the tetragonal structure of $K_{0.33}Ba_{0.67}AgTe_2$,[165] obtained by conventional crystallography, is inconsistent with its semiconducting behavior. This is because conventional crystallography gives only an average structure, which shows a perfect square Te-net. In reality, this compound possesses an incommensurately modulated structure which was solved within a (3 + 1)D higher dimensional crystallographic formalism.[166] These types of structures need to be tackled with higher-dimensional crystallographic techniques (super space group approach), which at this stage makes their full structural characterization far from routine. The compound was shown to crystallize in the monoclinic symmetry, $P2_1(\alpha 0\gamma)$ super-space group in a symmetry different from that reported for the average structure (tetragonal) or that assumed from electron diffraction measurements (orthorhombic). The results are rather intriguing because the Te-net in this compound shows two different distortions at the same time. One distortion features only Te_3^{2-} fragments, while the other has both Te_5^{2-} and Te^{2-} ions. The two distortions alternate in a wave-like fashion (see Figure 58). This is the first time two different distortion motifs were found to coexist.

The structure of $K_{2.5}Ag_{4.5}Ce_2Te_9$ is shown in Figure 59. The $K_{2.5}Ag_{4.5}Ce_2Te_9$ is an intergrowth compound between two components $K_{2.5}Ag_{4.5}Te_3$ and $CeTe_3$ and can also be described as $(K_{2.5}Ag_{4.5}Te_3)(CeTe_3)_2$. There are Te nets in both components. In the $K_{2.5}Ag_{4.5}Te_3$ section, only Te^{2-} ions with no distortions exist; however, the atoms in the Te-net of the $CeTe_3$ section have an average formal charge < -2 and generate incommensurate modulations (see electron diffraction pattern in Figure 59). The nature of these modulations is currently an active area of research. It is anticipated that full structural characterization of these fascinating distortions will be accomplished within the next decade.

4.2 Polychalcogenide, Chalcophosphate and Related Fluxes

The application of salt fluxes in the synthesis of new solid-state compounds has witnessed significant development in the past decade. Particularly important has been the

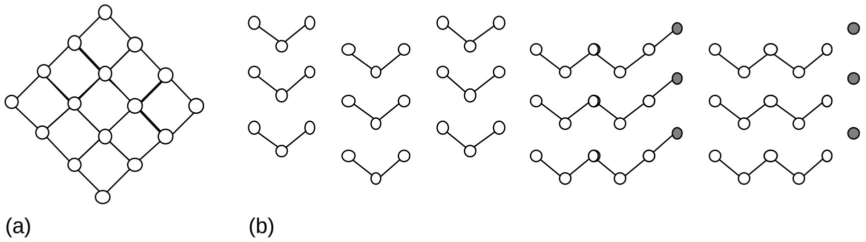

Figure 58 Striking difference between (a) the structure of the square Te-net determined by conventional crystallography (average tetragonal structure) which predicts a metallic compound and (b) the structure of the incommensurately modulated Te-net determined by higher dimensional crystallography. Two motifs are observed: Te groups with a 'V' shape and Te groups with a 'W' shape. Occasionally, as the motif changes from V to W, the lone Te atom (black dots) found between two W motifs is at a distance slightly shorter than 3.1 Å of a W motif (one such example is observed in the figure). This structure explains the narrow band gap semiconductor behavior of this compound

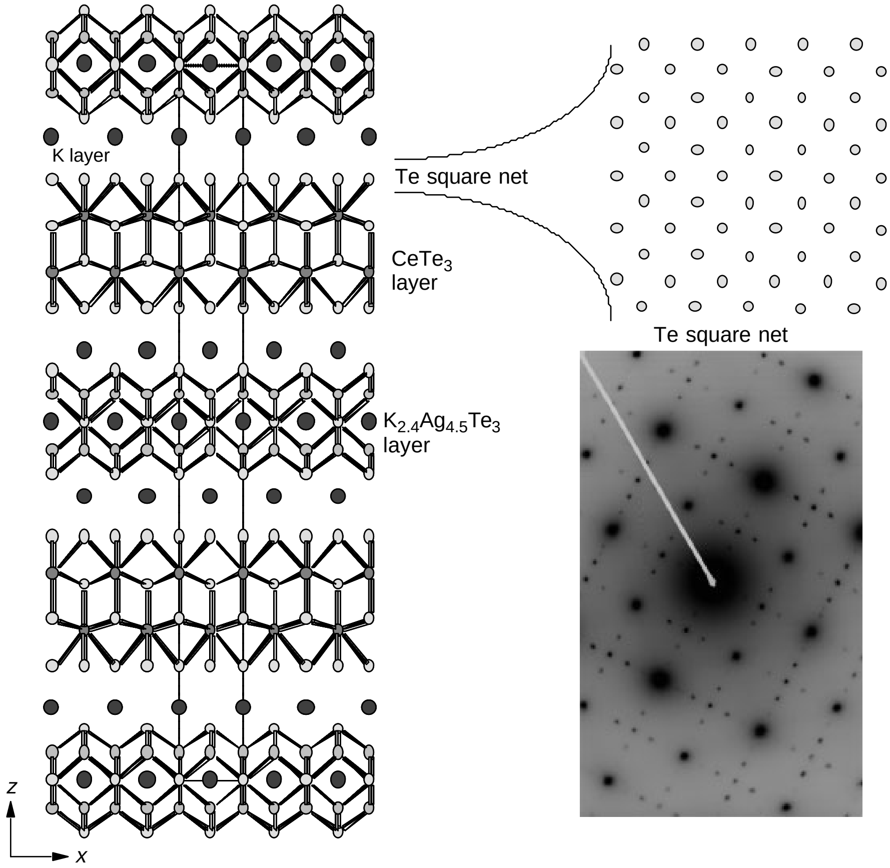

Figure 59 The structure of $K_{2.5}Ag_{4.5}Ce_2Te_9$ and representative electron diffraction pattern with the e-beam perpendicular to the square Te-net. The weak supercell spots appear between the strong subcell reflections

emergence of the molten polychalcogenide flux methodology in the exploratory synthesis of complex chalcogenides. This approach to new chalcogenides has been developed and brought to the main stream of inorganic chemistry methodology mainly in our laboratories. This method of synthesis and exploration has simplified access to low and intermediate temperatures (160–600 °C) and contributed to the discovery of some very interesting materials. In many cases, the compounds stabilized under polychalcogenide flux conditions are only kinetically stable and cannot be synthesized at higher temperatures. Lower temperatures, coupled with the presence of a liquid, also make possible the use of molecular assemblies as building blocks for incorporation into solid-state structures, and consequently the construction of complex multinary solids.

An excellent way to search for new solid-state materials is the use of molten salts as solvents in which to carry out exploratory synthetic reactions. For the discovery of chalcogenide materials, the use of alkali metal polychalcogenides, of the type A_2Q_x (A = alkali metal, Q = chalcogenide) as solvents, is very appropriate as we and others have demonstrated already. As solvents for intermediate temperature reactions, A_2Q_x salts are especially well-suited because the melting points range between the extremes of K_2S at about 850 °C to K_2S_4 at 145 °C, with the majority of compositions melting at $<$ 300 °C. The polytelluride versions melt between 300–500 °C. Low melting, A_2Q_x fluxes remain nonvolatile over a wide temperature range, and so once above the melting point, reaction temperatures can be varied considerably without concern for solvent loss. Polychalcogenide fluxes are highly reactive towards metals because they are very strong oxidants. Reactions between metals and molten A_2Q_x are performed in situ.

The polychalcogenide salts can be made by allowing stoichiometric amounts of elemental chalcogenide to react an with alkali metal in liquid NH_3 at −70 °C or by direct combination reactions between the alkali metal and the chalcogen. In the latter case, care must be taken to avoid explosions owing to the highly exothermic nature of the reaction. To synthesize new compounds, one or more metals are added directly to the A_2Q_x/Q reaction mixture and heated in a sealed Pyrex or quartz container. Crystalline products either precipitate from the melt or form on slow cooling of the melt, depending on the specific stoichiometric and processing conditions. Presumably, the nucleated species are in equilibrium with the soluble intermediates, especially if the flux is present in excess, and hence a solvation/reprecipitation effect (often referred to as the mineralizer effect) occurs. This aids in the growth of high quality single crystals because the flux can redissolve small or poorly formed crystallites and then reprecipitate the species onto larger, well-formed crystals. The advantage of the flux method is that one allows the system to end up where it wants in the kinetic or thermodynamic sense without attempting to force upon it a certain stoichiometry or structure. Provided the temperature and time are appropriate, the reaction system has all the ingredients to form a new phase. The benefit of this becomes apparent from the unsual compositions often found for the new materials which most certainly could not have been predicted a priori.

Chalcophosphates are compounds that contain phosphorus and chalcogen atoms in which phosphorus is oxidized and there exists at least one P–Q bond, where Q = S or Se. To date, there are no examples with Q = Te. There exists a wonderful structural diversity among these compounds due primarily to the various $[P_yQ_z]^{n-}$ building blocks that can be stabilized and their fascinating variety of binding modes. In addition to their rich structural chemistry, several of these phases possess interesting ion-exchange, intercalation, magnetic, electrical, and optical properties. Therefore, it is important to inquire about chalcophosphates, develop their syntheses and explore their properties.

4.2.1 Chalcometallate Salts

By chalcometallate compounds we mean those that are based on complex anions of the type $[M_xQ_y]^{z-}$ where M is a high oxidation state metal or metalloid and Q is a chalcogen. The most well-known chalcometallate anions are $[PQ_4]^{3-}$, $[P_2Q_6]^{4-}$, $[GeQ_4]^{4-}$, $[SnQ_4]^{4-}$, $[AsQ_3]^{3-}$, and $[SbQ_3]^{3-}$, but a large variety of others also exist. These anions can be regarded as building blocks for constructing ternary and quaternary chalcogenide frameworks. They can form in situ during synthesis or be introduced in the reaction as their alkali metal salts. When combined with various metal cations, these anions can lead to an astonishing variety of compositions and structural arrangements.

A convenient way to stabilize these anions and make them available for reaction is through a flux methodology. This approach to new metal chalcogenides has simplified access to low and intermediate temperatures (160–600 °C) and contributed to the discovery of many fascinating solid-state materials. Lower temperatures, coupled with the presence of a flux, also make possible the use of molecular assemblies as building blocks for incorporation into solid-state structures.

When using the flux approach, the best way to generate chalcometallate anions such as $[PQ_4]^{3-}$, $[P_2Q_6]^{4-}$, $[GeQ_4]^{4-}$, $[SnQ_4]^{4-}$, $[AsQ_3]^{3-}$, and $[SbQ_3]^{3-}$ is to introduce P, Ge, Sn, As, or Sb in the appropriate amount into the A_2Q_x melt. For example, the polychalcophosphate fluxes form by simple in situ fusion of $A_2Q/P_2Q_5/Q$, (Q = S, Se) (see equation (2)). The acid/base characteristics of the $A_x[P_yQ_z]$ fluxes are very different from those of A_2Q_x fluxes in that they tend to be more basic. The relatively good solubility properties of $A_x[P_yQ_z]$ salts in water and polar organic solvents allow for easy isolation of products.

$$\left(\frac{x}{2}\right) A_2Q + \left(\frac{y}{2}\right) P_2Q_5 + zQ \xrightarrow{T > 300\,^\circ C} A_x[P_yQ_{x+y+z}]$$

(A = alkali metal) (2)

In these melts, various $[P_yQ_z]^{n-}$ species are solubilized in excess polychalcogenide flux. The melting points of $A_xP_yQ_z$ are in the intermediate temperature range 300–400 °C, making possible the synthesis of even metastable phases. The existence of various $[P_yQ_z]^{n-}$ species in the melt is influenced by the $A_xP_yQ_z$ composition. Their exact distribution as a function of composition, however, is not well-known; however, one can reasonably speculate the equilibria shown in Figure 60. Recognizing that there are such equilibria that can be controlled is important because flux composition determines the product outcome. Similar considerations apply for the $[GeQ_4]^{4-}$, $[SnQ_4]^{4-}$, $[AsQ_3]^{3-}$, and $[SbQ_3]^{3-}$ anions.

Although early investigations concentrated on the reactivity of Bi, almost all elements have good reactivity in them, as

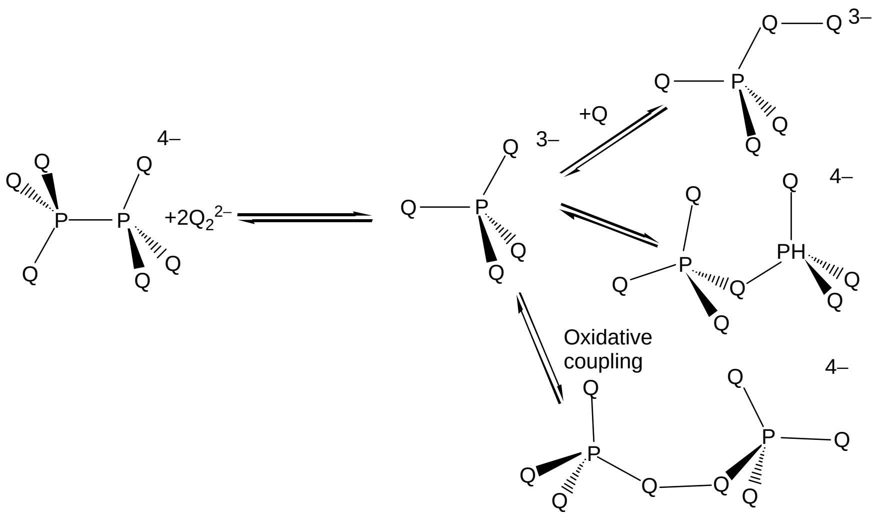

Figure 60 Possible chalcophosphate anion equilibria present in alkali metal polychalcogenide fluxes

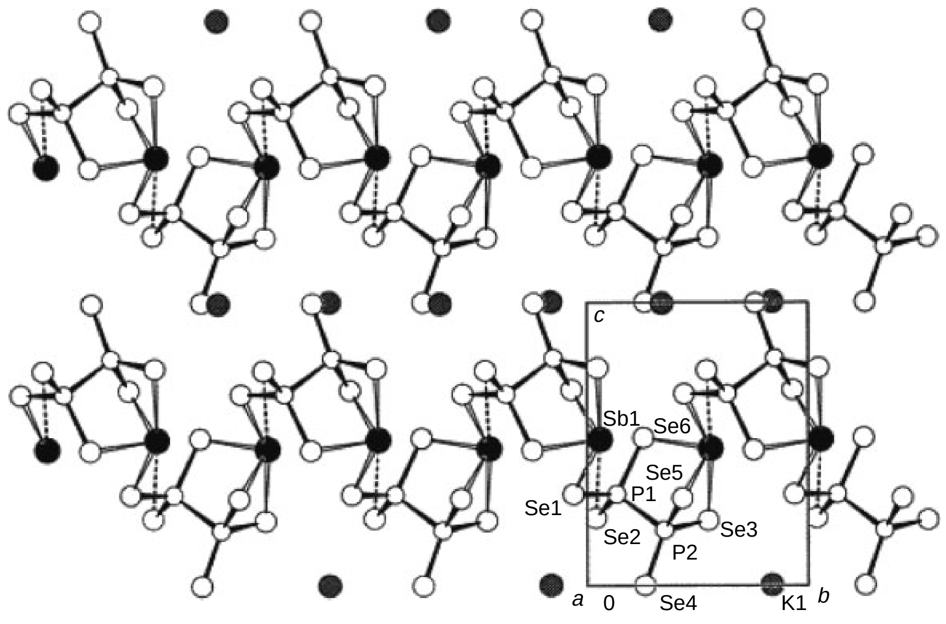

Figure 61 View of β-$KSbP_2Se_6$ perpendicular to the screw axis. The weak interchain bond is emphasized with a dashed line

has been demonstrated for a large fraction of the metallic elements. Many quaternary chalcophosphate compounds have been generated in this fashion including $ABiP_2S_7$ (A = K, Rb),[167] $A_3M(PS_4)_2$ (A = K, Rb, Cs; M = Sb, Bi),[168] $Cs_3Bi_2(PS_4)_3$, and $Na_{0.16}Bi_{1.28}P_2S_6$, α-, β-KMP_2Se_6 (M = Sb, Bi),[169] $A_2MP_2Se_6$ (A = K, Rb, Cs; M = Pd, Zn, Cd, Hg),[170] $APdPS_4$,(A = Na, K, Rb),[171] $K_2PdP_2S_6$,[172] $Cs_2PdP_2Se_6$,[172] $Rb_8Hg_4(Se_2)_2(PSe_4)$,[173] Tl_2AuPS_4,[173] $KAu_5P_2S_8$,[174] $K_4In_2(PSe_5)_2(P_2Se_6)$,[175] $Rb_4Ti_2(P_2Se_7)(P_2Se_9)_2$,[176] $Na_{1.5}Pb_{0.75}PSe_4$, $K_3RuP_5Se_{10}$,[177] $K_3Cu_3P_3Se_9$,[178] $Cs_2CuP_3S_9$,[179] $KInP_2Se_6$,[180] $NaCrP_2S_6$, $ANb_2P_2S_{12}$ (A = K, Rb, Cs),[181] K_2AuPS_4[182] and $A_2AuP_2Se_6$ (A = K, Rb).[182]

The new quaternary niobium thiophosphates $ANb_2P_2S_{12}$ (A = K, Rb, Cs) form by allowing Nb metal, A_2S, P_2S_5, and S to react at 600−700 °C. They crystallize as 'stuffed' variants of the tetragonal $TaPS_6$ structure-type. Their structures are based on double helices formed from interpenetrating, noninteracting spiral chains of binuclear $[Nb_2S_{12}]$ cluster units and $[PS_4]$ thiophosphate groups. The cavities and tunnels, which are formed by the helical chains, are filled with A^+ ions. Temperature-dependent conductivity studies reveal thermally activated electrical transport behavior. $ANb_2P_2S_{12}$ may be considered a chalcogenide analogue of metal phosphate bronzes.

The α-, β-KMP_2Se_6 (M = Sb, Bi) set presents an interesting case of thermodynamically metastable acentric compounds which were found to crystallize in the polar chiral space group $P2_1$, even though they are built up from the centrosymmetric, 'ethane-like' $(P_2Se_6)^{4-}$ group. These are kinetic crystallization products that transform to the more thermodynamically stable α-KMP_2Se_6 (M = Sb, Bi)[183] structure upon extended exposure to elevated temperature. The β-$KSbP_2Se_6$ has a pseudo-one-dimensional structure containing Sb^{3+} tri-coordinated by one $(P_2Se_6)^{4-}$ unit (see Figure 61). β-$KSbP_2Se_6$ crystallizes as a single phase by heating an amorphous precursor of the same composition to slightly above the glass transition temperature. At temperatures above 250 °C, β-$KSbP_2Se_6$ transforms slowly to α-$KSbP_2Se_6$. In other words, there are three states to this composition, amorphous, α-, and β-, and therefore it might be possible to utilize the unique transformation properties of the $KSbP_2Se_6$ system in a three-state logic gate.

The compound $K_3RuP_5Se_{10}$ forms from the reaction of Ru with a molten mixture of K_2Se/P_2Se_5/Se at 490 °C. It is a unique compound in that it is the first chalcophosphate to feature direct metal-phosphorus Ru–P bonds. It has infinite chains of $[Ru(P_2Se_6)(P_3Se_4)^-]$ separated by K^+ cations (Figure 62). The chains have the polymeric $[P_3Se_4{}^-]$ unit that contains P^{2+} and P^{3+} atoms, which is the backbone upon which each chain is built. Every P atom of this unit makes metal-phosphorus bonds with a Ru^{2+} center. The latter completes its *fac* octahedral coordination with three Se ligands that belong to $[P_2Se_6]^{4-}$ units. This M–P bonding is very much analogous to the bonding encountered in conventional M/phosphine complexes.

A number of lanthanide, actinide, and related compounds have been synthesized as well. $A_3REP_2Se_8$,[184] and $A_2REP_2Se_7$ (A = Rb, Cs; RE = Ce, Gd), $K_3CeP_2S_8$,[185] $KREP_2Se_6$ (RE = Y, La, Ce, Pr, Gd),[186,187] $Rb_4U_4(Se)_2(Se_2)_4(PSe_4)_4$,[188] $K_3La(PSe_4)_2$, $K_4La_{0.67}(PSe_4)_2$, $K_2La(P_2Se_6)_{0.5}(PSe_4)$,[189] $NaREP_2S_6$,(RE = Yb, Sm),[190] $KSmP_2S_7$,[190] $LiEuPSe_4$ and $KEuPSe_4$,[191] $NaCeP_2Se_6$, $Cu_{0.4}Ce_{1.2}P_2Se_6$, and the incommensurately modulated $AgCeP_2Se_6$.[192]

Actinide compounds have been prepared as well including $Cs_8U_5(P_3S_{10})_2(PS_4)_6$,[193] $K_{10}Th_3(P_2S_7)_4(PS_4)_2$, and $A_5An(PS_4)_3$, (A = K, Rb, Cs; An = U, Th), $K_2UP_3Se_9$,[194] $A_2ThP_3Se_9$ (A = K, Rb),[195] and $Cs_4Th_2P_5Se_{17}$, and $A_{11}U_7(PS_4)_{13}$ (A = K, Rb).[196] Particularly interesting are the radioactive plutonium compounds $KPuP_2S_7$ and $K_3PuP_2S_8$.[197]

The $LiEuPSe_4$ structure is three-dimensional and composed of $EuSe_8$ distorted square antiprisms and PSe_4 tetrahedral building blocks that create tunnels, running down the a-axis, in which the Li ions reside. The Li ions are in a highly distorted tetrahedral coordination (Figure 63(a)).

The structure of $KEuPSe_4$ has two-dimensional character. Looking down the a-axis in Figure 63(b), one can see layers of $[EuPSe_4]_n{}^{n-}$ separated by K^+ cations that have a distorted bicapped trigonal prismatic coordination. The layers are composed of wedge-like $EuSe_6$ trigonal prisms and PSe_4 tetrahedral units. Each Eu is connected to four PSe_4 tetrahedral units. With two of the tetrahedra it shares an edge; with the other two it shares only corners. The $EuSe_6$ trigonal prisms share rectangular edges in such a way that the trigonal faces of the prisms (i.e. the wedges) point alternately up as they form parallel chains along the b-axis. The PSe_4 tetrahedra connect these chains along the a-axis by sharing their edges with the rectangular faces of the trigonal prisms and the opposite edges. $KEuPSe_4$ is closely related to $CsPbPSe_4$.[198]

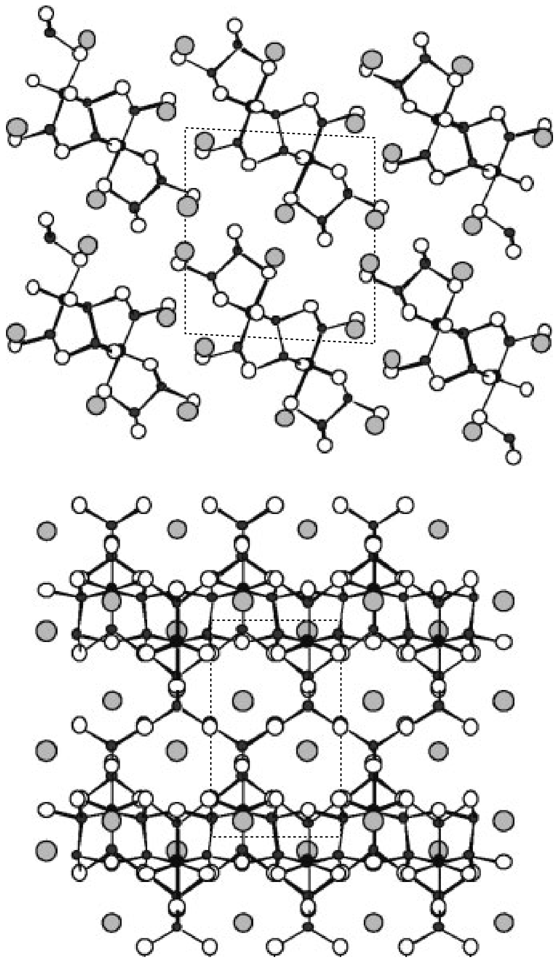

Figure 62 Two views of the low dimensional structure of the $K_3RuP_5Se_{10}$

The $K_{11}U_7(PS_4)_{13}$ features an interesting tunnel framework composed of eight interlocking uranium $U_7(PS_4)_{13}$ screw helices, with alkali metal cations residing inside the framework channels. The uranium atoms are coordinated in a bi- or tricapped trigonal prismatic fashion. The screw helices are built up from uranium atoms interconnected by PS_4, tetrahedral units.

Finally, the first series of plutonium thiophosphates has been identified and described. It appears that the chemistry of plutonium is neither similar to that of U nor any of the rareearth

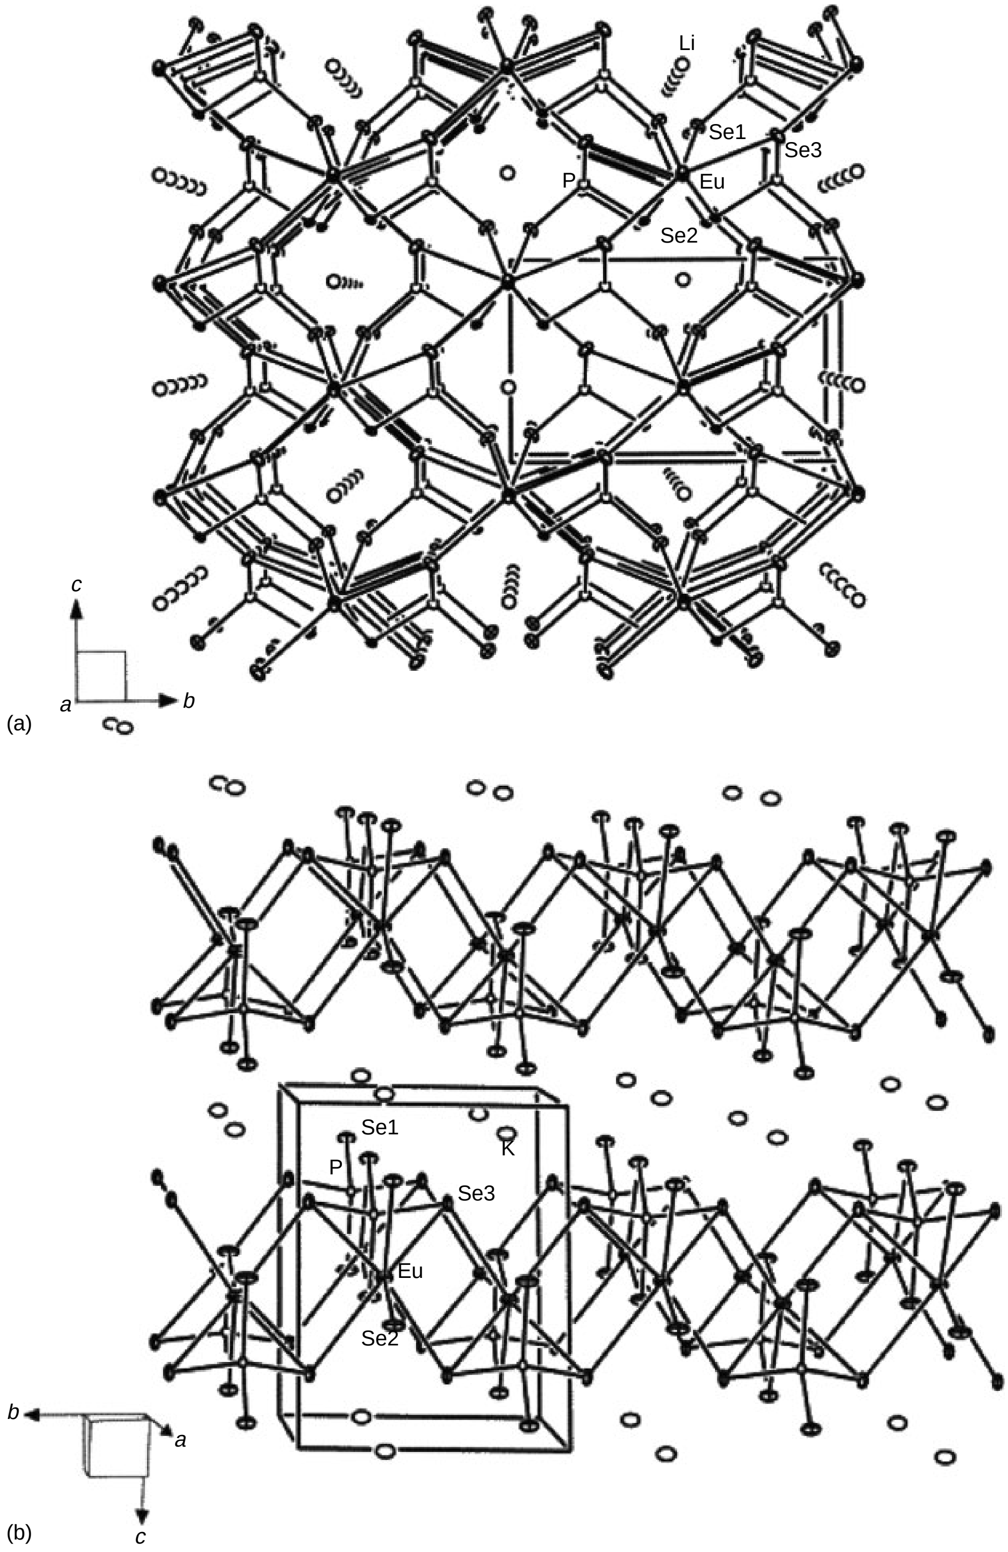

Figure 63 (a) The structure of $LiEuPSe_4$ viewed down the *a*-axis with thermal vibrational (80%) ellipsoids. This view shows the $^{1}_{\infty}[EuPSe_4]^-$ framework that creates tunnels for the Li ions to reside. (b) The structure of $KEuPSe_4$

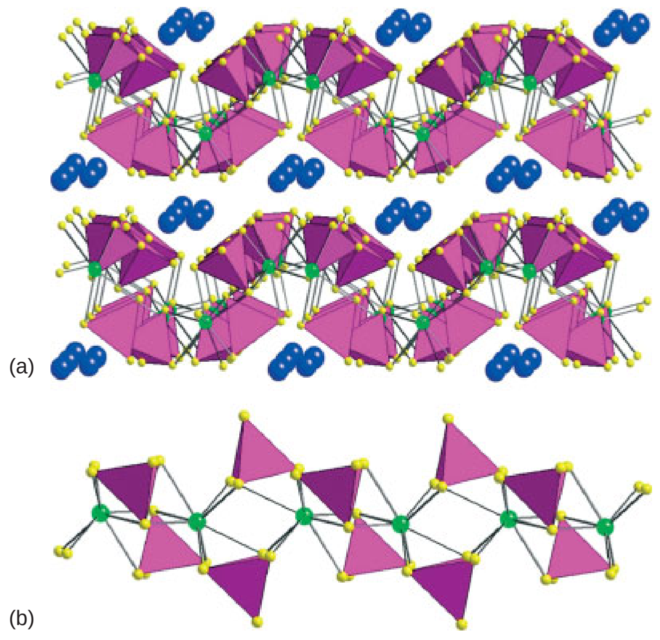

Figure 64 The structure of (a) $KPuP_2S_7$ and (b) $K_3PuP_2S_8$

element compounds. The $KPuP_2S_7$ and $K_3PuP_2S_8$ possess layered and chain-like structures, respectively (Figure 64).

The flux chemistry can be easily adapted for chalcogermanate and -stannate chemistry as well as chalcoantimonate and arsenate chemistry. The compounds $Na_8Pb_2[Ge_2S_6]_2$, $Na_8Sn_2[Ge_2S_6]_2$,[199] K_2MnSnS_4,[200] α-, β-$A_2Hg_3M_2S_8$ (A = K, Cs, Rb; M = Sn, Ge),[201,202] $ASmGeSe_4$ (A = K, Rb, Cs)[203] $A_{0.5}Pb_{1.75}GeS_4$ (A = Li, Na),[204] Li_2PbGeS_4 and Li_2EuGeS_4,[205] K_2EuMSe_5 and $KEuMS_4$ (M = Si, Ge),[206] the chalcoantimonates A_2AuSbS_4 (A = Rb, Cs),[207] $K_2Gd_2Sb_2Se_9$[208] and $K_2La_2Sb_2S_9$, $Ba_3Sb_{4.66}S_{10}$,[209] $Ba_{2.62}Pb_{1.38}Sb_4S_{10}$, K_2AuAsS_4, $KSnAsS_5$ and $K_2SnAs_2S_6$, have been synthesized using the flux protocol.

The α-, β-$A_2Hg_3M_2S_8$ (A = K, Rb; M = Ge, Sn) are closely related phases discovered using the alkali polychalcogenide flux method. They present structure types with a polar noncentrosymmetric character and strong nonlinear second-harmonic generation (SHG) properties. The polar character of the structure of α-$K_2Hg_3Ge_2S_8$ is evident when viewed down the *b*-axis (see Figure 65). The structure can be described in terms of a three-dimensional covalent anionic $[Hg_3Ge_2S_8]^{2-}$ framework filled with K^+ ions. The

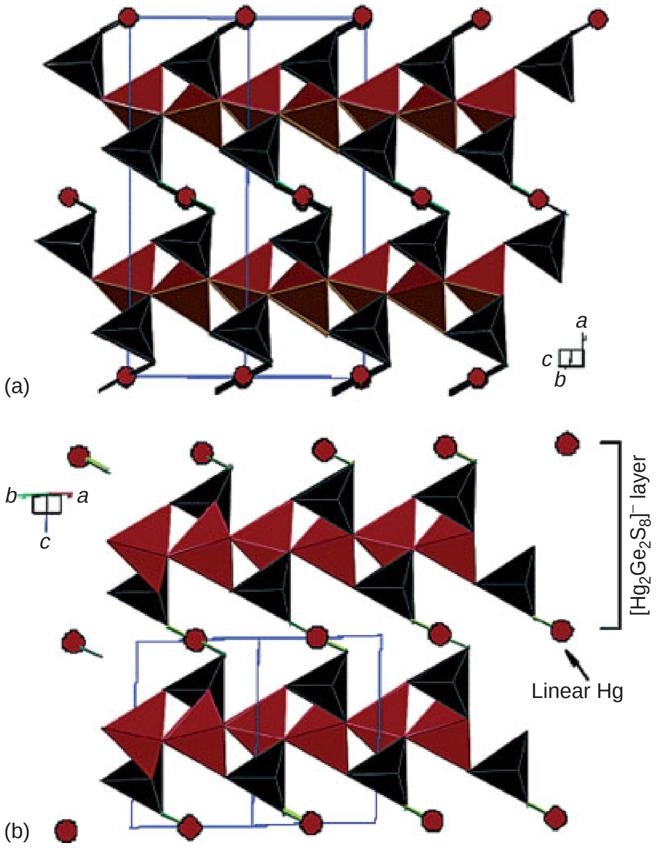

Figure 65 Polyhedral representation of the structure of (a) α-$K_2Hg_3Ge_2S_8$ and (b) β-$K_2Hg_3Ge_2S_8$ showing the bridging role of the linearly coordinated Hg atoms

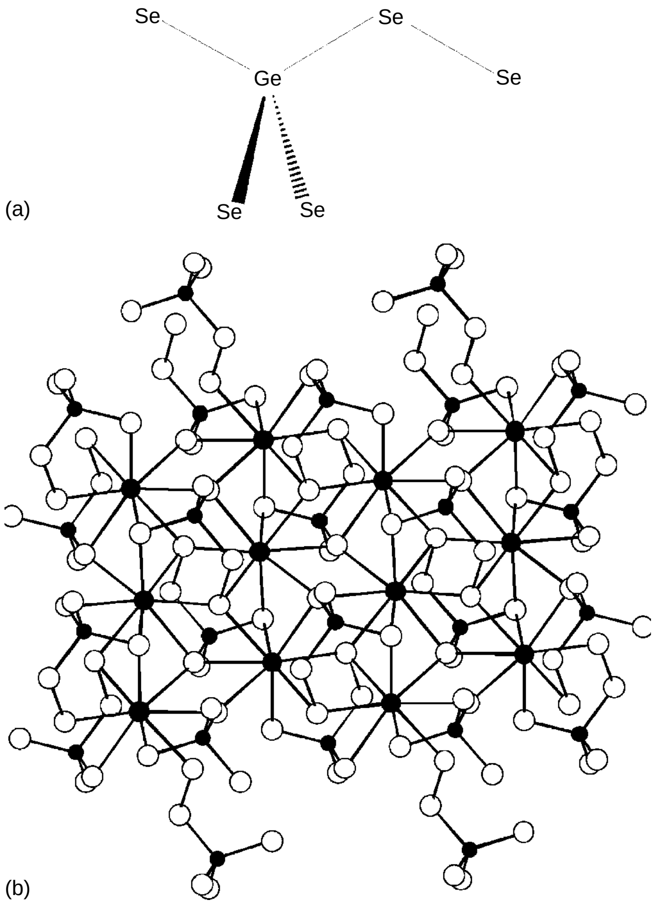

Figure 66 (a) The $(GeSe_5)^{4-}$ unit and (b) the $[EuSiSe_5]^{2-}$ framework

framework can be viewed as slabs of $[Hg_2Ge_2S_8]^{4-}$ linked by linear Hg(1) atoms. There are two types of Hg^{2+} atoms, a highly distorted tetrahedral [Hg(2) 'seesaw-shaped' HgS_4] and a linearly coordinated Hg(1) atom. The β-form is similar but it differs in how the linear Hg atoms link the $[Hg_2Ge_2S_8]^{4-}$ slabs (Figure 65).

The compounds $K_2EuSiSe_5$, $K_2EuGeSe_5$ are isostructural and they have a layered structure in which 9-coordinate Eu(II) atoms are linked into a layer by $(GeSe_5)^{4-}$ units. The $(GeSe_5)^{4-}$ unit, shown in Figure 66(a), is a Ge(IV) tetrahedron with one of its arms being a diselenide $(Se_2)^{2-}$ unit. It is isoelectronic to the $[PSe_5]^{3-}$ unit observed in thiophosphate chemistry. Five different $(GeSe_5)^{4-}$ units are coordinated to each europium atom. Two units are bound to europium with one selenium atom, two units are bound with two selenium atoms, and the fifth $(GeSe_5)^{4-}$ unit is bound to europium with three of its selenium atoms. Each $(GeSe_5)^{4-}$ unit links four different Eu^{2+} atoms within a layer as seen in Figure 66(b).

A classical example of reactivity of main group metal in thioarsenate melts and how Lewis flux basicity affects the chemistry is that of Sn. Low Lewis basicity fluxes favor the formation of $KSnAsS_5$, and as the basicity increases (e.g. by adding more K_2S) the reaction lead to layered $K_2SnAs_2S_6$ instead.[210] The former compound has infinite chains and the rare pyramidal β-$[AsS_4]^{3-}$ ligand (Figure 67(a)). The key unit in the chain is a centrosymmetric $[Sn(AsS_2(S_2))]_2$ dimeric core that propagates down the chain with bridging μ_2-S^{2-} ions. The pyramidal β-$[AsS_4]^{3-}$ anion features the As^{3+} ion and a disulfide unit, and it is very different from the well-known As^{5+} species α-$[AsS_4]^{3-}$. All three terminal sulfur atoms are involved in binding the two Sn^{4+} ions. The terminal atom, S(1), of the disulfide group serves to bridge the Sn atoms in the core (Figure 67(b)). This pyramidal unit is to be contrasted with the highly symmetrical tetrahedral α-$[AsS_4]^{3-}$ anion, which is formally an As^{5+} species and isostructural to the more familiar $[PS_4]^{3-}$ anion. Therefore, we see here a drastic departure of the thioarsenate flux chemistry from that of the thiophosphate which is attributed to the electronegativity difference in the two elements. It is possible that the two isomers are in fact in equilibrium with each other. Presumably, this equilibrium would be sensitive to the basicity of the flux which to a large extent is controlled by the formal $K_2S/As_2S_3/S$ ratio, and by the nature of the alkali ion. Thus, by controlling such equilibria in the flux, one could favor different thioarsenate anions to produce different outcomes.

The $K_2SnAs_2S_6$ compound is trigonal with layers consisting of SnS_6 octahedra and $[AsS_3]^{3-}$ pyramids (Figure 68). The layers are separated by seven coordinate K^+ ions. Topologically, the structure is TiS_2-type with Sn^{4+} cations in the octahedral Ti positions and $[AsS_3]^{3-}$ anions at

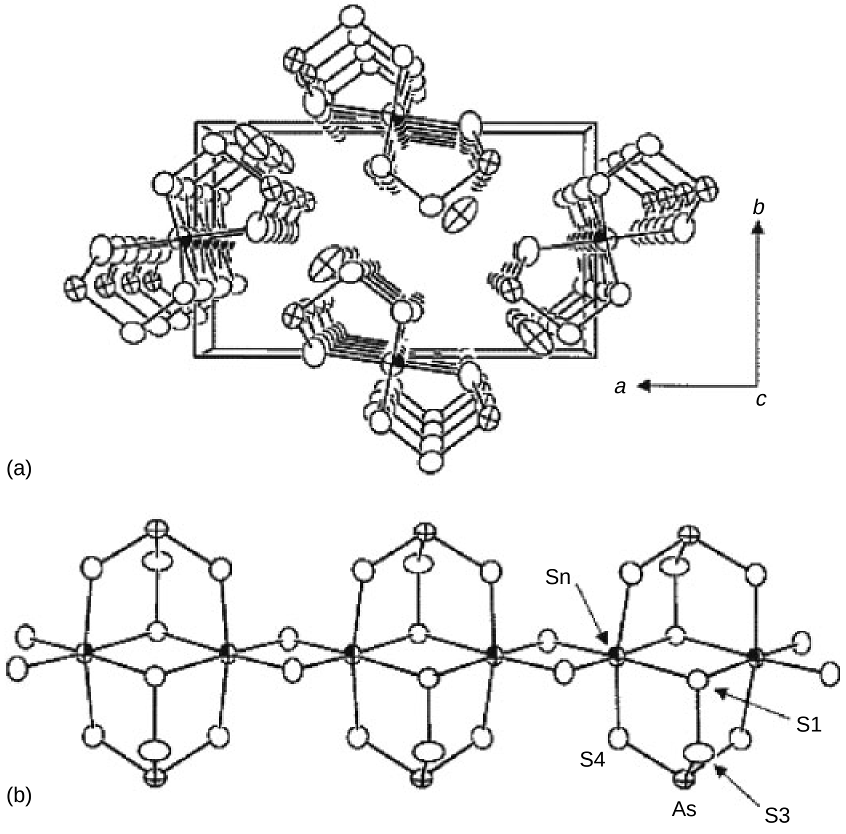

Figure 67 (a) The structure of $KSnAsS_5$ looking down the c-axis (b) A single chain of $KSnAsS_5$

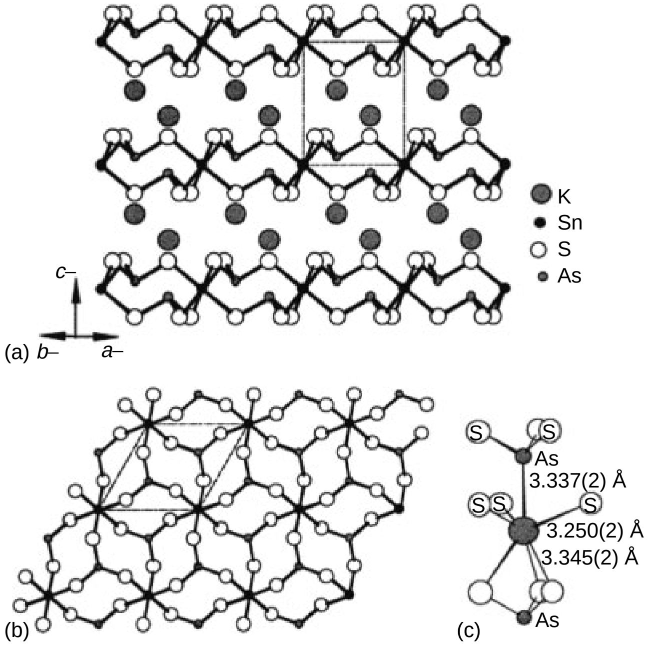

Figure 68 (a) Structure of $K_2SnAs_2S_6$ looking down the *c*-axis. Large gray circles between the layers are K^+ ions. Small black circles are Sn atoms, small gray circles are As atoms, and open circles are sulfur atoms. (b) Single layer of $[SnAs_2S_6]^{2-}$ with the eight member –S–Sn–S–As–S–Sn–S–As–rings. (c) Local coordination environment of K ions with bond lengths and apparent bonding interaction of the As atom with the K ion at 3.337(2) Å is shown

the pyramidal S positions. However, the $[AsS_3]^{3-}$ pyramids are inverted in a way that the As^{3+} atoms of a $[AsS_3]^{3-}$ anion on the topside of a $[SnAs_2S_6]^{2-}$ slab lie toward the slab's interior so that the lone electron pair is directed to the bottom side (Figure 68). This 'expanded TiS_2' structure creates large rings in the layers that dominate the two-dimensional network. Noteworthy is the unusual and surprising interaction at 3.337(2) Å between K^+ ions in the layers and the As atom of a $[AsS_3]^{3-}$ ligand, which in fact lies on the opposite side of the $[SnAs_2S_6]^{2-}$ slab (Figure 68(c)). This is possible because of the inverted nature of the $[AsS_3]^{3-}$ anion.

5 CONCLUDING REMARKS

The highly diverse class of solid-state chalcogenides marks an important area of inorganic chemistry. Its importance stems from multiple perspectives, including its role in being part of the foundation on which inorganic chemistry advances, its role as a basis for compounds with exceptional structural as well as physical properties, and finally its capacity to provide materials of technological relevance. The last two aspects were not touched upon in this article for reasons of space. Undoubtedly, a remarkable diversity in structure, composition, and properties exists in chalcogenide systems. Thanks to exploratory synthesis, a wealth of new materials is becoming available for study and investigation. Most of these could not have been anticipated prior to their synthesis. The rich chemistry that still lies within the less explored systems presages similar exciting materials discoveries in future investigations.

1 INTRODUCTION

The elements of group 17, fluorine, chlorine, bromine, iodine, and astatine, are collectively called the halogens and these are the most representative nonmetals in the periodic table (*see* ***Periodic Table: Trends in the Properties of the Elements***). The nonmetallic feature is indicated by the high value of the ionization potentials of the halogens, which are only 1−4 eV lower than those of the corresponding noble gas atoms. As a result, the halogens are extremely electronegative with strong electron affinities. Many general references are available and we list only a few.[1–4] The name 'halogen', based on a Greek word, is intended to describe the ability of these elements to combine directly with metals to form salts.

The diatomic nature of the elemental halogens clearly indicates their nonmetallic nature. Only hydrogen, nitrogen, and oxygen share this property under normal conditions. The increase of the boiling points, melting points, and volatility of the halogens are compatible with the increase in the van der Waals' forces with advancing size and *Polarizability* of the atoms and molecules.

Everyday uses of halogens or their compounds are well known, such as the use of chlorine in purifying drinking water, the use of iodine as an antiseptic, and the use of bromine in photographic films as the compound silver bromide.

The title of this article includes all the halogens except the first: fluorine (*see* ***Fluorine: Inorganic Chemistry***). Although the halogens form a remarkable homologous series, certain discontinuities are evident. Principal among these is the exceptional nature of fluorine and its chemically reactive compounds. It has, therefore, become customary to separate the discussion of fluorine chemistry from the rest of the halogens and treat this as a separate subject.

2 ATOMIC STRUCTURE

Some atomic properties are summarized in Table 1 and these are further discussed in the sections that follow.

2.1 Electronic Configuration

The electronic configuration of the halogen atoms in their ground state is ns^2np^5, just one electron short of the corresponding noble gas electronic configuration with the so-called inert octet. This electronic structure makes the halogens extremely powerful electron acceptors with the highest electron affinities of all atomic elements (*see Electron Affinity*). Consequently, the ionization potentials of the halogens are the highest known, except for the noble gases (*see Ionization Potential*). As a result, the dominant feature of the halogens is the ease with which their atoms accept an electron, forming either a uninegative anion X^-, or a single covalent bond –X. The compounds formed therefore range from ionic salts at one extreme to covalent molecules at the other.

In addition to the possibility of forming monoatomic anions at the −1 valency state or monovalent covalent bonds, the halogens can also form bridges between two other atoms, in a manner similar to hydrogen bonding, through the formation of covalent bonds with the two-bridged atoms. Many halogen compounds exist, in which the central halogen has a formal oxidation state of +1, +3, +5, and +7, as in the oxyhalogen species, and some cationic species are also known.

2.2 Stable Isotopes

Several chlorine isotopes exist with mass numbers ranging between 32 and 40. The two stable isotopes are ^{35}Cl and ^{37}Cl with natural abundances of 75.77% and 24.23% respectively, while the others are radioactive. Bromine also has two stable isotopes, ^{79}Br and ^{81}Br, with natural abundances of 50.69% and 49.31% respectively, while the others are radioactive. Iodine has only one stable isotope, ^{127}I, and numerous radioactive ones are known. Astatine is known only as its radioisotope (*see Radioactive Decay*).

Radioisotopes of the halogens have found uses in studies of exchange reactions and reaction mechanisms. A radioactive iodine isotope is used in medical diagnostics.

Table 1 Atomic properties of the halogens

Property	Cl	Br	I	At
Atomic number	17	35	53	85
Atomic weight	35.453	79.904	126.9045	209.99
Ionization energy ($kJ\,mol^{-1}$)	1255.7	1142.7	1008.7	(926)

2.3 Magnetic Moments

The fluorine atom has a nuclear spin number of 1/2, similar to that of hydrogen, and is therefore suitable for NMR measurements, giving narrow lines. The other halogens have nuclear spin numbers $>1/2$ (3/2 for chlorine and bromine, 5/2 for iodine), and so are unsuitable for NMR studies.

3 MOLECULAR PROPERTIES

3.1 Occurrence

Chlorine was the first halogen to be isolated and sodium chloride, common salt, has been known from early times as being essential to the human diet; as such it has been mentioned in the Bible. Aqua regia, a mixture of hydrochloric and nitric acids, has been known since the thirteenth century as a liquid for dissolving the very inert metal, gold. The ancient color mentioned in the Bible as purple has been identified as a brominated organic compound, namely 6,6-dibromoindigo, which used to be extracted from a small snail.

Since the halogens are very reactive, they are never found in nature as free elements. However, they are widespread and abundant in the form of salts, mostly containing the halide anion. Large quantities of NaCl and KCl are found in pure form as mineral deposits and can be mined directly. However, larger quantities are dissolved in water, as in oceans, inland seas, lakes, and brines (e.g. the Great Salt Lake of Utah and the Dead Sea in Israel). The liquid sources are usually concentrated by solar evaporation and the concentrated brines are then processed to obtain the salts present. Iodine is found in the sea as the iodide and also in Chile as an iodate salt, IO_3^-. Chlorine is the 20th most abundant element in crystal rocks, bromine the 46th, and iodine the 60th.

3.2 Production and Uses

Chlorine can be obtained in the laboratory by oxidation of HCl with a strong oxidizer such as manganese dioxide (equation 1). The industrial production of chlorine is a major section of the heavy chemical industry and is based on electrolytic oxidation of the chloride anion. Chlorine, sodium hydroxide, and hydrogen are produced by the electrolysis of aqueous solutions of sodium chloride (equation 2), whereas in the electrolysis of the molten NaCl salt, the coproduct is sodium metal, rather than sodium hydroxide. The old Deacon process was based on the copper-catalyzed reaction (equation 3). This has been made more efficient by passing HCl over CuO at 200 °C to give $CuCl_2$ and H_2O after which $CuCl_2$ at 300 °C is treated with O_2.

$$MnO_2 + 4HX \longrightarrow MnCl_2 + X_2 + 2H_2O \ (X = Cl, Br) \quad (1)$$

$$Cl^- + H_2O \longrightarrow OH^- + \tfrac{1}{2}Cl_2 + \tfrac{1}{2}H_2 \quad (2)$$

$$2HCl + \tfrac{1}{2}O_2 \longrightarrow Cl_2 + H_2O \quad (3)$$

The main uses of chlorine are the following: (1) the production of chloro-organic compounds, such as vinyl chloride and ethylene dichloride for the plastics industry, as solvents, refrigerants, insecticides, and dyes (about 70%); (2) as a bleaching agent of paper, pulp, and textiles, and the disinfection of water supplies (about 20%); and (3) for the production of a large variety of inorganic chemicals, particularly covalent compounds.

Bromine can be obtained by oxidation of HBr with manganese dioxide (equation 1) or nitric acid. Industrially, bromine is produced by oxidation of the bromide anion with elemental Cl_2 (equation 4). Elemental Br_2 is then blown out of the solution by passing steam or air through it. The vapor is then condensed or fixed chemically and finally purified.

$$2Br^- + Cl_2 \longrightarrow Br_2 + 2Cl^- \quad (4)$$

The industrial use of bromine was dominated by the production of ethylene dibromide as a valuable additive to gasoline to act as a scavenger for lead in the antiknock additive tetraethyllead. Now that the use of Et_4Pb in gasoline has been reduced, this consumption of bromine has also been reduced. The pesticide industry uses large quantities of bromine, and an increasing demand also exists in fire-retardant materials such as fibers and wood. A well-known use of bromine is as AgBr in the photographic industry.

Iodine is produced by similar methods, namely, oxidation of the iodide anion from brines by chlorine. However, iodine is also produced in a reductive process by reacting $NaIO_3$, extracted from the natural source of Chilean saltpeter, with sodium hydrogen sulfite. The pentavalent iodine is reduced to iodide (equation 5), which is then treated and oxidized with a sufficient amount of the mother liquor to liberate elemental iodine (equation 5). In contrast to chlorine and bromine, which have large industrial uses, iodine has no predominant commercial use.

$$[IO_3]^- + 3[HSO_3]^- \longrightarrow I^- + 3[HSO_4]^- \quad (5)$$

$$5I^- + [IO_3]^- + 6H^+ \longrightarrow 3I_2 + 3H_2O \quad (6)$$

The artificial radioactive element astatine is prepared by bombarding bismuth metal or bismuth oxide by α particles,

producing 20 isotopes. Among them, the longest-living species are ^{210}At (8.3 h) and ^{211}At (7.2 h). The astatine is separated from the bismuth source either by distillation or by extraction. In the first method, on the basis of the high volatility of astatine, the reaction takes place in a current of nitrogen or in vacuo, by heating the source to 300–600 °C. The astatine is then condensed on a cold surface. In the extraction process, the bismuth source is dissolved in perchloric acid containing some iodine that serves as a carrier of the astatine. The bismuth is then precipitated as a phosphate and the remaining liquid can serve as an aqueous solution of astatine iodide, AtI.

3.3 Physical Properties

The halogens are volatile, diatomic elements whose color increases with increasing atomic numbers. Chlorine is a yellow–green gas at room temperature, bromine is a dark red liquid, and iodine is a lustrous, black, crystalline solid with a high vapor pressure that sublimes easily.

Although the thermodynamically stable form of the halogens is as diatomic molecules, these can easily dissociate into halogen atoms by using various techniques such as thermal dissociation at elevated temperatures, discharge reactions by electrodes, microwave, or photochemical reactions. In an electrical discharge at ambient temperatures and gas pressures of less than 1 mmHg, the degree of atomization can be 10–40%. In many organic halogenation processes, it is assumed that the reactions involve atomic halogen and the property of photodissociation is actually used in some organic halogenations.

The enthalpy of dissociation decreases as the mass number increases along the series. However, there exists a discontinuity (the value for F_2 is similar to that of I_2), and thus there is an increase when going from F_2 to Cl_2. This trend is also observed in other groups of the periodic table. In groups 15 and 16, the single bonds of the first elements in those groups, N–N in hydrazine and O–O in peroxides, are weaker than those of the following heavier elements, P–P and S–S, respectively. Some of these properties are summarized in Table 2.

3.4 Bonding in Diatomic Molecules

The bonding in the diatomic halogen molecules can be described in terms of simple ***Molecular Orbital Theory***, as

Table 2 Physical properties of the molecular halogens

Property	Cl_2	Br_2	I_2
Melting point (°C)	−101.0	−7.25	113.6
Boiling point (°C)	−34.9	59.5	185.2
H_{dissoc} (kJ mol^{-1})	242.58	192.77	151.10
Vibrational frequency (cm^{-1})	$^{35}Cl_2$ 559.72	$^{79}Br\,^{81}Br$ 324.24	$^{127}I_2$ 214.52

depending on the balance between six electrons in bonding orbitals ($\sigma_g^2\pi_u^4$) and four in antibonding orbitals (π_g^4). This fits a diamagnetic ground state with a bond order of unity.

The electronic spectra of the halogens arise from absorption bands corresponding to the electronic transitions, in which an electron is excited from the antibonding π_g to the antibonding σ_u orbital (equation 6). The separation between these two orbitals decreases as the atomic number of the halogen increases.

$$\sigma_g^2\pi_u^4\pi_g^4 \longrightarrow \sigma_g^2\pi_u^4\pi_g^3\sigma_u^1 \qquad (7)$$

3.5 Solution and Charge-transfer Complexes

The halogens are soluble in numerous solvents, although their great chemical reactivity can cause solvolysis or halogenation of the solvent to take place.

Chlorine is moderately soluble in, but reactive with, water. It can form a gas hydrate $Cl_2{\cdot}7.3H_2O$ from Cl_2 on aqueous $CaCl_2$ at 0 °C. Bromine is also soluble in H_2O; it gives a crystalline hydrate, which appears to have a unique, noncubic structure, with a formula of $Br_2{\cdot}7.9H_2O$. In addition, 16 different crystals of distinct compositions ($Br_2{\cdot}8.62H_2O$ to $Br_2{\cdot}10.68H_2O$) and morphologies[5] show that there is just a single, tetragonal structure as proposed in 1963.

Iodine dissolves only slightly in water but its solubility can be increased in aqueous iodide solutions as a result of the formation of polyiodides (equation 8).

$$I_2 + I^- \longrightarrow [I_3]^- \qquad (8)$$

Iodine is also readily soluble in a variety of organic solvents, such as EtOH, CCl_4, benzene, and others. The color of these solutions depends on the solvent type. Solutions in strong donors such as alcohols, ethers, or amines are deep brown with maximum absorbance in the visible region of 450–480 nm. In aliphatic halocarbons, such as $CHCl_3$ or CCl_4, the color is violet with maximum absorbance in the region of 520–540 nm, whereas in aromatic hydrocarbons, such as benzene or toluene, the color is pink or reddish brown with maximum absorbance in the region of 490–510 nm.

It is assumed that the weak donor–acceptor interactions which form charge-transfer complexes L → X–X between the donor solvent and the halogen acceptor are the source of the different optical transitions. The existence of the vacant antibonding σ_u orbital in the halogen furnishes their acceptor capacity and allows a donor molecule to transfer charge to the halogen molecule. The acceptance of electrons in the antibonding orbital weakens the intramolecular X–X bond, which can even dissociate in extreme cases. With the increase of the D → A bond strength, the intramolecular bond of the halogen molecule becomes attenuated. In a notable case, of the complex $2C_5H_5N{\cdot}I_2$, the weakening of the I–I bond is so great as to break the covalent bond and to form the ionic complex $[(C_5H_5N)_2I]^+ [I_3]^-$.

Two kinds of donors can be considered: (1) σ-donors that possess nonbonding electrons, such as various nitrogen bases (e.g. amines, pyridines, and nitriles), oxygen bases (e.g. alcohols, ethers, and carbonyl compounds), and organic sulfides and selenides, forming $\sigma-\sigma$ complexes; (2) π-donors in which the donor function is performed by bonding π-orbitals such as in aromatic compounds (e.g. benzene and polycyclic aromatics), forming $\sigma-\pi$ complexes.

Numerous solid complexes, as chains or sheets, have been crystallized from brown solutions of iodine, whether from σ-donors (particularly from those which have two coordination sites, such as the two separate oxygens in dioxane or one coordination atom with several nonbonding electron pairs of the oxygen of the carbonyl group in ketones), or from π-donors such as benzene. A well-known complex is the blue-colored starch–iodine, which serves as an analytical identification for iodine. Other examples are those of I_2/acridine dimers. $[(\text{acridine}\cdot I_2)_2]I_2$ adopts a zigzag shape (Figure 1), whilst those of the 9-chloroacridine analogue adopt a 'C' shape in the solid state and are decomposed by the loss of two I_2 molecules to generate $[(\text{9-Cl-acridine})_2I_2]$, which consists of two 9-Cl-acridine molecules bridged through N···I charge-transfer interactions with a single I_2 molecule.[6]

Cl_2 and Br_2, as well as ICl and IBr, have been found to behave similarly to I_2. For example, the interaction between *N*-methylbenzothiazole-2-selone with sulfuryl chloride in the solid state results in molecules of mbts·Cl_2. In the solid state, these T-shaped molecules interact via Cl···Cl intermolecular contacts to generate an extended structure of interlocking molecules with a zipper-like arrangement.[7] The low-temperature single-crystal structure of $C_6H_6\cdot Br_2$ and $MeC_6H_5\cdot Br_2$ revealed a localized form of bonding rather than the coaxial structure reported previously. The Br_2 molecule is oriented essentially perpendicular to the aromatic ring and is located at the rim of the molecule as shown in Figure 2.

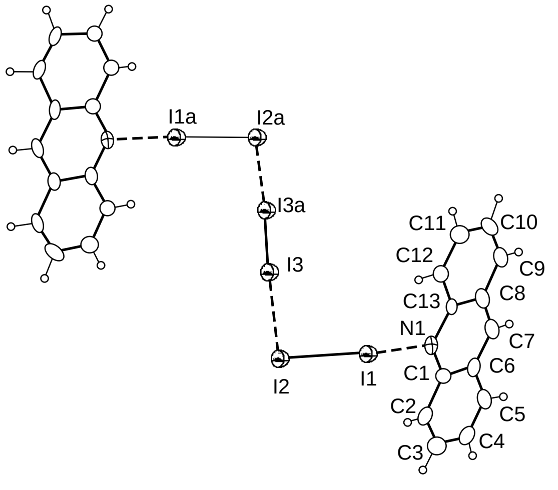

Figure 1 A perspective view of the Zigzag conformation of the $[(\text{aridine}\cdot I_2)_2]I_2$ dimer. (Reproduced by permission of Wiley-VCH)

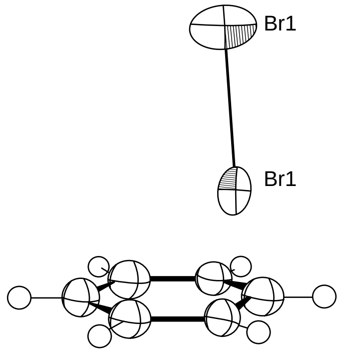

Figure 2 A view of the $C_6H_6\cdot Br_2$. (Ref. 8. Reproduced by permission of The Royal Society of Chemistry)

By considering all the Br···C distances, the interaction is interpreted as having a hapticity of 1.5, that is, it lies half-way between over-atom (η^1) and over-bond (η^2) for $C_6H_6\cdot Br_2$, whilst in $MeC_6H_5\cdot Br_2$, preference is shown for an over-bond interaction ($\eta = 1.7-1.86$) centered on the *ortho*- and *para*-carbons.[8]

Two intercalation compounds, $CsF\cdot Br_2$ and $2CsF\cdot Br_2$, were isolated from the reaction of CsF with Br_2. In the 1:1 compound, X-ray analysis revealed eclipsed Cs···F layers (Cs^+ positioned above Cs^+), whereas the layers in the 2:1 compound are staggered. In both compounds, the Br–Br distance is larger than that for free gaseous bromine, suggesting some charge transfer from fluoride to bromine.[9]

The structurally characterized charge-transfer complexes between Ph_3PS and ICl/IBr consist of discrete molecular units with linear S···I–Cl/Br interactions.[10]

Although charge transfers generally involve organics, halogen adducts of metal complexes are known. An example is that the reaction of the metal-based Lewis acid $[Rh_2(O_2CCF_3)_4]$ system with I_2 results in a bridging coordination mode for iodine. As shown in Figure 3, in the solid state, dimeric rhodium complexes are linked together in a zigzag chain by interacting with neutral I_2 molecules, in which each I_2 molecule is believed to be functioning as an electron-pair donor to the rhodium atoms.[11] The reaction of $[NBu_4][PtX_3(CO)]$ (X =

Cl, Br) with dibromine gave rise to the platinum(IV) salts $[NBu_4]_2[Pt_2Br_{10}]\cdot(Br_2)_7$ and $[NBu_4]_2[PtBr_4Cl_2]\cdot(Br_2)_6$, which in the solid state form a polymeric network of bromine–bromine interactions.[12]

The relative acceptor strengths of the halogens and diatomic interhalogens to a given donor is: ICl > BrCl > IBr > I_2 > Br_2 > Cl_2. Similarly, the donor capacity to a given halogen is: benzene < polyalkylbenzenes ∼ alkyl iodides ∼ alcohols ∼ ethers ∼ ketones < organic sulfides < organic selenides < amines. Many organic halogenation reactions are explained on the basis of the presence of intermediates of halogen charge-transfer complexes.

3.6 Biological Action of Halogens

As vapors, all the halogens are highly irritating and react with the respiratory system, mucous membranes, eyes, and lungs. Exposure to high concentrations can be fatal.[13] This is true more for chlorine and bromine than for iodine, which is less volatile; in World War I, chlorine was used as an agent in chemical warfare.

4 HALOGEN COMPOUNDS

A majority of the halides of the pretransition metals in groups 1 and 2 of the periodic table, as well as those of the lanthanides and actinides at the valence states of +2 and +3, are usually ionic compounds, whereas the nonmetals and metals with valency states ≥3 are usually covalent halides.

4.1 Ionic Halides

In general, the greater the difference in electronegativity between the element and the halogen, the greater will be the charge separation and the better will be the ionic model. On the other hand, with an increase in the formal charge on the central atom or with a decreasing electronegativity difference, the better will be the covalent model.

The ionic halides, such as those of groups 1 and 2, exist as involatile solids with a three-dimensional lattice, whereas the semiionic halides, such as those of groups 11 and 12, form layers and chain structures.

In a series of the more ionic halides with the same metal, the melting and boiling points decrease with the increasing atomic number of halogen, following the sequence $MF_n > MCl_n > MBr_n > MI_n$; in a covalent series this sequence will be reversed: $MI_n > MBr_n > MCl_n > MF_n$.

Ionic halides dissolve easily in polar coordinating solvents with a high dielectric constant, such as water, whereas the covalent halides dissolve better in nonpolar, organic solvents.

Halide anions can also react with covalent halides to form complexed anionic species.

4.2 Covalent Halides

Covalent halides can be prepared by various synthetic routes. The simplest are direct reactions of elemental halogens (equation 9), or hydrogen halides with elements (equation 10) or oxides (equation 11). In other processes, the oxides are reacted with a halogen halide in the presence of carbon to combine with the oxygen (equation 12) or other reactive carbon–halides (equation 13). Exchange of halogens can also take place (equations 14–16). Anhydrous halides can also be obtained by dehydration of metal halide hydrates, using reactants such as thionyl halide, which react with the hydrated water (equation 17).

$$M + X_2 \longrightarrow MX_2 \quad (9)$$

$$2M + 2HX \longrightarrow 2MX + H_2 \quad (10)$$

$$MO + 2HX \longrightarrow MX_2 + H_2O \quad (11)$$

$$Ta_2O_5 + 5C + 10Br_2 \xrightarrow{>460\,^\circ C} 2TaBr_5 + 5COBr_2 \quad (12)$$

$$Nb_2O_5 + 5CBr_4 \xrightarrow{370\,^\circ C} 2NbBr_5 + 5COBr_2 \quad (13)$$

$$FeCl_3 + xs\ BBr_3 \longrightarrow FeBr_3 + BCl_3 \quad (14)$$

$$MCl_3 + xs\ 3HBr \longrightarrow MBr_3 + 3HCl \quad (15)$$

$$3TaCl_5 + xs\ 5AlI_3 \longrightarrow 3TaI_5 + 5AlCl_3 \quad (16)$$

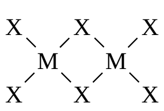
$$MCl_x\cdot yH_2O + ySOCl_2 \longrightarrow MCl_x + ySO_2 + 2yHCl \quad (17)$$

In general, with the same central atom, the covalency of the corresponding halides will decrease with a decreasing halogen mass, namely, $MI_n > MBr_n > MCl_n$, as a result of the decrease of the polarizability, which is greatest in iodine and least in chlorine. The covalent halides have lower melting and boiling points than related ionic halides with isoelectronic central elements.

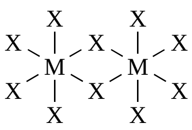
Usually, covalent halides hydrolyze in aqueous solutions forming oxides or hydroxides, but many transition element halides form ionic hydrates.

4.3 Covalent Polymeric Halides

The odd coordination numbers 1, 3, and 5 are not as stable as the even coordination numbers 2, 4, and 6 (*see* ***Coordination Numbers & Geometries***). Therefore, binary covalent halides of group 13 and 15 elements, MX_3 and MX_5, tend to dimerize into M_2X_6 (**1**) and M_2X_{10} (**2**), the central atoms having coordination numbers of four or six, respectively. In these dimers, halogen-bridging bonds exist in addition to the terminal halogen bonding.



(**1**)



(**2**)

Although the vapor of phosphorous pentachloride is a covalent compound, in the solid phase it exists as a complexed ionic salt, in which both ions have a high degree of symmetry, the cation being tetracoordinated and the anion hexacoordinated (equation 18).

$$(PCl_5)_2 \longrightarrow [PCl_4]^+[PCl_6]^- \quad (18)$$

In contrast to fluorine, which can form binary fluorides in very high oxidation states such as six, even seven, and perhaps eight (*see* ***Fluorine: Inorganic Chemistry***), few hexahalides are known for the other halogens; there are three chlorides, WCl_6, $ReCl_6$, and UCl_6, and only one bromide, WBr_6.

4.4 Halide Complexes

Covalent mono-, tri-, tetra-, and pentavalent halides tend to form anionic complexes with coordination numbers of two (equation 19), four (equations 20 and 21), and six (equations 22 and 23). Such reactions take place mostly through the addition of halide anions.

$$AgCl + Cl^- \longrightarrow [AgCl_2]^- \quad (19)$$

$$Al_2Cl_6 + 2Cl^- \longrightarrow 2[AlCl_4]^- \quad (20)$$

$$HgI_2 + 2I^- \longrightarrow [HgI_4]^{2-} \quad (21)$$

$$SnBr_4 + 2Br^- \longrightarrow [SnBr_6]^{2-} \quad (22)$$

$$SbCl_5 + Cl^- \longrightarrow [SbCl_6]^- \quad (23)$$

Some liquid covalent halides can act as nonaqueous solvents[14] based on Lewis acid–base behavior, according to the donor–acceptor definition. The self-dissociated ions consist of a cation formed by subtraction of a halide ion from the neutral compound, while the anion is formed by its addition (equation 24). Salts derived from such covalent halides can be considered as titration products of the parent acidic and basic compounds (equations 25 and 26). In such cases, both the cation and the anion usually possess a stable coordination number with a high geometrical symmetry.

$$2MX_n \longrightarrow [MX_{n-1}]^+ + [MX_{n+1}]^- \quad (24)$$

$$PCl_5 + SbCl_5 \longrightarrow [PCl_4]^+[SbCl_6]^- \quad (25)$$

$$PBr_5 + BBr_3 \longrightarrow [PBr_4]^+[BBr_4]^- \quad (26)$$

4.5 Molecular Structures and its Determination

The geometric structure of the covalent binary halides, whether neutral or complexed ions, can be explained on the basis of the Nyholm–Gillespie rules known as the Valence Shell Electron Pair Repulsion Model (VSEPR) theory; the geometrical arrangements of the bonds around an atom in a species depends on the total number of electron pairs in the valence shell of the central atom, including both bonding pairs and nonbonding (unshared) pairs. The electron pairs in the valence shell adopt the arrangement that maximizes the distance between any two pairs, thereby decreasing their electrostatic interaction.

Table 3 Stereochemistry of halogen compounds[a]

Number	Geometry (symmetry)	Coordination examples
1 AXE_3	Diatomic unit	X_2, HX, XY
2 AX_2E_3	Linear ($D_{\infty h}$)	$[X_3]^-$, $[XY_2]^-$, $[XYZ]^-$
AX_2E_2	Angular (C_{2v})	$[XY_2]^+$, XO_2, $[XO_2]^-$
3 AX_3E	Trigonal pyramid (C_{3v})	PCl_3, $[XO_3]^-$
AX_3	Trigonal planar (D_{3h})	BCl_3
AX_3E_2	T-shaped, trigonal bipyramid with two vacant equatorial sites (C_{2v})	XF_3, $RICl_2$
4 AX_4	Tetrahedral unit (T_d)	$SnCl_4$, $[XO_4]^-$, $FClO_3$
AX_4E_2	Square-planar unit (D_{4h})	$[XY_4]^-$, I_2Cl_6

[a]E = nonbonding electron pair.

Experimentally, the structures are determined by the use of various physical methods such as vibrational spectroscopy, both in the Raman and IR, NMR, or diffraction methods. Other accepted physical measurements, such as conductivity, cryoscopy, magnetic properties, electronic spectra in the UV and visible ranges, nuclear quadrupole resonance (NQR), and Mössbauer spectroscopy have also been applied. Table 3 summarizes various geometric structures found in halogen compounds, coordination numbers, bonding and nonbonding electronic arrangements, and symmetries.

5 INTERHALOGEN COMPOUNDS[15,16]

All halogens can combine with each other to form interhalogen compounds with compositions XY, XY_3, XY_5, and XY_7. The central halogen, X, is always the heavier and less electronegative one and, therefore, no interhalogen exists in which fluorine is the central atom. All interhalogens XY_n, in which $n > 1$ are halogen fluorides, XF_n, except for ICl_3, which exists only as the solid dimer I_2Cl_6. On the other hand, compounds XY exist in which Y = F, Cl, and Br. IF_7 is the only compound with this high coordination number, whereas XY, XF_3, and XF_5 compounds exist with X = Cl, Br, and I.

5.1 Preparation of Interhalogens

Most preparations take place by direct reaction of the two elements to form binary interhalogens (equations 27 and 28). Since the reactions between the same pair of halogens are equilibria, interhalogens with different compositions can be formed, depending on the working conditions such as relative concentrations, temperature, and pressure (equations 29–32).

$$I_2 + Br_2 \longrightarrow 2IBr \qquad (27)$$

$$I_2 + 3Cl_2 \longrightarrow I_2Cl_6 \qquad (28)$$

$$X_2 + 3F_2 \xrightarrow{200-300\,°C} 2XF_3 (X = Cl, Br) \qquad (29)$$

$$I_2 + 3F_2 \xrightarrow{-78\,°C} 2IF_3 \qquad (30)$$

$$Cl_2 + xs\ F_2 \xrightarrow[250\,atm]{350\,°C} 2ClF_5 \qquad (31)$$

$$I_2 + 5F_2 \xrightarrow{25\,°C} 2IF_5 \qquad (32)$$

The compound BrF can be prepared by fluorinating bromine not with elemental fluorine but with a higher bromine fluoride in a disproportionation reaction (equations 33 and 34). Fluorination of halides (equation 35) instead of elemental halogen is sometimes preferable, leading to purer products. Interhalogen compounds also include astatine ones such as AtCl, AtBr, and AtI.

$$Br_2 + BrF_3 \longrightarrow 3BrF \qquad (33)$$

$$2Br_2 + BrF_5 \longrightarrow 5BrF \qquad (34)$$

$$KI + 4F_2 \longrightarrow KF + IF_7 \qquad (35)$$

The interhalogens, particularly the halogen fluorides, are chemically very reactive materials and hydrolyze easily. The handling and manipulation of these, their derivatives, and cationic or anionic species have to be performed using the safety precautions customary in fluorine chemistry (exclusion of moisture and air, and in vacuum lines constructed from materials that are resistant to fluorine). The properties of the interhalogens are intermediate between those of their parent halogens, and some physical properties are summarized in Table 4.

5.1.1 *Diatomic Interhalogens XY*

All six possible interhalogens of this type exist. Out of these, the gaseous ClF is very stable, ICl and IBr are moderately stable and are pure crystalline materials at room temperature, whereas BrCl dissociates easily and reversibly into its elements (equation 36); BrF and IF disproportionate into a higher fluoride and Br_2 or I_2 (equation 37). IBr, a solid resulting from direct combination of the elements, is endothermic and extensively dissociated in the vapor. The structure of ClF, determined at – 188 °C, represents the only

Table 4 Physical properties of the interhalogens

Compound	Mp (°C)	Bp (°C)	Form at room temp.
ClF	−155.6	−100.1	Colorless gas
BrF	−33	20	Pale brown gas
BrCl	−66	5	Red-brown gas
ICl	27.2	100	Ruby red crystals
IBr	41	116	Black crystals
ClF_3	−76.3	11.8	Colorless gas/liquid
BrF_3	8.8	125.8	Straw-colored liquid
I_2Cl_6	101	Dissociates	Bright yellow solid
ClF_5	−103	−13.1	Colorless gas
BrF_5	−60.5	41.3	Colorless liquid
IF_5	9.4	104.5	Colorless liquid
IF_7	6.5	4.8	Colorless gas

example of a halogen monofluoride structure. The structure is not like α- or β-ICl or IBr. The ClF molecules form infinite planar ribbons characterized by very short intermolecular Cl···Cl contacts [3.070(1) Å].[17]

$$2BrCl \underset{25\,°C}{\overset{CCl_4}{\rightleftharpoons}} Br_2 + Cl_2 \qquad K = 0.145 \qquad (36)$$

$$3XF \longrightarrow XF_3 + X_2 \qquad (X = Br, I) \qquad (37)$$

The chemical reactivities of the interhalogens are usually characterized by halogenation by the more electronegative element (equations 38 and 39). Sometimes, both halogens act as halogenation agents to form bonds with the same compound (equations 40–43).

$$W + 6ClF \longrightarrow WF_6 + 3Cl_2 \qquad (38)$$

$$Se + 4ClF \longrightarrow SeF_4 + 2Cl_2 \qquad (39)$$

$$CO + ClF \longrightarrow COFCl \qquad (40)$$

$$RCN + 2ClF \longrightarrow RCF_2NCl_2 \qquad (41)$$

$$SO_3 + ClF \longrightarrow ClOSO_2F \qquad (42)$$

$$SF_4 + ClF \longrightarrow SF_5Cl \qquad (43)$$

The interhalogens AtI, AtBr, and AtCl can also be formed by direct reaction of astatine with iodine, bromine, and chlorine respectively; excess of the lighter halogen can be pumped off in vacuo.

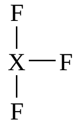
5.1.2 *Halogen Fluorides XF_3, XF_5, and IF_7*

Four tetraatomic interhalogens are known, namely, ClF_3, BrF_3, IF_3, and ICl_3, which is actually the solid dimer I_2Cl_6.

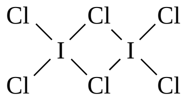
ClF_3 and BrF_3 are well-characterized volatile molecular liquids with a T-shaped structure (**3**). However, the related ICl_3 exists only as the solid dimer I_2Cl_6 with a planar structure (**4**) containing four terminal I–Cl bonds and two bridging I–Cl–I bonds with differing bond distances. The halogen fluorides are extremely powerful fluorinating agents. In particular, ClF_3 acts as such even at room temperature,

while reacting elemental fluorine, under similar conditions, may require some preheating. This extreme reactivity of ClF_3 seems to result from the fact that it is in equilibrium with the dissociated species, ClF, and fluorine atoms, the fluorine radicals being more reactive than molecular fluorine itself (equation 44).

$$ClF_3 \longrightarrow ClF + 2F \qquad (44)$$



(**3**)



(**4**)

As shown in Figure 4, IF_3 has a polymeric structure based on planar T-shaped molecules [F–I–F = 160.3(2)°]. Intermolecular interactions to two adjacent molecules occur, which result in an unusual planar pentagonal coordination geometry around the iodine atom; this is quite unlike that seen for BrF_3 or ClF_3.[18]

All the halogens form hexaatomic halogen fluorides ClF_5, BrF_5, and IF_5, with a square pyramidal structure of C_{4v} symmetry, but IF_7 is the only one known with the highest coordination number of seven. This latter compound has a pentagonal bipyramidal structure with D_{5h} symmetry. All the halogen fluorides are very vigorous fluorinating agents, the least of them being IF_5. The order of reactivity is approximately $ClF_3 > ClF_5 > BrF_5 > IF_7 > ClF > BrF_3 > IF_5 > BrF > IF_3 > IF$.

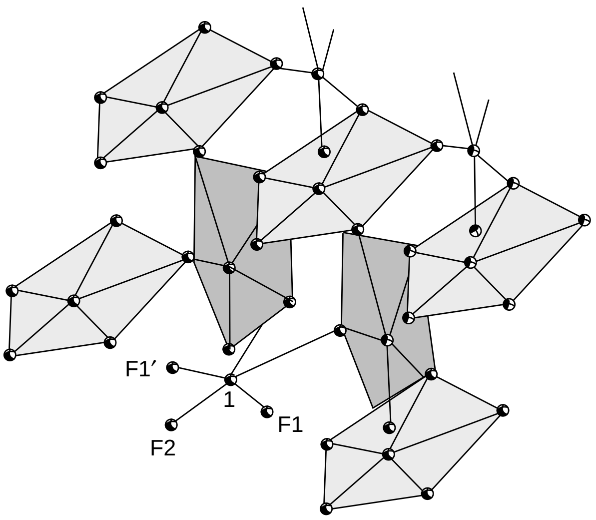


Figure 4 A view of the solid-state structure of IF_3 showing the intermolecular contacts resulting in a planar pentagonal geometry around each iodine center. (Reproduced by permission of Wiley-VCH)

5.2 Polyhalogen Cations[19–21]

Cation formation is not restricted, as normally observed, to association with metallic species. It can also occur among nonmetals and even the most typical ones such as halogens or interhalogens, which are usually more noted for halide and polyhalide anion formation.

There are two kinds of polyhalogen cations. The isopolyhalogen cations contain several atoms of the same halogen, whereas the heteropolyhalogen cations contain several atoms of at least two different halogens.

The formation of these cations can be considered as being derived from the self-ionic dissociation of the neutral halogens or interhalogens (equation 45). As with the interhalogens, the central atom is always the heavier and less electronegative one, even if this causes an unsymmetrical structure such as Cl–Cl–F (instead of Cl–F–Cl; equation 46). Sometimes the derived cation becomes polymerized, as in $[I_3Cl_2]^+$, which is a derivative of ICl (equation 47). In the case of elemental halogens, several ionic equilibria are possible, and different isopolyhalogen cations can be obtained from the same halogen (equations 48–50) depending on reaction conditions such as the acidity of the reactants. All the different varieties of such cations have been synthesized, characterized, and studied.

$$2XY_n \longrightarrow [XY_{n-1}]^+ + [XY_{n+1}]^- \qquad (45)$$

$$3ClF \longrightarrow [Cl\text{-}Cl\text{-}F]^+ + [F\text{-}Cl\text{-}F]^- \qquad (46)$$

$$4ICl \longrightarrow [I_3Cl_2]^+ + [ICl_2]^- \qquad (47)$$

$$3X_2 \longrightarrow [X_3]^+ + [X_3]^- \qquad (48)$$

$$4X_2 \longrightarrow [X_5]^+ + [X_3]^- \qquad (49)$$

$$5X_2 \longrightarrow 2[X_2]^+ + 2[X_3]^- \qquad (50)$$

5.2.1 Preparation of Polyhalogen Cations

On the basis of self-ionic dissociation, these compounds can be prepared by acid–base reactions. Heteropolyhalogen cations are usually prepared by reacting the parent compound with a Lewis acid (equation 51) in which XY_n = interhalogen and MY_m = Lewis acid, for example, halides of B, Al, P, As, and Sb, and so on (equations 52 and 53). Such reactions can be performed by direct interaction of the reactants with an excess of the more volatile reactant, which can then be pumped off, after completion of the reaction, leaving behind the pure product. Sometimes it is preferable to perform such reactions in solution, such as in anhydrous hydrogen fluoride (AHF), and pump off the solvent at the end of the reaction.

$$XY_n + MY_m \longrightarrow [XY_{n-1}]^+ + [MY_{m+1}]^- \qquad (51)$$

$$ICl_3 + AlCl_3 \longrightarrow [ICl_2]^+[AlCl_4]^- \qquad (52)$$

$$BrF_5 + AsF_5 \longrightarrow [BrF_4]^+[AsF_6]^- \qquad (53)$$

Another synthetic route is the oxidative process, which is mostly applied to the formation of isopolyhalogen cations

from elemental halogens or from diatomic interhalogens. An oxidizer is required in addition to the Lewis acid (equations 54–58), but sometimes the Lewis acid itself can also serve as an oxidizing agent (equations 59 and 60). Some heteropolyhalogen cations can also be obtained by oxidation reactions (equation 61).

$$7I_2 + KIO_3 + 8AlCl_3 \longrightarrow 5[I_3]^+[AlCl_4]^- \quad (54)$$

$$X_2 + S_2O_6F_2 \xrightarrow{\text{in } HSO_3F} \xrightarrow{SbF_5} [X_3]^+[Sb_3F_{16}]^- \quad (55)$$

$$Cl_2 + ClF + AsF_5 \xrightarrow{-78\,^\circ C} [Cl_3]^+[AsF_6]^- \quad (56)$$

$$\tfrac{3}{2}Br_2 + [O_2]^+[AsF_6]^- \longrightarrow [Br_3]^+[AsF_6]^- + O_2 \quad (57)$$

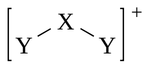
$$Au(s) + 4BrSO_3F \longrightarrow [Br_3]^+[Au(SO_3F)_4]^- + \tfrac{1}{2}Br_2 \quad (58)$$

$$3I_2 + 3MF_5 \longrightarrow 2[I_3]^+[MF_6]^- + MF_3 \ (M = As, Sb) \quad (59)$$

$$2I_2 + xs\ SbF_5 \longrightarrow 2[I_3]^+[Sb_2F_{11}]^- \quad (60)$$

$$I_2 + 2SbCl_5 + xs\ Cl_2 \longrightarrow 2[ICl_2]^+[SbCl_6]^- \quad (61)$$

Polyhalogen cations in solution can also be prepared in oxidative liquids such as sulfuric acid, oleum, or fluorosulfonic acid. The most common isopolyhalogen cations are $[X_3]^+$ and the higher oxidized ones $[X_2]^+$, although additional species such as $[X_5]^+$ and $[X_4]^{2+}$ have also been identified, with the $[I_7]^+$ ion being possible but uncertain. The preparation of the more highly oxidized cations $[X_2]^+$ requires stronger acidic conditions than the less oxidized $[X_3]^+$ types. All triatomic polyhalogen cations ($[X_3]^+$, $[XY_2]^+$) have a bent structure (**5**) with C_{2v} symmetry, while $[X_5]^+$ ions have planar, trans Z-type structures. For the $[I_2]^+$ ion, dimerization occurs to give a brown diamagnetic $[I_4]^{2+}$ ion when solutions are cooled. Salts containing this cation, for example, $[I_4{}^{2+}][AsF_6{}^-]_2$ have been isolated. This weak dimerization may be due to the overlap of half-filled p* orbitals on the two $[I_2]^+$ units.



(**5**)

It is interesting to note that oxidation reactions (equations 62–73) can produce heteropolyhalogen cations such as $[IBr_2]^+$, $[ClF_6]^+$, and $[BrF_6]^+$, although their parent interhalogens, IBr_3, ClF_7, and BrF_7, have never been isolated.

$$[Br_3]^+[Au(SO_3F)_4]^- + Br_2 \longrightarrow [Br_5]^+[Au(SO_3F)_4]^- \quad (62)$$

$$8Br_2 + 3[XeF]^+[AsF_6]^- \longrightarrow 3[Br_5]^+[AsF_6]^- + 3Xe + BrF_3 \quad (63)$$

$$2I_2 + ICl + AlCl_3 \longrightarrow [I_5]^+[AlCl_4]^- \quad (64)$$

$$2ClF + AsF_5 \longrightarrow [FCl_2]^+[AsF_6]^- \quad (65)$$

$$I_2Cl_6 + 2SbCl_5 \longrightarrow 2[ICl_2]^+[SbCl_6]^- \quad (66)$$

$$ClF_3 + AsF_5 \longrightarrow [ClF_2]^+[AsF_6]^- \quad (67)$$

$$Br_2 + IOSO_2F \longrightarrow [IBr_2]^+[SO_3F]^- \quad (68)$$

$$BrF_5 + 2SbF_5 \longrightarrow [BrF_4]^+[Sb_2F_{11}]^- \quad (69)$$

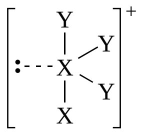
$$ClF_5 + PtF_6 \longrightarrow [ClF_6]^+[PtF_6]^- \quad (70)$$

$$2ClF_5 + 2PtF_6 \longrightarrow [ClF_6]^+[PtF_6]^- + [ClF_4]^+[PtF_6]^- \quad (71)$$

$$BrF_5 + [KrF]^+[AsF_6]^- \longrightarrow [BrF_6]^+[AsF_6]^- + Kr \quad (72)$$

$$IF_7 + BrF_3 \longrightarrow [IF_6]^+[BF_4]^- \quad (73)$$

Heteropolyhalogen cations with coordination numbers ≥4 exist only with fluorine ligands, namely, $[XF_4]^+$ and $[XF_6]^+$ (X = Cl, Br, and I). The pentaatomic polyhalogen cations $[XF_4]^+$ have a pseudo-trigonal bipyramidal structure (**6**) with C_{2v} symmetry, two fluorines being in the axial positions and two others in the equatorial triangular plane.



(**6**)

The structure of $[ClF_4]^+$ $[SbF_6]^-$ has a pseudo-trigonal bipyramidal geometry for the cation with two longer, more ionic, axial bonds and two shorter equatorial bonds. A pseudo-octahedral arrangement around the central chlorine atom results from interactions between the chlorine and neighboring fluorides of two adjacent $[SbF_6]^-$ anions to produce an infinite zigzag chain of alternating $[ClF_4]^+$ and $[SbF_6]^-$ moieties (Figure 5).[22] In the cases of $[BrF_4]^+$ and $[IF_4]^+$, they adopt a trigonal bipyramidal shape with one equatorial site occupied

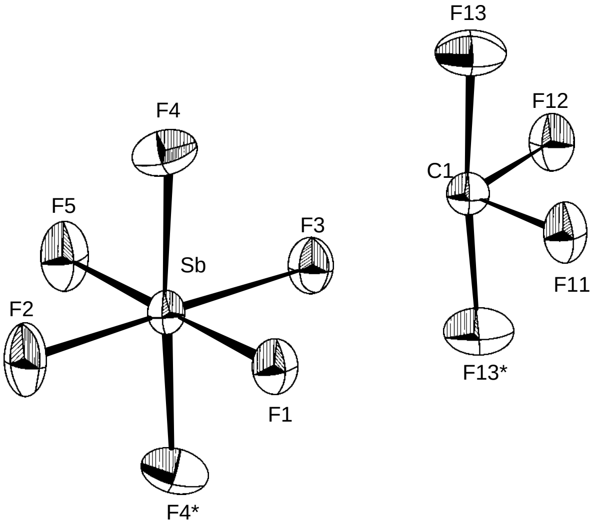


Figure 5 A view of the solid-state structure of $[ClF_4]^+$ $[SbF_6]^-$. (Reprinted with permission from Ref. 22. © 2001 American Chemcial Society)

by a lone pair of electrons. However, strong anion–cation interactions in $[BrF_4]^+$ $[Sb_2F_{11}]^-$ result in an infinite zigzag chain and distortion of the equatorial F–Br–F bond angle. In comparison, for $[IF_4]^+$ $[SbF_6]^-$, an infinite polymeric sheet motif is observed owing to four short I···F interactions, which results in a compression of the axial F–I–F angle.[23] The heptaatomic cations $[XF_6]^+$ are octahedral (O_h symmetry).

5.3 Polyhalide Anions[16,24–26]

A large number of polyhalide anions $[X_mY_nZ_p]^-$ exist in which $m + n + p = 3, 5, 7, 9$, and so on. Each of the numbers m, n, or p can equal 0. Thus, polyhalide anions can exist as isopolyhalide anions such as $[X_3]^-$, $[X_5]^-$, and $[X_7]^-$, or as binary or ternary heteropolyhalide types.

5.3.1 Preparation of Polyhalide Anions

The isopolyhalide anions can be prepared by reacting elemental halogen with the same monoatomic halide (equation 74). As mentioned before, polyhalide anions are the counterions of the self-dissociation process of interhalogens, and as such their preparation can take place by reacting an interhalogen with a Lewis base (equations 75–77). Some heteropolyhalides can be prepared by oxidation of simple halide anions (equations 78 and 79). The unique $[IF_8]^-$ anion can be made as its Me_4N^+ salt by interaction of IF_7 with Me_4NF in MeCN.

$$X_2 + X^- \longrightarrow [X_3]^- \quad (74)$$

$$[Et_4N]^+Cl^- + ICl_3 \longrightarrow [Et_4N]^+[ICl_4]^- \quad (75)$$

$$KF + BrF_3 \longrightarrow K^+[BrF_4]^- \quad (76)$$

$$MCl + 2F_2 \longrightarrow M^+[ClF_4]^- (M = K, Rb, Cs) \quad (77)$$

$$6MCl + xs\ 8BrF_3 \longrightarrow 6M^+[BrF_4]^- + 3Cl_2 + Br_2 (M = K, Ag, \tfrac{1}{2}Ba) \quad (78)$$

$$IF_7 + Me_4NF \longrightarrow [Me_4N]^+[IF_8]^- \quad (79)$$

In all the heteropolyhalide anions, the central atom is always the heavier and least electronegative halogen. Although three reactions (equations 80–82) with different starting anions can occur, a single anionic product, $[ICl_2]^-$, is obtained and no isomers are identified. The structure of $[PPh_4][ICl_2]$ shows an anion that is symmetric and nearly linear [Cl–I–Cl = 178.10(6)°].[27]

$$KI + Cl_2 \longrightarrow K^+[ICl_2]^- \quad (80)$$

$$PBr_5 + IBr \longrightarrow [PBr_4]^+[IBr_2]^- \quad (81)$$

$$K^+[ICl_4]^- + KI \longrightarrow 2K^+[ICl_2]^- \quad (82)$$

Astatine interhalogens AtY (Y = Br and I) also react with I^-, Br^-, and Cl^- to form heteropolyhalide anions (equation 83).

$$AtY + X^- \longrightarrow [AtYX]^- (X = I, Br, Cl; Y = Br, Cl) \quad (83)$$

The triatomic polyhalide anions have a linear structure (**7**), the pentaatomic ones $[XY_4]^-$ are square planar (**8**) with a D_{4h} symmetry, while the heptaatomic $[XF_6]^-$ have a distorted octahedral structure. The $[IF_8]^-$ ion has a square antiprismatic structure.

$[Y—X—Y]^-$

(**8**)

5.3.2 Stability

A solid polyhalide salt with the structure M^+ $[X_mY_nZ_p]^-$ tends to dissociate into a simple monohalide derivative of the cation M^+ with the most electronegative halogen, and a neutral halogen or interhalogen.

The stability of various polyhalide compounds with the same cation are as follows: $[I_3]^- > [IBr_2]^- > [ICl_2]^- > [I_2Br]^- > [Br_3]^- > [BrCl_2]^- > [Br_2Cl]^-$. The most stable compounds are those with iodine at the center. Similarly, the symmetric anions are more stable than the asymmetric ones, $[Cl–Br–Cl]^- > [Br–Br–Cl]^-$.

It is well known that a wide range of polyhalides exist for iodine, and most of these can be considered as arising from combinations of I_2, I^-, and $[I_3]^-$. Linear $[I_3]^-$ anions have been identified in numerous compounds such as $Co(C_6H_{12}S_3)(I_3)_2$,[28] $[Pr^nMe_2PhN](I_3)$,[29] and $Ag([18]aneS_6)(I_3)$.[30] The $[I_4]^{2-}$ anions are present in $[Cr(NH_3)_6](I_3)(I_4)$[31] and $[NH_4]_2[(AuI_4)AuI_2(\mu\text{-}I_4)]$.[32]

The V-shaped pentaiodide anions in $[\{Rh(\mu\text{-pz})I(CO)(PMe_2Ph)\}_2][I_5]$,[33] $[(Bu_3PSe)_2I][I_5]$,[34] $[C_{19}H_{16}FeNS][I_5]$,[35] and $[EtMe_3N][I_5]$[36] form extended polymeric layers, while $[EtMePh_2N][I_5]$ is of the rare isolated types.[37]

The anionic networks identified for $(DMFc)_4(I_{26})$[38] and $Ag([18aneS_6])(I_7)$,[30] despite the significantly different empirical compositions, are quite similar. For the former (Figure 6), the network may be derived from a primitive cubic lattice of iodide ions with I_2 bridges on all edges by systematically removing 1/12 of the I_2 molecules, while for the latter the iodide ions occupy the lattice points of a primitive rhombohedral lattice with I_2 bridges along all edges.

Cations embedded in a three-dimensional polyiodide network of cages of $[I_5]^-$ ions and diiodine molecules are presented in $[RhCl_2(C_{12}H_{24}S_4)](I_5){\cdot}I_2$.[39] In $[Pr^iMe_2PhN](I_8)$, the anion is best described as $[I_{16}]^{2-}$, which is present as 14-membered rings, catenated by diiodine molecules, and linked into layers with 10-membered and types of 14-membered rings.[30] In $[Pd_2Cl_2([18aneN_2S_4])_{1.5}I_5(I_3)_2$, infinite chains of

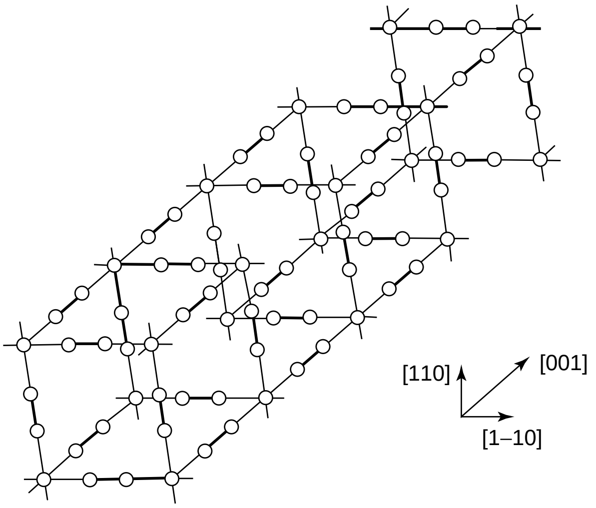

Figure 6 Primitive cubic lattice of iodide ions bridged by I_2 molecules in $(DMFc)_4(I_{26})$. (Reproduced by permission of Wiley-VCH)

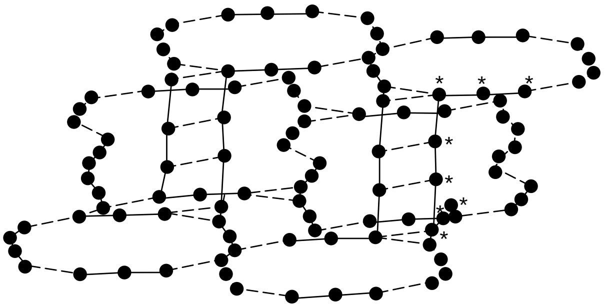

Figure 7 Anionic matrix in $[Pd_2Cl_2([18]aneN_2S_4)]_{1.5}I_5(I_3)_2$ (dicationic chains run through vertical channels). Starred atoms represent one $[I_8]^{2-}$ unit. (Reproduced by permission of Wiley-VCH)

binuclear cations are embedded in a matrix of the anions (Figure 7).[40]

Regular anionic shapes are present in the solid-state structures of $[(Crypt\text{-}2,2,2)H_2](I_8)$, $[Ni(phen)_3](I_8)\cdot 2CHCl_3$, and bis(*N*-methylurotropinium)octaiodide, but that in bis(N-methylurotropinium)octaiodide represents a new configuration, which is somewhere between $(I_3^-\cdot I_2\cdot I_3^-)$ and broken (I_3^-, I_5^-).[41]

Nonaiodides are very rare, but two, as $[Pr^iMe_2PhN]^+$[29] and $[K([15]aneO_5)]^+$[40] salts, have been structurally characterized. The anion in the former contains 14-membered rings tied by two iodine bridges into 10-membered rings, while that in the latter is best described as an $[I_3^-\cdot(I_2)_3]$ charge-transfer complex.

Meanwhile, $[I_{10}]^{2-}$ anions have been structurally characterized as counterions to a $[Cd(12\text{-}crown\text{-}4)_2]^{2+}$ complex cation. This anion, which adopts a twisted ring conformation, is composed of two triiodide ions linked by two I_2 molecules.[42]

As shown in Figure 8, the $[I_{11}]^-$ anion in $[([16]aneS_4)MIM([16]aneS_4)]I_{11}$ can be described either as two $[I_5]^-$ groups linked via an iodide ion or two $[I_3]^-$ groups and two iodine molecules linked via an iodide ion, that form a 14-membered polyiodide ring (9.66 × 12.64 Å) around the complex cation with the metal-bridging iodide at the center of the ring; these rings also link into an infinite two-dimensional sheet. This compound represents the first synthesis of a cyclic polyhalide array in which the complex cation acts as a template.[43]

The dodecaiodide dianion in $[Ag_2([15]aneS_5)_2](I_{12})$ is described as a charge-transfer complex $[(I^-)_2\cdot(I_2)_5]$ bound to the cation by Ag–I bonds with weak I···S interactions combining to build up an extended three-dimensional, spiral superstructure.[30] In marked contrast, the same anion in bis[potassium(dibenzo-18-crown-6)] dodecaiodide nearly a discrete entity $(I_2\cdot I_3^-\cdot I_2\cdot I_3^-\cdot I_2)$.[44] In $[Cu(Dafone)_3](I_{12})$, iodine–iodine interactions assemble novel, planar, $[I_{12}]^{2-}$ anions into a network around the strained tris-chelate complex of Cu(II).[45]

The $[I_{13}]^{3-}$ anion in $[Me_2Ph_2N]_3I_{13}$ consists of zigzag chains of iodide ions and iodine molecules, in which the iodide ions are coordinated to $[I_5]^-$ groups. The $[I_{16}]^{2-}$ anion in $[Me_2Ph_2N]_2I_{16}$ consists of two $[I_7]^-$ groups bridged by an iodine molecule.[46]

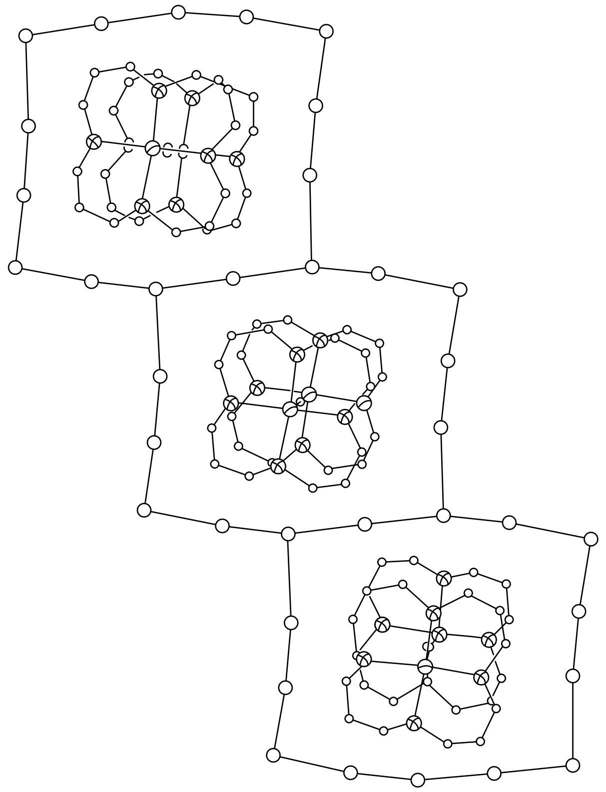

Figure 8 Perspective view of $[([16]aneS_4)PdIPd([16]aneS_4)][I_5]_2I$. (Ref. 43. Reproduced by permission of The Royal Society of Chemistry)

The $[I_{22}]^{4-}$ anion in $[MePh_3P]_4I_{22}$ consists of two L-shaped $[I_5]^-$ units bridged by an iodine molecule and completed by two end-on $[I_5]^-$ groups.[47]

Much larger iodine catenates are obtained when metal iodides are present; the reaction of TlI with $(Me_3S)I_7$ resulted in a number of species from which $(Me_3S)_3I_{26}$ has been structurally characterized, and shown to be of $[I_5]^-$ and $[I_7]^-$ anions with intercalated iodine molecules.[48] A mixture is identified in $[Me_3PNHPMe_3]_4(I_{28})$, the linear $[I_3]^-$, the Z-shaped $[I_8]^{2-}$, and the zigzag chains of $[I_{14}]^{4-}$.[49] In $[Cp_2Fe]_3[I_{29}]$, the most iodine-rich polyiodide, the ferrocenium cations, are made to interact in the cavities of an anionic three-dimensional network cage structure described by the formula $[\{(I_5{}^-)_{1/2}\cdot I_2\}\cdot\{(I_{12}{}^{2-})_{1/2}\cdot I_2\}\cdot I_2]$.[50]

Discrete linear symmetric $[ICl_2]^-$ anions have been reported in $[H_2Phen][ICl_2]Cl$[51] and $[Hphen]_2[ICl_2][I_2Cl]$.[52] For later, the columnar stacking of cations produces cavities for the $[ICl_2]^-$ anions and channels in which the polyanionic $[I_2Cl]^-$ chains are found. Unremarkable anionic geometries are reported in $[Pd(C_6H_{12}S_3)_2](IBr_2)$, $[Pd(C_{10}H_{20}S_4)](IBr_2)$,[53] and $[Cs(18\text{-crown-}6)](ICl_2)$.[54]

The structure of $[PPh_4][I_3Br_4]$, derived from the reaction of $[PPh_4]Br$ with IBr, has a seven-membered polybromide $[I_3Br_4]^-$ with a distorted C_{3v} symmetry, which is best described as a bromide coordinated to three IBr units via the iodine atoms.[55]

6 HYDROGEN HALIDES

The name hydrogen halides, HX, is used for the anhydrous compounds, whereas their aqueous solutions are called hydrohalic acids. In their anhydrous condition, these are molecular compounds, whereas solutions in water bring about ionic dissociation to give the protonated solvent and the halide anion (equation 84).

$$HX + H_2O \longrightarrow [H_3O]^+ + X^- \qquad (84)$$

Hydrogen chloride is produced industrially on a huge scale and is used as the anhydrous gas as well as a hydrochloric acid in aqueous solution. Several industrial routes to synthesize HCl are in use: (1) direct burning of hydrogen in chlorine, which results in a very pure product (equation 85); (2) reaction of an inorganic metal halide with a less volatile protic acid, such as sulfuric acid, to form the more volatile hydrogen halide (equation 86) and (3) as a by-product of the chlorination of hydrocarbons (equation 87).

$$H_2 + Cl_2 \longrightarrow 2HCl \qquad (85)$$

$$NaCl + H_2SO_4 \longrightarrow NaHSO_4 + HCl \qquad (86a)$$

$$NaCl + NaHSO_4 \longrightarrow Na_2SO_4 + HCl \qquad (86b)$$

$$RH + Cl_2 \longrightarrow RCl + HCl \qquad (87)$$

Similar reactions lead to the formation of HBr and HI. The latter can also be prepared by reacting the element with phosphorus and water (equation 88, X = Br or I).

$$2P + 6H_2O + 3X_2 \longrightarrow 6HX + 2H_3PO_3 \qquad (88)$$

Isotopic variants of the hydrohalides, such as with deuterium and tritium, can be prepared by hydrolytic reactions of covalent halides such as PX_3, PX_5, $AlCl_3$, and PhCOCl with D_2O or T_2O (equation 89).

$$PhCOX + D_2O \longrightarrow DX + PhCO_2D \qquad (89)$$

6.1 Physical Properties of Hydrogen Halides

Whereas the heavier HX are diatomic gases at room temperature, HF is a volatile liquid boiling at 19.5 °C. This exceptional property of HF is explained on the basis of its polymeric structure $(HF)_x$, due to the very strong F–H–F hydrogen bonding (*see* ***Fluorine: Inorganic Chemistry***). The order of the boiling and melting points of the hydrogen halides is HF > HCl < HBr < HI. This trend also exists for the group 16 and 15 hydrides, namely, $H_2O > H_2S < H_2Se < H_2Te$ and $NH_3 > PH_3 < AsH_3 < SbH_3$. This is in contrast to the properties of the hydrides of group 14, in which the order is as expected, that is, $CH_4 < SiH_4 < GeH_4 < SnH_4$. The discontinuity results from the fact that hydrogen bonds can be formed easily with the lighter elements, F, O, and N. Some physical properties of the hydrogen halides are summarized in Table 5. All are colorless, fume easily with moist air, and have penetrating odors.

6.2 Nonaqueous Solvents[56]

Except for hydrogen fluoride, the hydrogen halides have only a limited use as nonaqueous solvents. AHF plays an important role as a nonaqueous solvent[57] in fluorine chemistry, and it also serves as an important liquid medium for numerous synthetic preparations. It is easily handled owing to its boiling point (19.5 °C) being close to ambient temperature, and is a liquid under its own vapor pressure; it has a long liquid range of about 100 °C, has low viscosity, and a high dielectric constant. The physical properties of AHF therefore make it an excellent solvent for both inorganic polar solutes as well as organic nonpolar solutes, compounds, and even biological materials.

Table 5 Physical properties of the hydrogen halides

Property	HF	HCl	HBr	HI
Melting point (°C)	−83.4	−114.7	−88.6	−51
Boiling point (°C)	19.5	−84.2	−67.1	−35.1
Liquid range (°C)	102.9	30.5	21.5	15.9
Dielectric constant	84 (0 °C)	9.28 (−95 °C)	7.0 (−85 °C)	3.39 (−50 °C)

The properties of all other hydrogen halides are far removed from those of AHF and, therefore, their use as nonaqueous solvents is rather limited. Nevertheless, they are used for physical studies of solutions and for some synthetic purposes, such as in the formation of salts with HCl_2^- or BCl_4^- and related anions. Anhydrous HX can be considered to undergo self-ionization (equation 90) and can therefore be used to perform reactions of an acid–base nature, and solvolytic and redox reactions (equations 91–93).

$$3HX \longrightarrow [H_2X]^+ + [HX_2]^- \quad (90)$$

$$SbF_3 + 3HCl \longrightarrow SbCl_3 + 3HF \quad (91)$$

$$I^- + 2Cl_2 \longrightarrow [ICl_4]^- \quad (92)$$

$$PCl_3 + X_2 + HCl \longrightarrow [PCl_3X]^+ + [HClX]^- (X = Cl, Br) \quad (93)$$

6.3 Hydrohalic Acids

Hydrohalides dissolve easily in water to form hydrohalic acids and undergo virtually complete ionic dissociation (equation 84). All the hydrohalic acids, except HF, are very strong acids. Although AHF is one of the most acidic liquids, as measured by its Hammett function, hydrofluoric acid is a weak acid.

Hydrochloric acid is of great importance and is widely used in industrial processes. The largest use is in the metallurgical industry for the pickling of metals to remove oxide scales. Other uses include the production of inorganic halides from metals, oxides or carbonates, extraction of metals from ores in metallurgical processes, and various organic reactions.

Hydrobromic acid is used in the production of inorganic bromides as well as in organic brominations, particularly in the production of pesticides. Some physical properties of the hydrohalide acids are summarized in Table 6.

6.4 Biological Action

In addition to their action on the respiratory system and attacking the mucous membrane and skin, a major hazard of concentrated hydrohalic acids is direct contact with the skin, causing chemical burns. Some of these compounds, however, are important in biochemical processes. The hydrochloric acid in the stomach, for example, is extremely important in the digestive system, and iodine is of importance in thyroid function.

Table 6 Physical properties of hydrogen halides in aqueous solution

Property	HF	HCl	HBr	HI
Solubility in water (g/100 g soln at 1 atm and 0 °C)	all proportions	45.15	68.85	71
pK_a for acid	3.2	−7	<−7	<−7
Azeotrope				
Boiling point at 1 atm (°C)	112	108.58	124.3	126.7
Solubility (g/100 g solution)	38	20.22	47.63	56.7

7 HALOGEN OXIDES

A large number of binary halogen oxides are known, from shock-sensitive liquids to rather stable solids. Similarly, a large number of oxoacids and oxoacid salts are also known.

Most halogen oxides are not very stable and decompose easily. This stems from the fact that the number of electrons in these molecules is an odd number. Therefore, the ions formed by the addition of an electron, whether in oxoacids or in oxoacid salts, are more stable.

Dichlorine oxide, Cl_2O, is best prepared on a laboratory scale by reacting chlorine with mercury oxide (equation 94). On an industrial scale, it can be prepared by reacting chlorine with moist carbonate (equation 95). This oxide is readily soluble in water to form hypochlorous acid (equation 96). Its salts, the hypochlorites, are quite stable and are used in the textile industries and to bleach wood pulp. The low-temperature crystal structure of Cl_2O reveals an essentially molecular structure [d(O–Cl) = 1.7092(4) Å] with weak secondary interactions [d(O···Cl) = 2.7986(4) Å] affording a distorted tetrahedral coordination around the O atom.[58]

$$2Cl_2 + 2HgO \longrightarrow HgCl_2{\cdot}HgO + Cl_2O \quad (94)$$

$$2Cl_2 + 2Na_2CO_3 + H_2O \longrightarrow 2NaHCO_3 + 2NaCl + Cl_2O \quad (95)$$

$$Cl_2O + H_2O \longrightarrow 2HOCl \quad (96)$$

Cl_2O_3, generated in the reaction of ClO with ClO_2, has a relatively short lifetime and is not expected to be an important reservoir for ClO_x.[59]

Chlorine dioxide, ClO_2, is a stable oxide and can be prepared by reducing chlorates (equation 97) or in reaction with moist oxalic acid (equation 98). Chlorine dioxide is a strong oxidizing agent toward both organic and inorganic materials.

$$[ClO_3]^- + Cl^- + 2H^+ \longrightarrow ClO_2 + \tfrac{1}{2}Cl_2 + H_2O \quad (97)$$

$$[ClO_3]^- + [C_2O_4]^{2-} \longrightarrow ClO_2 \quad (98)$$

Dichlorine hexoxide, Cl_2O_6, is best made by ozonolysis of ClO_2 (equation 99). It is assumed to be an ionic compound in the solid state, $[ClO_2]^+ [ClO_4]^-$.

$$2ClO_2 + 2O_3 \longrightarrow Cl_2O_6 + 2O_2 \quad (99)$$

The most stable oxide is dichlorine heptoxide, Cl_2O_7, the anhydride of perchloric acid, $HClO_4$. It can be obtained by dehydration of that acid with H_3PO_4 at 10 °C, followed

by low-temperature distillation at low pressure. Dissolution in water or alkali again produces the acid or perchlorates respectively. Table 7 summarizes some physical properties of the chlorine oxides. The ClO_4 radical is generated by thermal decomposition of Cl_2O_6 or Cl_2O_7 in Ar or Ne. It has a lifetime of only a few milliseconds but could be obtained in a matrix at low temperature and characterized by IR and UV/VIS specptroscopies, and indicates a dynamic Jahn–Teller effect.[60]

Bromine forms oxides such as Br_2O, Br_2O_3, and BrO_2, and these are less well characterized than for chlorine. They are stable at low temperatures but unstable at room temperature. For example, compound Br_2O_3 (synthesized from Br_2 and O_3) has been shown to form as an orange crystalline solid and on further ozonization to give a colorless oxide, which does not contain the colored O–Br(I) unit. It is insoluble in CH_2Cl_2, unlike Br_2O_3, and decomposes above −40 °C. However, it can be crystallized from propionitrile as $Br_2O_5\cdot(EtCN)_3$ and the structure determination shows symmetric $O_2Br–O–BrO_2$ to be present. The molecule has terminal bonds (1.62 Å), which are shorter than the bridging ones (1.87–1.89 Å). The bond angle at the bridging oxygen atom is 121°. This study brings into doubt the existence of Br_2O_4, which has a Raman spectrum very similar to that of Br_2O_3.[61] The gas-phase FTIR spectra of two important bromine-containing species, OBrO and Br_2O, have been reported.[62] The hydrolysis of $BrOTeF_5$ offers a new route to Br_2O. X-ray analysis shows that the compound is bent [114.2(2)°] with strong Br···Br interactions in the solid state resulting in chains.[63]

For the bromine oxides, the realization that the only well-characterized compounds use all the possible combinations of the only basic units in this area (i.e. terminal OBr and pyramidal $O–BrO_2$ in Br–O–Br, $Br–O–BrO_2$ and $O_2Br–O–BrO_2$) suggests that new homoleptic bromine oxides are likely to be even less stable than these derivatives.[64]

Iodine forms the most stable of all halogen oxides, I_2O_5, which exists as white, hygroscopic crystals. It can be prepared by dehydration of iodic acid, HIO_3, at 200 °C in a stream of air. It can also be prepared by direct interaction of iodine and oxygen in a glow discharge. I_2O_5 dissolves easily in water to form the parent compound (iodic acid). It can oxidize various inorganic chemicals and is one of the few agents that oxidizes carbon monoxide completely at room temperature (equation 100). This reaction is used to analyze the concentration of CO in air or in gaseous mixtures.

$$5CO + I_2O_5 \longrightarrow 5CO_2 + I_2 \qquad (100)$$

Table 7 Physical properties of the chlorine oxides

Compound	Mp (°C)	Bp (°C)	Form at room temp.
Cl_2O	−120.6	2.0	Yellow–brown gas
ClO_2	−59	11	Yellow–green gas
$ClOClO_3$	−117	44.5	Pale yellow liquid
Cl_2O_6	3.5	203	Dark red liquid
Cl_2O_7	−91.5	81	Colorless liquid

$(IO)_2SO_4$ has been shown to hydrolyze to a powder formulated as I_2O_4, which is monoclinic and thought to have a one-dimensional structure comprising alternating oxygen-bridged iodine(I) and iodine(V) units $–I–O–IO_2–O–(I–O–IO_2–O)_n–I–O–IO_2–O–$. It decomposes on heating to I_2O_5 and I_2 (equations 101 and 102).[65]

$$4(IO)_2SO_4 + 4H_2O \longrightarrow 4H_2SO_4 + I_2 + 3I_2O_4 \qquad (101)$$

$$5I_2O_4 \longrightarrow I_2 + 4I_2O_5 \qquad (102)$$

Reaction of H_5IO_6 with H_2SO_4 results in IO_3, whose structure consists of I_4O_{12} units (two IO_6 octahedra sharing an edge and two pyramidal IO_3 groups sharing two vertices with the double octahedron) linked through I···O bridges, and may be considered to be the mixed anhydride of H_5IO_6 and HIO_3.[66]

7.1 Halogen Oxide Cations

Reacting halogen oxides with Lewis acids or dissolving them in superacids such as fluorosulfonic acid or persulfuric acid produces the halogen oxide cation $[ClO_2]^+$, as in $[ClO_2]^+$ $[SO_3F]^-$, $[ClO_2]^+$ $[SbF_6]^-$, and $[ClO_2]^+$ $[BF_4]^-$. Other cations have also been identified, such as $[ClO]^+$. The reaction of Cl_2 with $[O_2]^+$ $[SbF_6]^-$ forms $[Cl_2O_2]^+$ $[SbF_6]^-$ or $[Cl_2O_2]^+$ $[Sb_2F_{11}]^-$ (Figure 9).[67] In the reaction of iodine oxide with SO_3 or $S_2O_6F_2$, the cation $[IO_2]^+$ is formed, but when dissolved in concentrated sulfuric acid the reduced $[IO]^+$ cation is formed. Whereas the chlorine oxide cations are discrete ions, the iodine oxide species appear to be polymerized, with I–O–I bridging networks, cross-linked to the anions.

7.2 Halogen Oxide Fluorides

Halogen oxides can be reacted with fluorine or halogen fluoride to form halogen fluoride oxides, F_nXO_m. Similar to the halogen fluorides, the central atom is always that of the

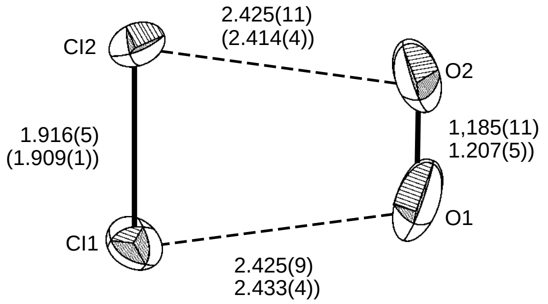

Figure 9 The $[Cl_2O_2]^+$ cation in $[Cl_2O_2][SbF_6]$. The cation in $[Cl_2O_2][Sb_2F_{11}]$ is practically identical and the bond length data (in Å) for it are given in parentheses. (Reprinted with permission from Ref. 67. © 2001 American Chemcial Society)

heavier halogen bonded directly to fluorine and to oxygen. Halogen oxide fluorides can be considered to undergo self-ionization, similar to interhalogens (equation 103), and can thus react with Lewis acids and bases to form the appropriate salts.

$$2F_mXO_n \longrightarrow [F_{m-1}XO_n]^+ + [F_{m+1}XO_n]^- \quad (103)$$

These compounds range from the thermally unstable FClO to the rather chemically inert perchloryl fluoride $FClO_3$. The structure and properties of this family of compounds resemble those of the halogen fluorides. Therefore, they have to be handled with the same care as elemental fluorine and its chemically reactive fluorides. The halogen oxide fluorides can be prepared by fluorination of halogen oxides with elemental fluorine or with halogen fluoride.

Of the six possible chlorine oxide fluorides,[68] five have been identified. Reacting chlorine nitrate with fluorine at low temperature (equation 104) gives F_3ClO in high yield. Fluorination of a chlorate with chlorine trifluoride at room temperature produces $FClO_2$ (equation 105). The stable colorless gas $FClO_3$ can be prepared by fluorination of potassium chlorate at −40 °C with elemental fluorine. It is best prepared, in a 97% yield on an industrial scale, by fluorination of perchlorate with antimony pentafluoride or with superacid (a mixture of SbF_5 and fluorosulfonic acid, $HOSO_2F$) (equation 106). $FClO_3$ is a rather inert compound, particularly at room temperature.

$$ClONO_2 + 2F_2 \xrightarrow[>80\%]{-35\,^\circ C} F_3ClO + FNO_2 \quad (104)$$

$$6NaClO_3 + 4ClF_3 \longrightarrow 6FClO_2 + 6NaF + 2Cl_2 + 3O_2 \quad (105)$$

$$KClO_4 \xrightarrow{HOSO_2F/SbF_5} FClO_3 \quad (106)$$

F_3ClO decomposes at 300 °C to chlorine trifluoride and oxygen (equation 107), whereas at room temperature this decomposition is rather slow, being increased by heating or by UV light. Similarly, $FClO_2$ decomposes to chlorine fluoride and oxygen (equation 108). These compounds can therefore serve either as fluorinating or oxidizing agents.

$$F_3ClO \longrightarrow ClF_3 + \tfrac{1}{2}O_2 \quad (107)$$

$$FClO_2 \longrightarrow ClF + O_2 \quad (108)$$

$FClO_3$ is considered to be chemically inert and yet it can be used in organic reactions to introduce either fluorine or the ClO_3 group, and it is used for selective fluorination. In spite of its so-called inertness, the handling of this reagent requires use of the safety precautions customary for fluorine chemistry and it should not be dealt with lightly.

The related bromine compounds are fewer than for chlorine and are more reactive. Of the bromine compounds, the most stable is $BrClO_3$, which can be prepared by fluorination of perbromate with AsF_5 or BrF_5 (equation 109).

$$KBrO_4 + 2AsF_5 + 3HF \longrightarrow FBrO_3 + [H_3O]^+[AsF_6]^- + KAsF_6 \quad (109)$$

The related iodine compounds are more stable at the higher oxidation states, +5 and +7, of the central iodine, for example, as the pentavalent FIO_2 and F_3IO compounds, and the heptavalent FIO_3, F_3IO_2, and F_5IO compounds. Similar to the iodine oxides, these also form polymers through oxygen bridging. Reacting diiodine pentoxide with fluorine produces FIO_2 (equation 110), but dissolving that same compound in IF_5 yields F_3IO (equation 111). The stable FIO_3 can be prepared by reacting periodic acid with fluorine in AHF solution. Some physical properties of halogen oxide fluorides are listed in Table 8. The structure of IO_2F has an alternating axial–equatorial-linked trigonal-bipyramidal arrangement. The equatorial plane contains the two I=O bonds [1.805(6) and 1.773(6) Å] with the apical positions being occupied by one fluorine and one oxygen substituent I–F = 1.903(5) and I–O = 2.226(6) Å] (Figure 10).[69] The structures of $ClOF_3$ and $BrOF_3$ have been determined and both show the trigonal bipyramidal geometry around the central halogen atom with two axial fluoride ligands. Interestingly, the structure of $ClOF_3$ is described as tubelike stacking of pseudo-hexagonal, eight-membered rings in which the different 'tubes' are weakly interconnected, giving rise to a formal coordination number of seven to each chlorine atom.[70]

Compounds containing iodine in two different oxidation states are rare, comproportionation often occurring to give the more stable oxidation state compound. $[Cl_2IOI(O)F_2]$ is the first example of iodine oxofluoride chloride with mixed valency iodine atoms. The structure of this compound is of two linked trigonal bipyramidal iodine centers, one formally +III, the other +V, linked by an oxygen bridge.[71]

$$I_2O_5 + F_2 \xrightarrow{HF/20\,^\circ C} 2FIO_2 + \frac{1}{2}O_2 \quad (110)$$

$$I_2O_5 + 3IF_5 \xrightarrow{105\,^\circ C} 5F_3IO \quad (111)$$

Table 8 Physical properties of the halogen oxide fluorides

Compound	Mp (°C)	Bp (°C)	Form at room temp.
F_3ClO	−43	28	Stable, colorless gas
$FClO_2$	−115	−6	Stable, colorless gas
$FClO_3$	−147.8	−46.7	Stable, colorless gas
F_3ClO_2	−81.2	−21.6	Stable, colorless gas
$FBrO_3$	−110	2.4	Stable, colorless gas
FIO_2	>200	–	Colorless polymeric solid
F_3IO	–	–	Colorless crystals
FIO_3	100 (decomposes)	–	White crystalline solid

7.3 Oxoacids and Oxoacid Salts[68]

The oxoacids and their salts are very stable, in contrast to the lack of stability of the halogen oxides themselves. A large number of these acids exist at the representative oxidation states of the halogens, namely, +1, +3, +5, and +7. Even perbromic acid, $HBrO_4$, has been synthesized by fluorination of bromates.

7.3.1 Hypohalous Acids and Hypohalites

The easiest preparation of aqueous solutions of the hypohalous acids is to dissolve the appropriate halogen in water (equation 112).

$$X_2 + H_2O \longrightarrow HOX + H^+ + X^- \quad (112)$$

The addition of silver or mercury oxide precipitates the metal halide, leaving behind the aqueous solution, which is very reactive and is used for bleaching and sterilizing purposes. Solutions of hypohalites can be made by introducing the appropriate halogen into basic solutions (equation 113), but these will also contain some halide anions. To obtain pure hypochlorites, it is necessary to carefully neutralize pure hypochlorous acid. The most stable hypochlorites are those of Li, Ca, Sr, and Ba, although some others are also known but are not as stable, or are not sufficiently pure.

$$X_2 + 2OH^- \longrightarrow OX^- + X^- + H_2O \quad (113)$$

Hydrated hypobromites are also known, for example, $NaOBr{\cdot}xH_2O$ and $KOBr{\cdot}3H_2O$, which can be crystallized from concentrated basic solutions into which bromine has been introduced; these solids decompose above 0 °C. No hypoiodites are known.

The hypohalites and their parent acids decompose to release oxygen (equation 114) and thus serve as very strong oxidizers in inorganic and organic chemistry. The hypohalites oxidize oxalates to carbon dioxide, nitrites to nitrates, sulfites to sulfates, divalent manganese to permanganate, halides to halates, and ketones to carboxylic acids, and so on.

$$2HOX \longrightarrow O_2 + 2H^+ + 2X^- \quad (114)$$

In addition to the existence of ionic hypohalites, molecular hypohalites are also known such as $ClONO_2$ and $ClOClO_3$ with the ClO–group.

7.3.2 Halous Acids and Halites

This group of compounds is the least stable of the various oxoacids and oxoacid salts, and is restricted to chlorous acid and its salts. Barium chlorite is prepared by reacting ClO_2 with a basic solution in the presence of H_2O_2, which serves as a reducing agent (equation 115). Adding dilute sulfuric acid to a suspension of $Ba(ClO_2)_2$ forms chlorous acid (equation 116).

$$Ba(OH)_2 + H_2O_2 + 2ClO_2 \longrightarrow Ba(ClO_2)_2 + H_2O + O_2 \quad (115)$$

$$Ba(ClO_2)_2 + H_2SO_4 \longrightarrow 2HClO_2 + BaSO_4 \quad (116)$$

Anhydrous $NaClO_2$ crystallizes out of solution above room temperature and serves as an oxidizing agent toward malodorous and toxic organic compounds.

Although bromous acid itself is unknown, $Ba(BrO_2)_2$ and the corresponding strontium salt can be prepared by treating hypobromite with Br_2 in strongly basic solutions at 0 °C, followed by slow evaporation.

7.3.3 Halic Acids and Halates

Introducing a halogen into a hot basic solution causes a disproportionation process. Part of the halogen is reduced to the halide anion and another part of it is oxidized to the halate anion (equation 117).

$$3X_2 + 6OH^- \longrightarrow [XO_3]^- + 5X^- + 3H_2O \quad (117)$$

Chlorate is the most important halate and is produced, on an industrial scale, by electrolysis of a halide solution in a diaphragmless cell, which promotes efficient mixing. This arrangement allows the chlorine produced at the anode to react with the hydroxyl anion at the cathode, forming the hypochlorous anion, which is then further oxidized to chlorate, whether by oxidation at the anode or through

$$Cl^- \longrightarrow \frac{1}{2}Cl_2 + e^- \text{ (anode)}$$

$$H_2O + e^- \longrightarrow OH^- + \frac{1}{2}H_2 \text{ (cathode)}$$

$$Cl_2 + 2OH^- \longrightarrow OCl^- + Cl^- + H_2O$$

$$OCl^- + 2H_2O \longrightarrow [ClO_3]^- + 2H_2 \text{ (anode)}$$

$$OCl^- \longrightarrow [ClO_3]^- + 2Cl^-$$

Scheme 1

disproportionation (Scheme 1). Bromates and iodates are also produced industrially but to a lesser extent.

The pure halic acids are produced by adding sulfuric acid to an aqueous solution of the appropriate barium salt and precipitating insoluble barium sulfate (equation 118).

$$Ba(XO_3)_2 + H_2SO_4 \longrightarrow 2HXO_3 + BaSO_4 \qquad (118)$$

All the halogens form halic acids in aqueous solution, which can be concentrated to about 40–50% when evaporated by heating carefully under reduced pressure. At higher concentrations, these disproportionate into perchloric acid, whereas the bromate decomposes to bromine and oxygen. Both chloric and bromic are strong acids in aqueous solution ($pK_a \leq 0$), whereas iodic acid is slightly weaker ($pK_a = 0.804$).

All the halates decompose on heating, usually above their melting point. In the presence of a transition metal catalyst such as MnO_2, the decomposition of $KClO_3$ to chloride and oxygen starts at 70 °C and is the source of pure oxygen in laboratory preparation. In a series of the halates with the same cation, the thermal stability decreases in the sequence of $[IO_3]^- > [ClO_3]^- > [BrO_3]^-$. Potassium chlorate is used in the mixture of 'safety' matches, in pyrotechnic formulations, and as intermediates in the production of perchlorates.

The oxidation of a halide anion with its own halate is sometimes quantitative and is used in the quantitative analysis of bromide and iodide (equation 119).

$$[XO_3]^- + 5X^- + 6H^+ \longrightarrow 3X_2 + 3H_2O \qquad (119)$$

A spectacular kinetic effect, known as the 'chemical clock', has been observed when an acidified sulfite solution is reacted with iodate in the presence of the starch indicator for elemental iodine, in which the color of the iodine complex alternately appears and disappears (Scheme 2.) Over the years, many more oscillating clocks like this have been discovered.

$$[IO_3]^- + 3[SO_3]^{2-} \longrightarrow I^- + 3[SO_4]_2^{-}$$

$$5I^- + [IO_3]^- + 6H^+ \longrightarrow 3I_2 + 3H_2O$$

$$3I_2 + 3[SO_3]^{2-} \longrightarrow 6I^- + 6H^+ + 3[SO_4]^{2-}$$

Scheme 2

7.3.4 Perhalic Acids and Perhalates

These compounds of the various halogens differ in their structure and properties and will therefore be treated separately.

The most stable chlorine compounds are the halides with the lowest oxidation state, −1, or the perhalates with the highest, +7. Perchloric acid and its salts are the most stable among the oxohalogen compounds. Aqueous solutions of perchlorates are not notable oxidizing agents at room temperature, but on heating become vigorous and even violent oxidants. Therefore special care has to be taken when handling these materials, particularly avoiding the presence of oxidizable materials, since explosions can take place.

Sodium perchlorate is produced industrially by electrolytic oxidation of $NaClO_3$. Perchloric acid is prepared by reacting a sodium or barium salt with concentrated HCl, filtering off the chloride, and concentrating the filtrate by distillation. The anhydrous acid can be obtained by low-pressure distillation in an all-glass apparatus in the presence of sulfuric acid, which combines with the rest of the water.

Pure perchloric acid is a colorless, hygroscopic, and shock-sensitive liquid. Although the anhydrous acid is a covalent compound, $HOClO_3$, the hydrates are considered to be ionic: $[H(H_2O)_n]^+ [ClO_4]^-$ ($n = 1$, 2, and 3). Hydration does not increase the coordination number of the chlorine atom above four, which is in contrast to a periodic acid having a coordination number of six (discussed later).

Anhydrous perchloric acid is a powerful oxidizing agent that reacts explosively with many organic and inorganic materials. On decomposition, various gaseous products are formed. However, aqueous solutions of perchloric acid are not oxidizing at room temperature. This is explained on the basis of kinetic activation barriers. Most metals form perchlorate salts, and even molecular compounds, such as NO and NO_2, also react with it to form ionic compounds such as $[NO]^+ [ClO_4]^-$. Ammonium perchlorate is used as a solid-fuel propellant, particularly in missiles. Potassium perchlorate is also used in pyrotechnic formulations such as fireworks and flares.

The perchlorate anion has long been considered as a noncoordinating ligand and has therefore been used in the preparation of 'inert' ionic solutions of constant ionic strength for physicochemical measurements. However, although this anion is definitely less coordinating than H_2O, it can be monodentate, bridging bidentate, or chelating bidentate. This is illustrated by structures of compounds such as $(CH_3)_3SnClO_4$, $Co(MeSC_2H_4SMe)_2(ClO_4)_2$, $(Ph_3BiOBiPh_3)(ClO_4)_2$, $Sb_2Cl_6(OH)(O)(ClO_4)$, and $Ti(ClO_4)_4$.

The existence of perbromic acid and perbromates were once considered an impossibility on the basis of thermodynamic considerations. Recently, however, these have been prepared on a regular laboratory scale. Perbromic acid or perbromates are synthesized by oxidation of BrO_3^- electrolytically or by fluorination of bromate with elemental fluorine (equation 120) or other strong fluorination agents such as XeF_2 (equation 121).

$$[BrO_3]^- + F_2 + 2OH^- \longrightarrow [BrO_4]^- + 2F^- + H_2O \quad (120)$$

$$[BrO_3]^- + XeF_2 + H_2O \longrightarrow [BrO_4]^- + Xe + 2HF \quad (121)$$

Salts such as $KBrO_4$ (dec. ~275 °C) and NH_4BrO_4 (dec. ~170 °C) are fairly stable thermally and isomorphorus with their perchlorate analogues. However, potassium perbromate is thermodynamically less stable than both the corresponding perchlorate and periodate analogues.

At least four series of periodates interconnected in aqueous solution by a complex series of equilibriums are known. All these are derived from the parent acid H_5IO_6 through deprotonation, dehydration, and aggregation; some are listed in Table 9.

The industrial preparation is based on electrolytic oxidation (equation 122) or with chlorine (equation 123).

$$[IO_3]^- + 6OH^- - 2e^- \longrightarrow [IO_6]^{5-} + 3H_2O \quad (122)$$

$$[IO_3]^- + 6OH^- + Cl_2 \longrightarrow [IO_6]^{5-} + 2Cl^- + 3H_2O \quad (123)$$

The polymeric structure of the various iodine compounds is achieved through oxygen bridging between iodine atoms. Being a multibasic acid, partial neutralization of the hydrogens by metal ions is possible, the rest of the hydrogens being retained as hydroxyl groups, such as in $Na_3IO_4(OH)_2$, which is a sodium salt of dihydrogen orthoperiodate.

Aqueous solutions of the periodic acid can be obtained by adding concentrated nitric acid to barium periodate. White crystals of H_5IO_6 can be obtained from these solutions, and heating to 120 °C yields a polymerized form of $H_7I_3O_{14}$. This compound in the solid state is a stoichiometric $H_5IO_6{\cdot}2HIO_4$ phase.[72] Spectroscopic and structural studies on $[Me_4N]^+[IO_4]^-$ confirm Pauling's 1930 proposal that the phase change in this system is due to the onset of free ion rotation and is not caused by positional disorder of the rotational oscillation axes.[73] In the room temperature structure (Phase II), the disordered $[IO_4]^-$ anion undergoes free rotation about one of the I–O bonds (Figure 11),

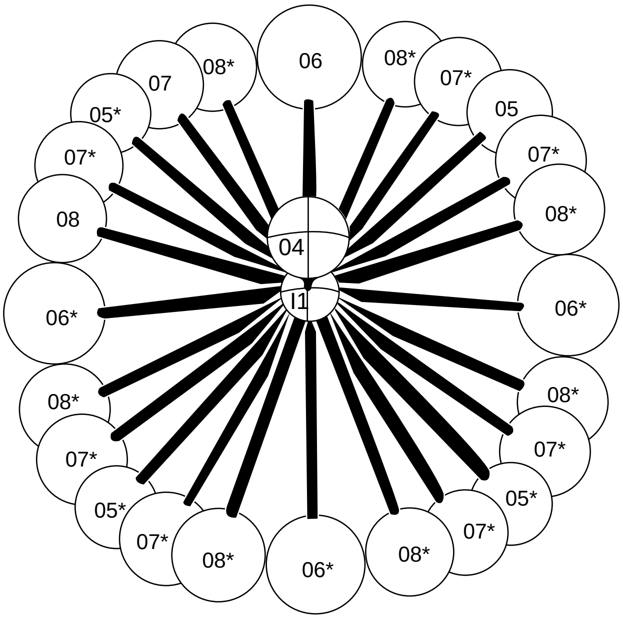

Figure 11 An ORTEP drawing of a single disordered $[IO_4]^-$ anion showing a detailed view of the rotational disorder about one I–O axis. (Reprinted with permission from Ref. 73. © 2001 American Chemcial Society)

while in the Phase III structure (determined at − 30 °C), the $[IO_4]^-$ anion is ordered. When heating to 100 °C at reduced pressure, it causes dehydration and forms HIO_4. Periodates are very potent oxidation agents and in acid solution can oxidize divalent manganese quantitatively from Mn^{II} to the heptavalent $[MnO_4]^-$. It is also used in organic chemistry for oxidation purposes. Periodates can act as ligands in the formation of complexes of transition metals in which the octahedral $[IO_6]^{5-}$ serves as a bidentate ligand. $[H_4I_2O_{10}]^{2-}$ anions in magnesium tetrahydrogen decaoxodiiodate $\{MgH_4I_2O_{10}{\cdot}6H_2O\}$ connected the $[Mg(H_2O)_6]^{2+}$ cations via a network of hydrogen bonds.[74] A single-crystal X-ray study indicates that this represents the first example of a chelating I_2O_{12} unit coordinating via vertices to give I_2InO_{12} chains.[75]

Table 9 Periodic acids

Formula	Name	Relation to H_5IO_6
H_5IO_6	Orthoperiodic	Parent
HIO_4	Periodic	H_5IO_6–$2H_2O$
'H_3IO_5'	Mesoperiodic	$2H_5IO_6$–$2H_2O$
$H_7I_3O_{14}$	Triperiodic	$3H_5IO_6$–$4H_2O$

7.4 Halogen Derivatives of Oxoacids

All halogens react to form compounds in which the halogen is bound through an oxygen atom in an oxoacid, and not directly to the central atom, for example, $XOClO_3$, $XOSO_2F$, and $XONO_2$ (X = F, Cl, Br, and I). Some trivalent halogen compounds are also known, such as $X(ONO_2)_3$ and $X(OSO_2F)_3$ (X = Br and I). In general, the thermal stability decreases with the increase of the atomic number of the halogen. They all decompose easily and violent reactions may occur. Of the halogen nitrates, fluorine nitrate is the most stable. The halogen fluorosulfates are among the more stable of the oxoacid derivatives.

8 ORGANIC POLYVALENT HALOGEN DERIVATIVES

The intention is not to cover the vast halo-organic chemistry in this context, but only organic polyvalent halogen compounds that are actually limited to derivatives with iodine (I), iodine (III), and iodine (V), though evidence for the divalent $L_2I^{\bullet}$ radical was obtained by the hemolytic cleavage of I–O bonds during thermolysis of *tert*-butyl-peroxyiodanes.[76]

8.1 Monovalent Iodine

Although Br^+ has been postulated to occur in reactions of Br_2, the evidence is usually only kinetic. However, the solvated linear ions $[L_2Br]^+$ and $[L_2I]^+$, where L may be pyridine, MeCN, quinuclidine, and so on are known.[77] The oxidants $[I(MeCN)_2]^+$ $[UF_6]^-$ can be prepared from reactions of UF_6 with 1/2 equiv of I_2 in MeCN. But Br^+ is too electrophilic to exist in MeCN. The reaction in liquid SO_2 gives a 95% yield of the salt $[I(MeCN)]^+$ $[AsF_6]^-$.[78]

8.2 Trivalent Iodine

Trivalent iodine compounds can be divided into the following categories: (1) with one carbon–iodine bond, such as in iodo salts, RIX_2, and iodoso compounds, RIO; (2) with two carbon–iodine bonds on the same iodine, such as RR′IX; and (3) with three carbon–iodine bonds on the same iodine, such as Ph_3I.

8.2.1 Iodo Disalts

Aromatic iodo disalts, $ArIX_2$, can be prepared by passing chlorine into an organic solution of an aryl iodide, ArI (equation 124). On standing, the material decomposes into HCl and a chlorine-substituted aromatic part (equation 125).

$$ArI + Cl_2 \longrightarrow ArICl_2 \quad (124)$$

$$C_6H_5ICl_2 \longrightarrow p\text{-}ClC_6H_4I + HCl \quad (125)$$

Iodobenzene dichloride can be used as a mild chlorinating agent in organic synthesis. From vibrational spectroscopy,[79] it seems that the $ArICl_2$ has a T-shaped structure in which the Cl–I–Cl is linear and the phenyl group is perpendicular to it. Such a structure could be attributed to a partially ionic compound with the halide part being an anion, $[Cl–I–Cl]^-$, and the phenyl unit more positively charged. This physical structure has also been established by X-ray data.

Perfluoroalkyl iododifluorides can be prepared with halogen fluorides (equation 126). Using an excess of halogen fluoride, the iodotetrafluoride is obtained (equation 127).

$$R_fI + XF_n \longrightarrow R_fIF_2 \quad (126)$$

$$R_fI + \text{xs } XF_n \longrightarrow R_fIF_4 \quad (127)$$

Dissolving an $ArICl_2$ in basic solution forms the iodoso compound, ArIO (equation 128). Another synthetic procedure to obtain iodoso compounds is by direct oxidation of ArI with ozone, fuming nitric acid, or $KMnO_4$.

$$ArICl_2 + OH^- \longrightarrow ArIO \quad (128)$$

$ArI(OAc)_2$ can be crystallized from a solution of either $ArICl_2$ or ArIO in acetic acid. $ArI(ONO_2)_2$ can be obtained by reacting silver nitrate with a solution of those iodine compounds in acetonitrile.

8.2.2 Diorganohalonium Compounds

Diaryliodonium compounds can be prepared by acid-catalyzed condensation of iodoso aryls with another aryl molecule (equation 129). Another method is the use of iodine trichloride in reaction with organometallic compounds (equations 130 and 131). $RICl_2$ may be prepared by direct chlorination of RI ($R = CF_3CH_2, CHF_2(CF_2)_5CH_2$) and these materials can be used to chlorinate iodobenzene to give the less hydrolytically stable compound $PhICl_2$.[80]

$$ArIO + Ar'H \xrightarrow{HX} ArAr'IX + H_2O \quad (129)$$

$$Ar_2Hg + ICl_3 \longrightarrow Ar_2ICl \quad (130)$$

$$CF_3CH_2I + Cl_2 \longrightarrow CF_3CH_2ICl_2 \quad (131)$$

Diaryliodonium compounds are good arylating agents, introducing a second aryl group where one already exists (equation 132).

$$Ph_2ICl + PhOH \longrightarrow Ph_2O + PhI + HCl \quad (132)$$

Among the compounds in which I^{3+} is combined with oxoanions are $I(OSO_2F)_3$, $I(NO_3)_3$, $I(OCOCH_3)_3$, IPO_4, and $I(OClO_3)_3$ (equations 133–137). These compounds contain essentially covalent I–O bonds. Preparative routes are shown as followings. These compounds are very sensitive to moisture and are not stable much above room temperature. They are hydrolyzed with disproportion of the I^{3+}, as shown for IPO_4 (equation 138).

$$2I_2 + 3AgClO_4 \longrightarrow I(OClO_3)_3 + 3AgI \quad (133)$$

$$I_2 + 6ClOClO_3 \longrightarrow 2I(OClO_3)_3 + 3Cl_2 \quad (134)$$

$$CsI + 4ClOClO_3 \longrightarrow Cs[I(OClO_3)_4] + 2Cl_2 \quad (135)$$

$$I_2 + HNO_3(\text{fuming}) + (CH_3CO)_2O \longrightarrow I(OCOCH_3)_3 \quad (136)$$

$$I_2 + HNO_3(\text{conc}) \longrightarrow IPO_4 \quad (137)$$

$$5IPO_4 + 9H_2O \longrightarrow I_2 + HNO_3 + 5H_3PO_4 \quad (138)$$

The structure of $I(OCOMe)_3$ is T-shaped as expected with three primary I–O–C bonds and longer I–O interactions. In $[Bu_4N][I(OTeF_5)_4]$, the anion has a square IO_4 unit.

8.3 Pentavalent Iodine

Iodooxo compounds are formed through the disproportionation of iodoso compounds (equation 139). These can also be prepared by oxidation of iodoso compounds with aqueous hypochlorite solution. In the solid state, these are rather unstable and detonate on heating or shock. They hydrolyze in water to form a base (equation 140), which, in a cold alkaline solution, can form a diphenyliodyl hydroxide (equation 138).

$$2ArIO \longrightarrow ArIO_2 + ArI \quad (139)$$

$$ArIO_2 + 2H_2O \longrightarrow [H_3O]^+ + [ArIO_2(OH)]^- \quad (140)$$

$$2[PhIO_2(OH)]^- \longrightarrow [Ph_2IO]^+[OH]^- + [IO_3]^- + OH^- \quad (141)$$

Adding acetic or trifluoroacetic acid to such a solution forms the salts of these acids. From such salts, other diphenyliodyl salts can be obtained, such as $[Ph_2IO]^+X^-$ ($X = F$, Cl, Br, IO_3). The structures of these compounds have been determined by IR spectra to be ionic. The iodine (V) compound with a chelating polydentate nitrogen ligand, $[PhI(O)(2,2'\text{-bipy})](Otf)_2$ has been reported.[81] The use of I_2O_5 and HIO_3 has been demonstrated for the mild and atom-efficient dehydrogenation of a wide range of substrates. When either of these compounds are added to DMSO, 1:1 complexes (**3** and **4**) are formed, which are mild and efficient oxidants and can be used for dehydrogenation of aldehydes and ketones.[82] Reacting $ArIO_2$ with AHF or with SF_4 can yield fluoro derivatives such as $ArIOF_2$ and $ArIF_4$ respectively.

1 INTRODUCTION

Of the transition elements proposed to be an essential trace element for mammals, Cr is probably the least understood. The evidence for an essential role for Cr is suggestive,[1] but not conclusive. Four lines of evidence are usually used in support of an essential role. The first evidence comes from studies in the 1990s of rats fed a purified, Cr-deficient diet (33 ng Cr/g diet). In glucose tolerance tests, these rats had elevated insulin areas compared to controls, suggesting the onset of insulin resistance.[2] Unfortunately, similar studies before 1990, including the classic studies by Mertz that originally led to the proposal that Cr was essential, have methodological problems that hinder interpretation.[1] Second, Cr absorption by humans is inversely proportional to intake, suggesting that intake is regulated.[3] However, this is not the case for rats.[4] Next, five cases of Cr deficiency in humans have been reported.[5] The subjects were all on total parenteral nutrition (TPN), developed symptoms similar to those of type 2 diabetes, and did not respond to insulin treatment. However, the symptoms were reversed upon the addition of Cr to the TPN. The limited number of patients, the range of blood Cr concentrations of patients, and the varying symptoms have led to questions about these cases.[6] Finally, urinary Cr loss is directly related to blood serum insulin concentrations.[7] Increases in serum insulin (as would result from increases in serum glucose) result in increases in urinary Cr excretion. Similarly, conditions that alter glucose metabolism (such as type 2 diabetes) alter urinary Cr output. Thus, a relationship appears to exist between glucose metabolism, insulin levels, and Cr mobilization in the body.[8] Fortunately, Cr deficiency is difficult to develop. Recently, the Food and Nutrition Board of the National Academy of Sciences has lowered the daily adequate intake (AI) of Cr from 50–200 μg to 25 μg for women and 35 μg for men.[9] These values reflect the average daily intake of Cr for Americans,[3] suggesting that few Americans have Cr-deficient diets. Nutritional studies have been hampered by the lack of a biomarker for Cr status. While Cr as the chromic ion may be essential, Cr in the 6+ oxidation state, in contrast, is a potent carcinogen and is present in the environment primarily as a result of human activity.

2 GLUCOSE TOLERANCE FACTOR

For Cr to be essential, chromic ions presumably must bind to some biomolecule(s) and the resulting complex must have an inherent function. The first Cr-containing species to be proposed as this molecule was glucose tolerance factor (GTF).[10] GTF was originally extracted from porcine kidney powder and Brewer's yeast and was the subject of considerable research in the 1960s and 1970s. The species was believed to be a complex of nicotinate and amino acids and to bind to insulin, enhancing insulin's binding to the insulin receptor. However, since this time, several groups have separated the Cr-containing species in the yeast extracts from the insulin-stimulating factor, and GTF has been shown to be an artifact of its isolation procedure. Recently, a suggestion has been made to drop the use of the term GTF.[1]

3 CHROMODULIN (LOW-MOLECULAR-WEIGHT CHROMIUM-BINDING SUBSTANCE)

The best candidate for a biologically active form of Cr is the oligopeptide chromodulin, formerly known as low-molecular-weight Cr-binding substance (LMWCr). Yamamoto, Wada, and coworkers have demonstrated that isolated rat adipocytes in the presence of chromodulin and insulin display an increased ability to metabolize glucose; this increase occurs without a change in the insulin concentration required for half-maximal stimulation,[11,12] suggesting a role for chromodulin inside the insulin-sensitive cells after insulin binds externally to the insulin receptor.[13] The stimulation of glucose metabolism by chromodulin is proportional to its chromium content.[14]

Chromodulin is a naturally occurring oligopeptide composed of glycine, cysteine, aspartate, and glutamate with the carboxylates comprising more than half of the total amino acid residues.[12,14] The lack of a published sequence

is a matter of concern. Despite its small size, the molecule has been shown to tightly bind four equivalents of chromic ions. The binding is quite tight ($K \sim 10^{21}\ M^{-4}$) and highly cooperative (Hill coefficient 3.47).[15] Spectroscopic studies suggest that the chromic ions comprise an anion-bridged multinuclear assembly supported by carboxylates from the oligopeptide.[16] Three of the Cr centers are arranged in an unsymmetric trinuclear assembly with the fourth mononuclear center in close proximity.[17] As holochromodulin can be prepared simply by addition of chromic ions to solutions of apochromodulin, these anionic bridges are probably hydroxide ions.[13,18,19] To date, the oligopeptide has been isolated and purified from mammalian liver (rabbit and bovine)[12,14] and kidney (porcine).[20] A related Cr-containing oligopeptide from bovine colostrum is composed of the same amino acids but in distinctly different ratios and also stimulates insulin-dependent glucose metabolism in rat adipocytes.[12] The significance of these differences remains unexplored, and the possibility that several low-molecular-weight, carboxylate-rich peptides exist for the binding of Cr is in need of investigation. Chromodulin appears to be maintained in the cytosol[21] and nucleus[22] of insulin-sensitive cells in the apo form. The oligopeptide is isolated as the holo-oligopeptide (so that it may be followed in the purification schemes by its Cr content), which means that an in vivo or in vitro Cr-loading step is required.[12,14] This observation and others have resulted in the suggestion that chromodulin may play a role in Cr detoxification; however, injection of chromic ions or chromate into mice does not stimulate the production of apochromodulin.[21] Thus, while chromodulin does carry Cr into the urine after intake of large dosages of Cr^{III} or Cr^{VI} and can serve to efficiently remove Cr,[22] the suggested detoxification role of chromodulin is unlikely to be its primary function.

Because the primary events between insulin binding to its receptor and glucose transport are signal transduction events, a role for chromodulin in these events has been probed. Chromodulin activates the tyrosine kinase activity of insulin-activated insulin receptor[18] and activates a membrane phosphotyrosine phosphatase in adipocyte membranes.[19] The addition of bovine liver chromodulin to rat adipocytic membranes in the presence of insulin results in a concentration-dependent eightfold stimulation of insulin-dependent protein tyrosine kinase activity (while no activation

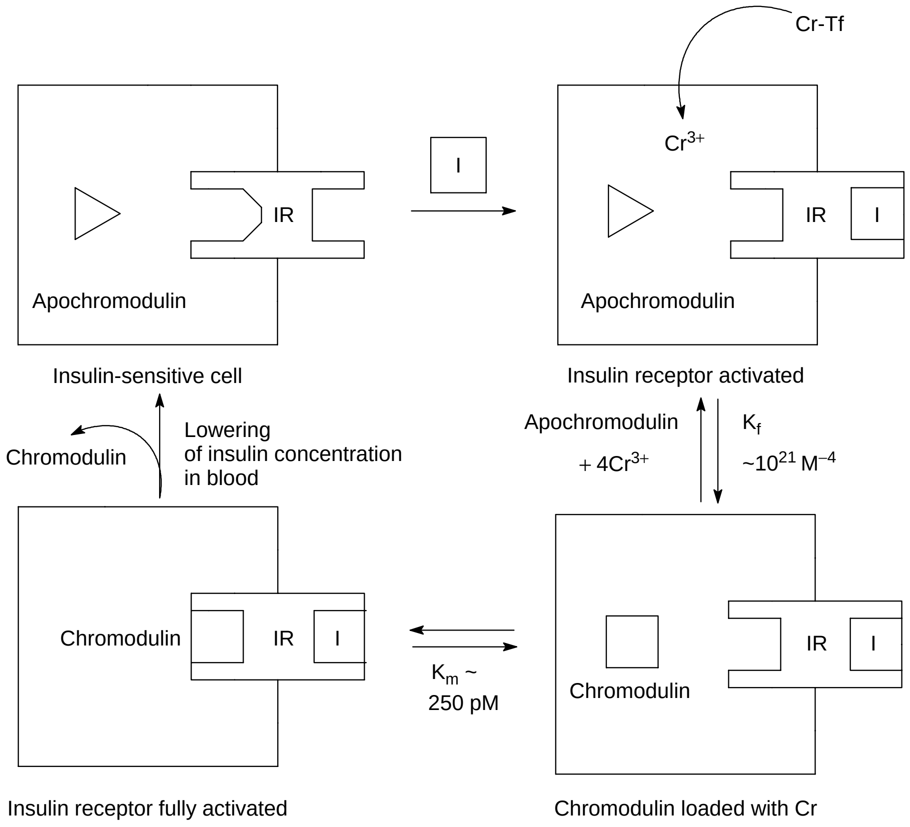

Figure 1 Proposed mechanism for the activation of insulin receptor kinase activity by chromodulin. The inactive form of insulin receptor (IR) is converted to the active form by binding insulin (I). This triggers a movement of Cr (in the form of Cr-transferrin, Cr-Tf) from the blood into cells, which in turn results in the binding of Cr to apochromodulin (triangle). Finally, holochromodulin (square) binds to insulin receptor, further activating the receptor's kinase activity. When the insulin concentration drops, holochromodulin is released from the cell to relieve its effects. (Ref. 1. Reproduced by permission of Elsevier)

of kinase activity is observed in the absence of insulin) with a dissociation constant of approximately 875 pM.[18] Blocking the insulin-binding site on the external α subunit results in the loss of the ability to activate insulin receptor kinase activity.[16] Isolated rat insulin receptor's kinase activity is activated by bovine chromodulin in the presence of insulin by approximately sevenfold, conclusively demonstrating that the receptor is the site of interaction with chromodulin. Similarly, studies with a catalytically active fragment (residues 941–1343) of the β subunit of human insulin receptor reveal that chromodulin can stimulate the kinase activity threefold. Thus, chromodulin appears to bind at or near the kinase active site.[23] Cr plays a crucial role in the activation of insulin receptor kinase activity by chromodulin.[18] Apochromodulin does not activate the receptor's insulin-dependent tyrosine kinase activity. However, titration of apochromodulin with chromic ions results in the total restoration of the ability to activate kinase activity; $\sim$ 4 chromic ions per oligopeptide are required for maximal activity, consistent with the number of Cr bound to an isolated holochromodulin. This reconstitution of chromodulin's activation potential is specific to Cr. Transition metal ions other than Cr that are commonly associated with biological systems are ineffective in potentiating the ability of apochromodulin to activate kinase activity. Thus, the ability of chromodulin to potentiate the effects of insulin is specific to Cr and is directly dependent on the Cr content of chromodulin.

On the basis of these results, chromodulin has been proposed to function as part of a unique autoamplification system for insulin signaling (Figure 1).[24] In this mechanism, apochromodulin is stored in insulin-sensitive cells. In response to increases in blood insulin concentrations, insulin binds to its receptor, bringing about a conformation change that results in the autophosphorylation of tyrosine residues on the internal side of the receptor. This transforms the receptor into an active kinase and transmits the signal from insulin into the cell. In response to insulin, Cr, stored in the blood plasma bound to the iron-transport protein transferrin (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***), is moved from the blood into cells via endocytosis.[25] The Cr flux results in loading of apochromodulin with Cr. The holochromodulin then binds to the insulin receptor, presumably assisting to maintain the receptor in its active conformation, amplifying its kinase activity. When insulin signaling is to be turned off, a drop in blood insulin levels facilitates relaxation of the conformation of the receptor, and the holochromodulin is excreted from the cell into the blood. Ultimately, chromodulin is excreted in the urine. The basis of the name chromodulin is the similarity of the proposed mechanism to that of the calcium-binding protein calmodulin.[26] Both bind four equivalents of metal ions in response to a metal ion flux; however, the four Ca ions that bind to the larger protein calmodulin rest in mononuclear sites. Both holoproteins selectively bind to kinases and phosphatases, stimulating their activity.

4 CHROMIUM PICOLINATE AND TOXICITY

After the first studies that suggested the nutritional supplement chromium picolinate, $[Cr(pic)_3]$, could have potentially beneficial effects on body mass and composition appeared in 1989,[27] the nutritional supplement has become amazingly popular; products containing the supplement generated nearly one-half billion dollars in sales in 1999, making the mineral supplement second only to Ca supplements.[28] Yet, studies of $[Cr(pic)_3]$ on healthy individuals since the initial reports have failed to support the early findings. This has resulted in a 'high degree of politicization and polarization apparent in this field... characterized by unproven claims and counterclaims and suspicion among investigators. Concerns about possible commercial interest have naturally emerged.'[29] Recent review articles[1,30–33] and meta-analyses[34–36] have concluded that the supplement has no demonstrated effects (body mass, body composition, or plasma glucose and insulin concentrations) on healthy individuals, even when taken in combination with an exercise program. Yet, six years after the initial report of potentially beneficial effects from $[Cr(pic)_3]$ supplementation, Wetterhahn and coworkers first reported potential concerns over the use of $[Cr(pic)_3]$.[37] The compound generated clastogenic damage in a Chinese hamster ovary (CHO) cell model. Stohs and coworkers have demonstrated similar damage and oxidative damage in murine macrophages.[38,39] Stearns, in continuing work with the CHO model, has observed mitochondrial damage and apoptosis generated by the supplement[40] and has reported that the supplement is mutagenic.[41]

The effects have been postulated to arise from the released picolinate ligand[37,40] or from reactive oxygen species catalytically generated by the intact complex.[15,42] Physiologically relevant concentrations of Cr as $[Cr(pic)_3]$ (e.g. 120 nM) and of biological reducing agents such as ascorbic acid and thiols resulted in catalytic production of reactive oxygen species, which cleaved DNA.[15,42] Most forms of Cr^{III} do not generate such species in the absence of a strong oxidant such as peroxide.[43] Hence, these studies are consistent with investigations that demonstrated that mutagenic forms of Cr^{III} possessed chelating ligands containing pyridine-type nitrogens or other imine nitrogens coordinated to the metal and generated reactive oxygen species.[44] Consequently, for this mechanism to lead to significant cell damage, $[Cr(pic)_3]$ needs to enter cells intact and remain intact long enough to produce a significant quantity of reactive oxygen species. Recently, $[Cr(pic)_3]$ has been shown to be able to rapidly pass from the bloodstream and enter cells intact, although the lifetime of the complex in cells is short.[45] In hepatocytes, Cr

from $[Cr(pic)_3]$ first appears in the nucleus and mitochondria, then the cytosol, and finally the lysosomes and microsomes; however, the complex has no propensity to bind to DNA. Kelley and coworkers have found that hepatocyte microsomes can catalytically modify the picolinate ligands, which would result in Cr release.[46]

Isolated incidents of deleterious effects of $[Cr(pic)_3]$ supplementation have been reported.[30] The nature of these incidents makes their significance difficult to ascertain. In contrast, Anderson *et al.*[47] fed rats diets containing up to 100-mg Cr as $[Cr(pic)_3]$ per kg diet for 24 weeks; no acute toxic effects were observed. No toxic effects of $[Cr(pic)_3]$ supplementation were noted in any of the studies from the review articles mentioned previously, which combined monitored hundreds of subjects.[1,30] No study has yet to examine the effects, positive or negative, of the long-term use of $[Cr(pic)_3]$. Animal studies looking for DNA damage and oxidative damage have started to appear. No effect on 5-hydroxymethyl uracil levels have been observed in 10 obese women who were given 400-μg $[Cr(pic)_3]$ (50-μg Cr) per day for 8 weeks.[48] In contrast, rats given $[Cr(pic)_3]$ daily by intravenous injection for 60 days have elevated levels of urinary 8-hydroxydeoxyguanosine and peroxidized lipids.[49] Potentially deleterious in vivo effects of $[Cr(pic)_3]$ have recently been examined using *Drosophila melanogaster*.[50] $[Cr(pic)_3]$, but not $CrCl_3$, at levels of 260-μg Cr/kg food or less were found to lower the success rate of pupation and eclosion and to arrest development of pupae in a concentration-dependent fashion. X-linked lethal analysis indicated that the supplement greatly enhances the rate of appearance of lethal mutations and of dominant female sterility.

5 CHROMIUM THERAPEUTIC AGENTS AND TYPE 2 DIABETES

While Cr supplementation of the diet of healthy humans appears to have no statistically significant effects, the effects of Cr on type 2 diabetic subjects are still an area of debate. The administration of pharmacological, rather than nutritional, amounts of Cr could potentially result in beneficial effects, especially for subjects with altered metabolisms that could potentially lead to altered Cr status. A recent meta-analysis of studies with diabetic subjects revealed that the combined data from all placebo-controlled studies but one, the largest study, indicated no effect from Cr administration.[35] The largest study by Anderson and coworkers gave 155 subjects in China 0-, 200-, or 1000-μg Cr daily for 4 months.[51] At the highest Cr dosage, subjects had reduced fasting serum glucose, insulin, and total cholesterol and lower 2-h insulin and glucose concentrations after a glucose challenge. Subjects also possessed lower HbA_{1c} levels. Anderson has reviewed studies on the effects of Cr administration on type 2 diabetics;[52,53] only studies using $\leq$200-μg Cr daily reported no effects from supplementation, suggesting that larger quantities of Cr are required for beneficial effects on type 2 diabetics. Significantly, the studies using $>$200-μg Cr per day are supported by studies on model rats.[54–56] Thus, continued rat and human studies are required to further elucidate the potential use of Cr administration as an adjuvant therapy for type 2 diabetes.

The existence of a multinuclear Cr^{III} carboxylate assembly in an active biomolecule has spurred an interest in the synthesis and characterization of multinuclear oxo(hydroxo)-bridged Cr^{III} carboxylate assemblies.[1] Well-characterized, water-soluble assemblies have been tested for the ability to stimulate insulin receptor's tyrosine kinase ability in a fashion similar to chromodulin. The trinuclear cation $[Cr_3^{III}O(O_2CCH_2CH_3)_6(H_2O)_3]^+$ was found in vitro to mimic the ability of chromodulin to stimulate this activity.[23] The biomimetic cation remains intact after injection into the bloodstream and is taken up by cells intact.[57,58] After 24 weeks of intravenous administration (0–20-μg Cr/kg body mass) in healthy rats, the cation resulted in a concentration-dependent lowering of levels of fasting blood plasma LDL cholesterol, total cholesterol, triglycerides, and insulin and of two-hour plasma insulin and glucose levels after a glucose challenge.[54] Zucker obese rats (a model of the early stages of type 2 diabetes) after 24 weeks of supplementation (20μg kg^{-1}) had lower fasting plasma total, HDL, and LDL cholesterol; triglycerides; and insulin levels and lower two-hour plasma insulin levels. The lowering of plasma insulin concentrations with little effect on glucose concentrations suggests that the cation increases insulin sensitivity.

6 CHROMATE TOXICITY

Given its similarity to $HPO_4{}^{2-}$ and $SO_4{}^{2-}$, chromate, $[Cr^{VI}O_4]^{2-}$, is able to travel via nonspecific anion transporters across the plasma membrane. Once inside a cell, cellular enzymatic and other systems are capable of reducing the chromate to Cr^{V}, Cr^{IV}, and Cr^{III} species, which are generally nondiffusing and thus trapped inside the cells. The mechanisms of these processes have been a subject of intense research[59,60] as they are directly related to the carcinogenicity and mutagenicity of Cr^{VI} (recently brought to public attention by the movie *Erin Brockovich*). Cr^{VI} is a potent carcinogen when inhaled, although the potential carcinogenicity when taken orally is currently actively debated. In cells, cysteine, glutathione, and ascorbate are probably significant players in chromate reduction. Most recent studies have focused on Cr^{V} as the species primarily responsible for carcinogenic effects. The involvement of Cr^{V} carbohydrate complexes in chromate-derived DNA damage has been proposed;[60] however, further research is required to establish their significance. The ultimate reduction product, Cr^{III}, accumulates in the nucleus of cells and

may form DNA protein and other cross-links; the deleterious potential of these cross-links is uncertain.

1 INTRODUCTION

The transition metal chromium has played a prominent role in the development of inorganic chemistry. Discovered in 1797 by the French chemist Louis N. Vauquelin in the rare mineral crocoite ($PbCrO_4$), it was named for the varied colors of its compounds (chroma ($\chi\rho\omega\mu\alpha$) = color). Chromium compounds exist in an unusually large number of formal oxidation states (−IV to +VI) (*see Oxidation Number*); however, only the +II to +VI states are accessible in water. Hexavalent chromium is a powerful oxidant and the use of chromium-based oxidants in organic synthesis[1–3] goes back well over a century (witness the Etard reaction of alkylbenzenes with chromyl chloride (CrO_2Cl_2), which was first described in 1880). Chromium(II), on the other hand, is strongly reducing, and by far the most stable oxidation state of the element is +III, giving rise to an extensive series of stable inorganic compounds.

The remarkable chemical and configurational stability of octahedral Cr^{III} complexes (*see Octahedral*) was responsible for their role in the groundbreaking work of Alfred Werner, the father of modern coordination chemistry (*see* ***Coordination Chemistry: History***). In the twentieth century, the same properties led to their use in studies of the reaction mechanisms of metal complexes. In recent years, the chemistry of the chromium−carbon bond has been the most active area of research in chromium chemistry (*see* ***Chromium: Organometallic Chemistry***), motivated in part by its importance in catalytic processes (notably ethylene polymerization).

2 THE ELEMENT

2.1 Occurrence

The only chromium ore of practical importance is chromite, a black spinel of the idealized composition $FeCr_2O_4$; in practice, it contains varying amounts of MgO, Al_2O_3, and SiO_2. Major producers of chromite include South Africa, Kazakhstan, India, and Turkey. Since 1900, the production of chromite has doubled roughly every decade, reaching an estimated 14.2 million tons in 1998. Chromium is more rarely found as the mineral crocoite ($PbCrO_4$) and minor amounts of the element occur in many other minerals. Traces of chromium ions are responsible for the color of emeralds ($Be_3Al_2Si_6O_{18}$) and rubies (Al_2O_3). At an average concentration of 100 ppm in the earth's crust, chromium ranks 21st in elemental abundance; its typical level in seawater is ca. 2×10^{-4} ppm.

2.2 Production and Uses[4]

The greater part (ca. 85%) of chromite ore production is reduced by heating with coal to give 'ferrochrome', used in the manufacture of alloy steels. Pure chromium metal for use in iron-free alloys and metal-containing ceramics is produced by reduction of Cr_2O_3. Common reducing agents are aluminum, carbon, or silicon. Another process involves the electrolysis of chrome alum ($NH_4Cr(SO_4)_2\cdot 12H_2O$) solutions. CrO_3 solutions are employed in electroplating of chromium on other metals to impart wear resistance and for decorative purposes.

Less than 15% of the ore is transformed into chromium compounds, principally chromates, dichromates, chromium(VI) oxide, chromium(III) oxide, and so on. Alkaline oxidative roasting of chromite in rotary kilns yields sodium chromate (see equation 1), which is leached out with water and typically converted into sodium dichromate with sulfuric acid (equation 2) or carbon dioxide (equation 3). Further treatment of sodium dichromate with sulfuric acid yields chromium(VI) oxide ('chromic acid'), while its reduction (with carbon, sulfur, or ammonium salts) produces chromium(III) oxide. Finally, basic chromium(III) salts, for example $Cr(OH)SO_4$, which are used as tanning agents for animal hides, also result from reduction of sodium dichromate. Heterogeneous chromium catalysts are used for the polymerization of ethylene.

$$4FeCr_2O_4 + 4Na_2CO_3 + 7O_2 \xrightarrow{>1000\,^{\circ}C} 8Na_2CrO_4 + 2Fe_2O_3 + 8O_2 \quad (1)$$

$$2Na_2CrO_4 + H_2SO_4 \longrightarrow Na_2Cr_2O_7 + Na_2SO_4 + H_2O \quad (2)$$

$$2Na_2CrO_4 + H_2O + 2CO_2 \longrightarrow Na_2Cr_2O_7 + 2NaHCO_3 \quad (3)$$

2.3 Atomic Properties[5–7]

Chromium has the atomic number 24. Of the 13 known isotopes (mass numbers 45–57), four are stable, giving chromium the relative atomic mass 51.9961 ($^{12}C = 12.0000$). Table 1 lists the properties of some isotopes. ^{53}Cr may be used for NMR spectroscopy;[8] however, its relative receptivity (8.62×10^{-5}, $^{1}H = 1.00$), quadrupole moment ($4.1 \times 10^{-30}\,m^2$), and low resonance frequency (16.956 MHz, $^{1}H = 300$ MHz) pose experimental difficulties. Radioactive ^{51}Cr is used in medical tracer studies.

Chromium atoms have the ground-state electronic configuration [Ar]$3d^5 4s^1$, giving rise to the term symbol $^7S_3$. Its *Electron Affinity* is 64.3 kJ mol^{-1} (0.67 eV) and its first through sixth ionization potentials are 652.7 (6.764), 1592 (16.50), 2987 (30.95), 4740 (49.12), 6690 (69.33), and 8738 (90.55) kJ mol^{-1} (eV), respectively (*see Ionization Potential*).

2.4 Physical Properties

Solid chromium adopts a body-centered cubic structure and crystallizes in the space group *Im*3*m* with $a =$ 288.46 pm; its density is 7.19 g cm^{-3} (at 293 K). The metal melts at 2130 (±20) K and boils at 2945 K; the corresponding enthalpies are $\Delta H_{fusion} = 15.3$ kJ mol^{-1} and $\Delta H_{vap} = 348.78$ kJ mol^{-1}. Values of various thermodynamic functions are listed in Table 2. Some other values are: thermal conductivity: 93.7 W m^{-1} K^{-1} (at 300 K), electrical resistivity: $12.7 \times 10^{-8}\,\Omega$ m (at 273 K), magnetic susceptibility: $+3.5 \times 10^{-6}$ cm^3 g^{-1} (ambient temperature), and linear coefficient of thermal expansion: 6.2×10^{-6} K^{-1}.

Table 1 Properties of chromium isotopes

Isotope	Atomic mass	Abundance (%)	Half-life	Decay mode	Nuclear spin
^{48}Cr			23 h	EC	
^{49}Cr			41.9 minutes	β^-	5/2
^{50}Cr	49.946046	4.35	Stable		–
^{51}Cr	50.944768		27.7 days	EC	7/2
^{52}Cr	51.940509	83.79	Stable		–
^{53}Cr	52.940651	9.50	Stable		3/2
^{54}Cr	53.938882	2.36	Stable		–
^{55}Cr			3.5 minutes	β^-	
^{56}Cr			5.9 minutes	β^-	

Table 2 Thermodynamic properties of chromium[a]

State	$\Delta H_f°$ (kJ mol^{-1})	$\Delta G_f°$ (kJ mol^{-1})	$S°$ (J K^{-1} mol^{-1})	C_p (J K^{-1} mol^{-1})
Solid	0.0	0.0	23.47	23.35
Gas	396.6	351.8	174.50	20.79

[a] $T = 298.15$ K; $P = 10^5$ Pa.

2.5 Chemical Properties

Chromium is fairly resistant to ordinary corrosive agents. However, at elevated temperatures it reacts with many elements, including the halogens, oxygen and sulfur, nitrogen, carbon, and boron. It dissolves readily in dilute HCl or H_2SO_4, but not in nitric acid, phosphoric acid, or even aqua regia. The oxidizing acids are thought to passivate the metal surface by formation of a thin protective oxide layer. Under certain conditions, this passivation layer may be formed and destroyed periodically, leading to oscillations in the hydrogen evolution upon dissolution of the metal. Nonpassivated chromium is a strong reducing agent; see equations (4) and (5).

$$Cr^{2+}(aq) + 2e^- \rightleftharpoons Cr(s) \qquad E° = -0.91\,V \tag{4}$$

$$Cr^{3+}(aq) + 3e^- \rightleftharpoons Cr(s) \qquad E° = -0.74\,V \tag{5}$$

The most common oxidation states of chromium in inorganic compounds are +II, +III, and +VI. By comparison, there are few stable compounds of tetravalent or pentavalent chromium; these oxidation states are largely represented by reactive intermediates in redox reactions. π-Acid ligands like CO (*see π-Acid Ligand*) stabilize chromium in very low formal oxidation states (down to −IV!). Table 3 lists oxidations states and coordination environments for representative chromium compounds.

2.6 Biological Properties[9–11]

Chromium(VI) compounds (e.g. dichromates, chromic acid, etc.) have long been known as skin irritants. Indeed, chromium has been shown to be one of the most important causes of occupational contact dermatitis. There is also strong evidence that chromium(VI) compounds are carcinogenic. Most of the available data comes from studies of occupationally exposed groups. There are no data linking cancer with chromium in the general environment.

Chromium(III), on the other hand, is an essential trace metal in mammalian nutrition, aiding in the metabolism of glucose (*see* ***Nutritional Aspects of Metals & Trace Elements***). The 'adequate intake' of chromium has been estimated as 25–35 µg day^{-1}. The 'glucose tolerance factor' (GTF) is a chromium containing extract of brewer's yeast, which enhances the action of insulin. There is no evidence for any toxic effects of Cr^{III}.

Table 3 Formal oxidation states and stereochemistry of chromium compounds

Oxidation state	Coordination number	Coordination geometry	Examples
Cr^{-IV}	?	?	$Na_4[Cr(CO)_4]$
Cr^{-II}	?	?	$Na_2[Cr(CO)_5]$
Cr^{-I}	6	Octahedral	$Na_2[Cr_2(CO)_{10}]$
Cr^{0}	6	Octahedral	$Cr(CO)_6$, $Cr(bipy)_3$
Cr^{I}	6	Octahedral	$[Cr(NCR)_6]^+$
Cr^{II}	4	Square planar	$Cr(O_2CCF_3)_2(Me_2py)_2$
	4	Tetrahedral	$CrCl_2(MeCN)_2$
	4	Cis-divacant octahedral	$Tp^{tBu,Me}CrCl$
	4	Trigonal pyramidal	$[Na(THF)_2(N_3N)Cr]$
	5	Trigonal bipyramidal	$[CrBr\{N(CH_2CH_2NMe_2)_2\}_3]^+$
	6	Octahedral	$CrCl_2$, $[Cr(en)_3]^{2+}$
	7	Capped trigonal prism	$[Cr(CO)(diars)_2X]^+$
Cr^{III}	3	Trigonal planar	$Cr\{N(SiMe_3)_2\}_3$
	4	Tetrahedral	$[CrCl_4]^-$
	5	Trigonal bipyramidal	$CrCl_3(NMe_3)_2$
	6	Octahedral	$[Cr(NH_3)_6]^{3+}$, $[Cr(CN)_6]^-$
Cr^{IV}	4	Tetrahedral	$Cr(NEt_2)_4$, $Cr(O\text{-}t\text{-}Bu)_4$
	6	Octahedral	$[CrF_6]^{2-}$
	8	Dodecahedral	$CrH_4(dmpe)_2$
Cr^{V}	4	Tetrahedral	$[CrO_4]^{3-}$
	5	Square pyramidal	$[CrOCl_4]^-$
	6	Octahedral	$[CrOCl_5]^{2-}$
	8	Dodecahedral	$[Cr(\eta^2\text{-}O_2)_4]^{3-}$
Cr^{VI}	4	Tetrahedral	$[CrO_4]^{2-}$, CrO_2Cl_2

3 BINARY COMPOUNDS AND SIMPLE SALTS

3.1 Hydrides

The solubility of hydrogen in chromium metal increases with temperature. The existence of two discrete hydrides of stoichiometry CrH and CrH_2 with different structures had been suggested in the older literature; however, the existence of the latter was called into question. Recent experiments involving the reaction of Cr atoms with H_2 and *Matrix Isolation* of the products have provided spectroscopic evidence for the molecules CrH and CrH_2. Species with higher hydrogen content are now thought to be dihydrogen complexes, for example, $(H_2)CrH$, $(H_2)CrH_2$, and $(H_2)_2CrH_2$.[12]

3.2 Compounds with Elements of Groups 13–15

Chromium borides have been prepared by heating mixtures of chromium and boron or Cr_2O_3 and boron; another preparation employed electrolysis of molten oxides of both elements. A number of phases have been identified; their compositions are Cr_4B, Cr_2B, Cr_5B_3, CrB, Cr_2B_3, Cr_3B_4, and CrB_2 (*see* ***Borides: Solid-state Chemistry***).[13] Crystals of several phases have been grown from high-temperature Al solutions.[14] The chromium borides are refractory materials with high melting points and metallic character, for example, they exhibit electrical conductivity. They are resistant to chemical attack.

Chromium carbides have been produced by melting mixtures of chromium and graphite under vacuum or by heating Cr_2O_3 with C. Chromium metal reacts with CH_4 at 600–800 °C, forming carbides and H_2. Three different compounds have been identified, namely, $Cr_{23}C_6$, Cr_7C_3, and Cr_3C_2 (*see* ***Carbides: Transition Metal Solid-state Chemistry***). They are very hard and high melting.

Chromium silicides have been isolated, inter alia, from melts of chromium/silicon mixtures, from the reduction of Cr_2O_3/SiO_2 mixtures (e.g. with Al), and from the electrolysis of Na_2SiF_6/CrF_2 melts. Tentatively identified compounds include Cr_3Si, Cr_2Si, Cr_5Si_3, Cr_3Si_2, CrSi, and $CrSi_2$. All of these appear metallic and conduct electricity. They are hard and brittle, have high melting points, and are resistant to attack by acids.

Chromium nitrides have been prepared by several routes: heating of chromium metal in N_2, reaction of chromium borides with NH_3, and heating of $CrCl_3$ in gaseous NH_3. The two stable nitrides have the composition Cr_2N and CrN (*see* ***Nitrides: Transition Metal Solid-state Chemistry***). At very high temperatures, both decompose into the constituent elements (CrN, >1425 °C; Cr_2N, >700 °C). CrN is very stable chemically, while Cr_2N dissolves in dilute acid with liberation of H_2.

The chromium phosphides Cr_3P, Cr_2P, CrP, Cr_2P_3, and CrP_2 have been described in the literature (*see* ***Phosphides:***

Solid-state Chemistry). They were prepared by direct reaction of the elements.

3.3 Oxides and Sulfides

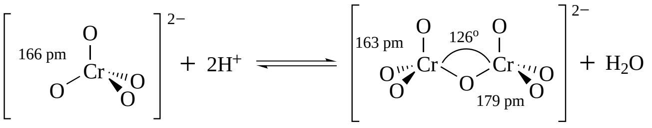
Of the chromium oxides, only Cr_2O_3, CrO_2, and CrO_3 are of significance.

Chromium(III) oxide (Cr_2O_3) is produced commercially by reduction of CrO_3. Other preparations include burning of chromium metal in O_2, thermal decomposition of CrO_3 or $(NH_4)_2Cr_2O_7$, and heating of the hydrous oxide ($Cr_2O_3 \cdot nH_2O$) obtained by adding hydroxide to aqueous solutions of Cr^{III} ion. When prepared in the latter way, it is reactive and amphoteric (*see Amphoterism*); dissolution in acid reforms the purple $[Cr(OH_2)_6]^{3+}$ ion (Cr^{III}(aq)), while treatment with base yields dark green 'chromite' solutions, that is $[Cr(OH)_6]^{3-}$. Cr_2O_3 is a green solid, which begins to decompose before it reaches its melting point (ca. 2435 °C). It adopts the corundum structure, that is, a hexagonally close-packed array of oxide ions with two-thirds of the octahedral holes occupied by Cr^{III} ions (*see Close Packing*). It is a semiconductor (conductivity: 10^{-6}–10^{-7} Ω^{-1} cm^{-1}) and an antiferromagnet with a Néel temperature of ca. 50 °C.

Chromium(IV) oxide (CrO_2) is formed as an intermediate in the thermal decomposition of CrO_3. It is commercially prepared by hydrothermal treatment ($T = 250$–500 °C, $P = 50$–3000 atm) of CrO_3. CrO_2 is a brown–black solid that decomposes to Cr_2O_3 upon heating to 250–500 °C. It has the rutile structure (slightly distorted hexagonal close packing of oxide ions with one half of the octahedral holes filled by Cr^{IV} ions). It exhibits metallic conductance and is ferromagnetic (*see Ferromagnetism*); the latter property leads to its use in magnetic recording tapes.

Chromium(VI) oxide (CrO_3, 'chromic acid') is made by treatment of dichromate (e.g. $Na_2Cr_2O_7$) with sulfuric acid. It is an orange–red solid with a melting point of only 197 °C. Upon heating it slowly loses oxygen, eventually yielding Cr_2O_3. The structure of the rather covalent oxide consists of chains of corner-sharing tetrahedra (*see Tetrahedral*). CrO_3 reacts vigorously with organic substances; it is widely used as an oxidant in synthetic organic chemistry.[1,2]

CrO_3 dissolves in base, forming yellow solutions of the tetrahedral chromate ion (CrO_4^{2-}) (**1**). Chromate is a weak base; upon lowering of the pH it forms $HCrO_4^-$ (pK_a 6.49) and eventually H_2CrO_4 (pK_a 0.74). The latter species are in equilibrium with the orange dichromate ion ($Cr_2O_7^{2-}$) (**2**) (equation 6). In strongly acidic media, further polymerization yields tri- and tetrachromates ($Cr_3O_{10}^{2-}$ and $Cr_4O_{13}^{2-}$), short chains of corner-sharing tetrahedra anticipating the structure of the end member CrO_3. A comparison of structural data for a series of mono- and polychromates showed a smooth correlation of the Cr–O distances with increasing degree of polymerization.[15] By comparison with the heavier Group 6 elements (Mo, W), chromium shows little tendency for the formation of ***Polyoxometalates***. This is probably due to its smaller size, favoring four over six coordination, and to the relative strength of the Cr=O multiple bond. Acidic dichromate solutions are strongly oxidizing. The nonhygroscopic $K_2Cr_2O_7$ has been used extensively as a standard reagent in redox titrations.



(**1**) (**2**)

(6)

Reduction of CrO_4^{2-} (chromates(VI)) yields CrO_4^{3-} ions (chromates(V)), which can be isolated in the form of their alkali metal and alkaline-earth metal salts, for example, Na_3CrO_4 and $Ba_3(CrO_4)_2$. The black or blue paramagnetic salts contain isolated CrO_4 tetrahedra and are hygroscopic; upon dissolution in water they disproportionate to Cr^{III} and Cr^{VI}.

Further reduction produces CrO_4^{4-}, an isolated tetrahedral anion found for example in the deep green Na_4CrO_4. The d^2 configuration of the Cr^{IV} ion gives rise to *Paramagnetism* consistent with two unpaired electrons.

The sulfide ion stabilizes chromium in its lower oxidation states. Thus, both Cr_2S_3 and CrS exist, but a chromium(VI) trisulfide does not. Heating of Cr_2S_3 causes decomposition, leading to CrS by way of a number of phases of intermediate composition. Both Cr_2S_3 and CrS are semiconductors and exhibit magnetic ordering; some of the other sulfides exhibit metallic character.

Several selenides and tellurides of chromium are also known; their stoichiometries parallel those of the sulfides.

3.4 Halides and Oxyhalides

The known halides of chromium are listed in Table 4 with some of their physical properties. The instability of a hexavalent chromium halide is noteworthy. The higher halides are prepared by direct reaction of the metal with the

Table 4 Chromium halides

Fluorides	Chlorides	Bromides	Iodides
'CrF_6'?			
CrF_5 red, mp 30 °C			
CrF_4 colorless, mp 277 °C	$CrCl_4$ gas phase only	$CrBr_4$ gas phase only	
CrF_3 green, mp 1404 °C	$CrCl_3$ violet, mp 1150 °C	$CrBr_3$ dark green, mp 1130 °C	CrI_3 black, mp >600 °C
CrF_2 green, mp 894 °C	$CrCl_2$ white, mp 824 °C	$CrBr_2$ white, mp 842 °C	CrI_2 red–brown, mp 868 °C

appropriate halogen. The chromium(II) halides are obtained by reduction of the trihalides with H_2 or by heating of the metal with HX.

A volatile yellow compound of the composition CrF_6 has been reported; however, those claims have been disputed.[16] Recent computational studies tend toward supporting the existence of the hexafluoride,[17] but definitive experimental work is still missing. Treatment of chromium with fluorine yields CrF_5, even at high temperatures (400 °C). CrF_5 is a sticky red solid with a vapor pressure of 3.3 mbar (330 Pa) at 20 °C. Gaseous CrF_5 is yellow and exhibits no tendency toward disproportionation up to 100 °C. It reacts rapidly with moisture, producing among others $CrOF_4$ and CrO_2F_2. The molecular structure of CrF_5 is a distorted trigonal bipyramid. In the solid state, it polymerizes by formation of fluoride bridges. CrF_4 has been prepared by fluorination of Cr, CrF_3, or $CrCl_3$, and by reaction of CrF_5 with Cl_2. It has been described as brown, dark green, 'bluish', and finally colorless (in a Ne matrix). In the gas phase, it adopts a regular tetrahedral structure (Cr–F, 170.6(2) pm).[18] CrF_3 is a nonvolatile green solid, which is best prepared by the reaction of $CrCl_3$ with HF at 500 °C. Its structure consists of hexagonally close-packed fluoride ions with chromium in octahedral coordination. Light green CrF_2 may be prepared by reduction of CrF_3 with hydrogen at 400 °C or by treatment of $CrCl_2$ with HF. It features a Jahn–Teller distorted rutile structure with chromium–fluorine distances of 200 and 243 pm.

The chromium chloride in the highest oxidation state is $CrCl_4$. This is not a stable compound under ordinary conditions; however, it may be produced by evaporation of anhydrous $CrCl_3$ at ca. 560 °C and trapped in an argon matrix. Its IR spectrum indicates a tetrahedral structure. Further heating of $CrCl_3$ yields molecular $CrCl_3$ at ca. 600 °C (trigonal planar) and finally $CrCl_2$ molecules at 780 °C (linear).[19] Probably the most important chromium halide is the violet $CrCl_3$, the starting material for much of synthetic chromium chemistry. In the solid state, it adopts an unusual layered structure consisting of a cubic close packing of chloride ions with two-thirds of the octahedral holes adjacent to every other anion layer occupied by chromium atoms. Pure $CrCl_3$ does not dissolve in water. However, addition of traces of reducing agents or Cr^{II} results in ready dissolution; this is thought to be due to electron transfer catalysis, that is, reduction of substitutionally inert Cr^{III} on the crystal surface to labile Cr^{II}, which readily dissolves and, in turn, functions as a reducing agent for further Cr^{III}. The same effect is used to practical advantage in the preparation of $CrCl_3(THF)_3$, a useful precursor for organometallic chromium compounds, which is prepared by Soxhlet extraction of $CrCl_3$ (with a little Zn metal added) with tetrahydrofuran (THF). Treatment of Cr metal with HCl or H_2 reduction of $CrCl_3$ (both at ca. 600 °C) yields colorless $CrCl_2$. The dichloride readily dissolves in water, yielding dark blue solutions of the strongly reducing Cr^{2+}(aq) ion.

Like the tetrachloride, $CrBr_4$ exists only in the gas phase. CrI_4 is not known. The structures and properties of the lower

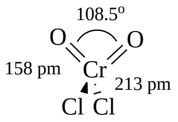
bromides and iodides parallel those of the corresponding chlorides.

The known oxyhalides of chromium are listed in Table 5 with some of their physical properties.[20] Only chromyl chloride (CrO_2Cl_2) (**3**) is of practical importance. The red liquid is prepared by treatment of CrO_3 with HCl or by heating a mixture of $K_2Cr_2O_7$ and KCl with concentrated H_2SO_4 (the latter reaction is the basis for a qualitative test for chloride). Chlorochromic acid ($CrO_2(OH)Cl$) is formed as an intermediate in these reactions; its salts can be isolated as crystalline solids. Chromyl chloride is light sensitive and, like all oxyhalides of chromium, easily hydrolyzed by water. It is also an extremely strong oxidant, reacting vigorously with many organic compounds. It adopts a pseudo-tetrahedral structure, with the O–Cr–O angle (108.5°) being smaller than the Cl–Cr–Cl angle (113°). The latter fact is in contradiction to the tenets of valence shell electron pair repulsion (VSEPR) theory. Numerous derivatives of chromyl chloride of the type CrO_2X_2 (X = NO_3, ClO_4, OAc, OR, N_3, etc.) are known. The electronic and vibrational spectroscopy of Cr^{VI} compounds, and chromyl derivatives in particular, has been reviewed.[21]



(**3**)

4 COORDINATION COMPOUNDS

4.1 Overview

Chromium complexes exist in a very wide range of formal oxidation states (−IV to +VI). The extremely low ones are stabilized by π-acid ligands, notably carbon monoxide; these are described in the article on organometallic compounds (*see* ***Chromium: Organometallic Chemistry***). The extensive coordination chemistry of Cr^{II} spans coordination numbers 3–7, but is dominated by octahedral complexes. Complexes of

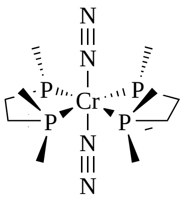
divalent chromium are usually strongly reducing and are often susceptible to air oxidation. By far the largest number of coordination compounds of chromium exists in the +III oxidation state. Commonly octahedral, they are substitution inert and often easily synthesized. In mononuclear complexes, the d^3 electronic configuration (t_{2g}^3) gives rise to spin-only magnetic moments (3.87 μ_B), but in polynuclear complexes, antiferromagnetic coupling between the Cr^{III} ions results in lower values (*see* ***Magnetism of Transition Metal Ions***). The electronic spectra and the photochemistry of trivalent chromium have been studied extensively. The oxidation states +IV and +V have attracted some attention recently. However, these oxidation states must still be considered unusual in the context of chromium chemistry. Finally, Cr^{VI} is a common and important oxidation state of this element, although the number of coordination compounds representing it is rather limited. The notion of a true Cr^{6+} ion is, of course, unrealistic, and the chemistry of Cr^{VI} is marked by strong *Covalent Bonds* to oxygen and halogens. These compounds are strong oxidants. By comparison to the heavier elements in group 6 (Mo, W), chromium shows much less tendency toward *Cluster* formation.

A comprehensive treatise of the coordination chemistry of chromium[22] is available.

4.2 Oxidation States 0 and I

Reduction of common chromium salts ($CrCl_3$, $CrCl_2$, $Cr_2(OAc)_4$) in the presence of chelating nitrogen heterocycles like bipy and phen provides access to formally neutral Cr^0 complexes $Cr(L–L)_3$ as well as salts of the type $[Cr(L–L)_3]X$ (L–L = bipy, phen; X = I, ClO_4). $[Cr(bipy)_3]$ is a black solid; its molecular structure is a trigonally distorted octahedron (Cr–N, 208 pm; N–Cr–N, 74.7°). Owing to the high ligand field strength of the nitrogen ligands, and as shown by their *Diamagnetism*, the $Cr(L–L)_3$ complexes adopt low-spin configurations (t_{2g}^6) (*see High-spin & Low-spin Compounds*). $[Cr(bipy)_3]X$ has an effective magnetic moment of 2.07 μ_B, consistent with one unpaired electron (t_{2g}^5). In solution, it exhibits an electron spin resonance (ESR) spectrum at $g = 1.9971$ with hyperfine splitting to both ^{53}Cr and ^{14}N evident. Electrochemical experiments in aprotic solvents (MeCN) show reversible redox processes involving $[Cr(L–L)_3]$ ions containing chromium in the oxidation states –I, 0, I, II, and III. The half-wave potential for the $[Cr(bipy)_3]^+/Cr(bipy)_3$ couple lies at −1.28 V versus the Ag/AgCl electrode.

Highly reduced chromium binds dinitrogen, for example in *trans*-$[Cr(dmpe)_2(N_2)_2]$ (**4**). Its crystal structure shows linearly bound N_2 ligands (Cr–N, 187.4 pm, N–N, 112.2 pm) and relatively short Cr–P distances (Cr–P_{av}, 229.6 pm). The related $Cr(dmpe)_3$ exhibits similarly short Cr–P bonds (231.7 pm). These short Cr–P distances are thought to be due to *π–Back Bonding* to the phosphine ligand. Both $Cr(dmpe)_3$ and $Cr[P(OMe)_3]_6$ were prepared by metal vapor synthesis (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***). The same technique may also be used to prepare the fluorophosphine complexes $Cr(PF_3)_6$ and $Cr[(PF_2)_2NR]_3$. The phosphine complexes are all diamagnetic and colorless or yellow, indicating large ligand field splittings.



(**4**)

There are Cr^0 and Cr^I complexes of both aryl and alkyl isocyanides (RNC) as well as cyanides; because of their Cr–C linkages, these are described elsewhere (*see* ***Chromium: Organometallic Chemistry***).

4.3 Oxidation State II

The coordination chemistry of Cr^{II} can be subdivided into the realm of mononuclear coordination compounds, which can be derived (at least formally) from the blue $[Cr(OH_2)_6]^{2+}$ ion, and the chemistry of metal–metal bonded species (analogs of $Cr_2(OAc)_4$). Most of the former are octahedral high-spin complexes with distinct tetragonal distortions caused by the *Jahn–Teller Effect*. With strong-field ligands, low-spin octahedral complexes are formed, and there are also some four-coordinate complexes of various coordination geometries. The metal–metal bonded species are described in Section 5.

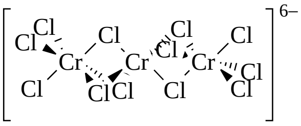
4.3.1 Hydride and Halide Ligands

Cr^{II} hydrides without Cr–C bonds are restricted to the seven-coordinate $[H_2Cr\{P(OMe)_3\}_5]$ and $[HCr\{(Me_2PCH_2)_3CMe\}_2]^+BEt_4^-$. The former complex results from oxidative addition of H_2 to $[Cr\{P(OMe)_3\}_6]$, while the latter was isolated from a reaction of $[CrCl_3\{(Me_2PCH_2)_3CMe\}]$ with $LiHBEt_3$. Both are diamagnetic molecules and their NMR spectra indicate fluxional behavior (*see Fluxional Molecule*).

The anhydrous halides CrX_2 (X = F, Cl, Br, I) were described earlier (Section 3.4). Through formal addition of halide ions, various halochromates(II) can be formed. These feature complex ions of the types CrX_3^-, CrX_4^{2-}, CrX_5^{3-}, and CrX_6^{4-}. These, when they contain fluoride ion, are, for example, the light blue $MCrF_3$ (M = Na, K, Rb, NH_4), dark blue Na_2CrF_4, or $MCrF_4$ (M = Ca, Sr, Ba), and Ba_2CrF_6. Most of these compounds contain six-coordinate Cr^{II}. All are more or less paramagnetic, because of the high-spin d^4 configuration ($t_{2g}^3e_g^1$); thus $KCrF_3$ has $\mu_{eff} = 4.9\,\mu_B$ and Na_2CrF_4 has $\mu_{eff} = 4.8\,\mu_B$. There is evidence for magnetic coupling at low temperatures. Among the corresponding chloro- and bromochromates(II),

the tetrahalochromates M_2CrX_4 (M = alkali metal, organic cations; X = Cl, Br) especially have been the subject of detailed structural and magnetic studies, because some of these materials show weak ferromagnetic coupling. While the overwhelming majority of magnetically coupled transition metal complexes exhibit *Antiferromagnetism*, ferromagnetic coupling is rare and of great interest for the preparation of novel magnetic materials (*see* ***Magnetism of Extended Arrays in Inorganic Solids***).

The colorless alkali metal salts adopt a distorted K_2NiF_4 structure, containing layers of tetragonally distorted $CrCl_6$ octahedra held together by the M^+ ions. At room temperature their effective magnetic moments slightly exceed the spin-only values; upon lowering the temperature, they rise (to ca. 9 μ_B per Cr atom at 90 K). Curie temperatures between 40 and 75 K have been found. Some of the tetrahalochromates(II) are antiferromagnets. For example, the structure of $[NMe_2H_2]_2[CrCl_4]$ contains isolated $[Cr_3Cl_{12}]^{6-}$ units (**5**) in which three distorted $CrCl_6$ octahedra are joined via shared trigonal faces to form a linear chain of three chromium atoms.

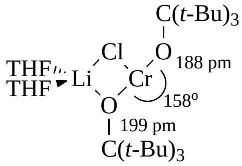


(**5**)

4.3.2 Oxygen and Sulfur Ligands

Solutions of the bright blue $[Cr(OH_2)_6]^{2+}$ ion can be prepared by dissolution of pure chromium metal in mineral acids or by reduction of Cr^{III} with exclusion of oxygen. Cr^{II}(aq) is a strong reducing agent (see equation 4) and has long been used in mechanistic investigations of electron transfer reactions; more recently it has also found applications as a reducing agent in synthetic organic chemistry. Even in the absence of O_2, aqueous Cr^{II} solutions slowly decompose with liberation of H_2; this reaction is catalyzed by various impurities. The electronic spectrum of the $[Cr(OH_2)_6]^{2+}$ ion exhibits a broad asymmetric absorption at 14 000 cm^{-1} and a weaker shoulder at 9500 cm^{-1}, features that are consistent with a tetragonally distorted octahedral complex. While the crystal structure of the $[Cr(OH_2)_6]^{2+}$ ion is not known, the structure of the closely related $Cr(OH_2)_4(SO_4)$ has been determined. The complex features *trans* sulfato oxygens with rather long bond distances (Cr–O, 242–246 pm) and four equatorial water oxygens with normal bond distances (Cr–O, 203–205 pm). This tetragonal elongation is the expected Jahn–Teller distortion.

Cr^{II} alkoxides $[Cr(OR)_2]$ are conveniently prepared by alcoholysis of chromium amides, for example $[Cr\{N(SiMe_3)_2\}_2(THF)_2]$. The alkoxides with bulky substituents are appreciably soluble in organic solvents, but those of primary alcohols are insoluble polymers. The wide variety of substituents gives rise to considerable structural complexity. In donor solvents such as THF, solvent adducts of the type $[Cr(OR)_2(THF)_2]$ are formed. They probably adopt square-planar geometries with *trans*-OR groups, as has been shown for $[(2,6\text{-}(t\text{-Bu})_2\text{-}4\text{-MeC}_6H_2O)Cr(THF)_2]$.[23] The complex $[Li(THF)_2]$ $[Cr\{OC(t\text{-Bu})_3\}_2Cl]$ features an unusual T-shaped geometry (**6**).



(**6**)

$Cr(acac)_2$ is a yellow paramagnetic solid with an effective magnetic moment (4.99 μ_B), consistent with a high-spin d^4 electronic configuration. Its crystal structure shows chromium coordinated by four oxygen atoms in a plane ($Cr–O_{av}$, 198 pm) and two long intermolecular contacts between the metal atom and the methine carbons of neighboring molecules (Cr–C, 305 pm), giving chromium a severely distorted octahedral coordination environment. A few other β-diketonates of Cr^{II} have been prepared.

A number of adducts of chromium(II) halides with oxygen-containing donor molecules have been characterized. They have the composition $CrX_2(L)_2$, where X = Cl, Br, I and L = THF, urea, biuret, dimethylsulfoxide (DMSO), phosphine oxide, arsine oxide, and so on. Most are blue high-spin molecules (μ_{eff} = 4.4–5.0 μ_B). Pale-green $[CrCl_2(THF)_2]$ loses one equivalent of THF in vacuo, thereby yielding colorless $[CrCl_2(THF)]$, which is a useful synthetic precursor for nonaqueous Cr^{II} chemistry.

Sulfur-based Cr^{II} coordination compounds include a series of dithiocarbamates of the type $[Cr(S_2CNR_2)_2]$ (R = Me, Et or $R_2 = C_4H_8$), which are antiferromagnetically coupled. The diethyl-substituted compound is an S-bridged dimer, making chromium five-coordinate. Square-planar Cr^{II} coordinated by sulfur occurs in the violet $[NEt_4]_2[Cr(S_2C_2H_4)_2]$. Finally, *Thiourea* and its derivatives form adducts with Cr^{II} halides, which are similar to the adducts with O-donors mentioned above.

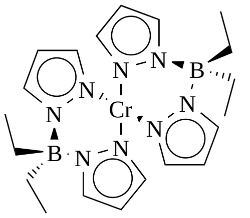
4.3.3 Nitrogen and Phosphorus Ligands

Ammonia deprotonates $[Cr(OH_2)_6]^{2+}$, resulting in precipitation of brown Cr^{II} hydroxide. However, treatment of solid halides CrX_2 or ethanol solutions of hydrated CrX_2 with NH_3 gas yields blue diammines $[Cr(NH_3)_2X_2]$, violet pentammines $[Cr(NH_3)_5X]X$, and greenish-gray hexammines $[Cr(NH_3)_6]X_2$. Their magnetic behavior is that expected of

high-spin complexes. Spectroscopic measurements and comparative X-ray powder diffraction studies are consistent with Jahn–Teller distorted octahedral structures.

Substitution of various chelating bi- and polydentate amines, for example, en, 1,3-diaminopropane, dien, trien, and so on, in nonaqueous media yields an extensive series of octahedral amine complexes, which range in color from blue to purple. Their effective magnetic moments (4.7–4.9 μ_B) and electronic spectra are best explained assuming tetragonally distorted octahedral geometries.

Nitrogen heterocycles, either monodentate or incorporated into chelating ligands, form many Cr^{II} complexes. Most common among these are compounds containing pyridine and its derivatives. Complexes of the types $[Cr(py)_4X_2]$ and $[Cr(py)_6]X_2$ are all high spin and their spectra show the usual pattern of distorted octahedral coordination of Cr^{II}. Analogous complexes have been prepared with pyrazoles and imidazoles. With the introduction of bidentate heterocyclic ligands (bipy, phen, etc.), the spin state eventually changes to low spin. Thus halide-bridged $[Cr(bipy)Cl_2]$ is high spin, but $[Cr(bipy)_2Cl_2]$ and $[Cr(bipy)_3]Cl_2$ are low-spin complexes ($t_{2g}{}^4$, $\mu_{eff} = 3.0\,\mu_B$). Polypyrazolylborate ligands (also called *scorpionates*) have attracted increasing attention recently.[24] Cr^{II} complexes of such ligands include $[Cr(HBpz_3)_2]$ and $[Cr(Bpz_4)_2]$, which are both high-spin, distorted octahedral complexes. More sterically hindered tris(pyrazolyl)borates facilitate isolation of four-coordinate (e.g. cis-divacant octahedral $Tp^{tBu,Me}CrCl$) and five-coordinate (e.g. trigonal bipyramidal $Tp^{tBu,Me}Cr(L)Cl$) complexes. Use of bidentate pyrazolylborates, as in $[Cr(H_2Bpz_2)_2]$ and $[Cr(Et_2Bpz_2)_2]$, yields square-planar Cr^{II} complexes, for example (**7**).



(**7**)

Aliphatic phosphines add to CrX_2 (X = Cl, Br), yielding adducts of uncertain composition, for example $[Cr(PR_3)_nX_2]$ (n = 1–3). With chelating diphosphines, for example dmpe, well-characterized six-coordinate complexes have been prepared. The latter have low-spin electronic configurations. A spin-crossover situation has been found in the complex $[Cr(depe)_2I_2]$ (depe = 1,2-bis(diethylphospino)ethane).[25] At ca. 170 K, this trans octahedral complex exhibits a discontinuous spin transition from $S = 1$ (2.8 μ_B) to $S = 2$ (4.8 μ_B).

Certain quadridentate tripod ligands featuring phosphine donors stabilize five-coordinate Cr^{II}. Examples of these are the cations $[Cr\{P(CH_2CH_2PPh_2)_3\}X]^+$, $[Cr\{N(CH_2CH_2PR_2)\}X]^+$ (R = Cy, Ph), and the N analogs $[Cr\{N(CH_2CH_2NR_2)\}X]^+$ (R = Me, Et). These complexes are thought to adopt trigonal bipyramidal structures in which the coordinated halide occupies an axial position.

4.4 Oxidation State III

Central to the coordination chemistry of Cr^{III} is six coordination in an essentially octahedral arrangement of ligands, because of the large ligand field stabilization energy of the d^3 configuration in this geometry. There are thousands of mononuclear Cr^{III} complexes, which exhibit effective magnetic moments close to or slightly below the spin-only value ($S = 3/2$, $3.88\,\mu_B$). There are also a large number of Cr^{III} *Polynuclear Complexes*, for example those with bridging hydroxide ligands, in which exchange coupling of the spins results in lower moments. The electronic spectra of Cr^{III} complexes are well understood. Consultation of the corresponding *Tanabe–Sugano Diagram* predicts three spin-allowed transitions, namely, ${}^4A_{2g} \rightarrow {}^4T_{2g}(F)$, ${}^4A_{2g} \rightarrow {}^4T_{1g}(F)$, and ${}^4A_{2g} \rightarrow {}^4T_{1g}(P)$, and three bands have indeed been found for many complexes. The lowest energy transition is a direct measure of the ligand field splitting (10 *Dq* or Δ_0); for the $[Cr(OH_2)_6]^{3+}$ ion, this transition lies at ca. 18 000 cm^{-1}. The photochemistry of Cr^{III} complexes has been studied in some detail and a recent review is available.[26]

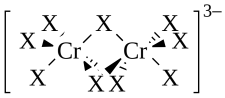
The reactivity of Cr^{III} complexes is marked by very slow *Ligand Substitution* reactions, resulting in unusual configurational stability. Many chiral complexes have been resolved. There has been a recent resurgence of interest in organochromium(III) complexes, owing to the importance of chromium in catalytic processes (*see* ***Chromium: Organometallic Chemistry***).

4.4.1 Hydride and Halide Ligands

The only known mononuclear Cr^{III} hydride is the recently described $[Li(THF)\{N(CH_2CH_2NSiMe_3)_3\}CrH]$, a trigonal bipyramidal molecule with a calculated $D_{Cr\text{–}H}$ of 297 kJ mol^{-1}.[27]

The simple halides (CrX_3) were described in Section 3.4. Addition of further halide ions generates ions of the compositions $[CrX_4]^-$ and $[CrX_6]^{3-}$. An example of the former is $K[CrF_4]$; its crystal structure consists of anionic columns of joined octahedra. The chromium atoms are weakly coupled antiferromagnetically. The highly symmetric $[CrF_6]^{3-}$ and $[CrCl_6]^{3-}$ ions have been the subject of many theoretical and experimental studies, owing to their perceived simplicity. Another set of heavily studied compounds are the dinuclear $[Cr_2X_9]^{3-}$ ions (**8**). Their structures consist of two octahedra sharing a trigonal face, that is, there are three bridging and six terminal halide ligands. The metal ions are weakly coupled (J = 0–16 cm^{-1}). The Cr–Cr distances range from 277 to 400 pm and metal–metal bonding has been ruled

out on the basis of spectroscopic and structural evidence. The chromium atoms are displaced from the centers of the octahedra formed by the halide ions, such that the Cr–Cr distance is increased. The interactions of adjacent Cr^{III} ions have indeed been called *repulsive*. This is in contrast to the isostructural Mo and W compounds, which show evidence for metal–metal bonding.



(**8**)

4.4.2 Oxygen and Sulfur Ligands

The violet hexaaquo ion $[Cr(OH_2)_6]^{3+}$ is a regular octahedron with Cr–O distances in the range 191.5–199.1 pm, depending on the particular compound used for the structure determination. EXAFS measurements on dilute solutions have provided information about the second hydration shell; it appears to contain an average of 13.5 water molecules at a Cr–O distance of 402(2) pm.[28]

The Cr^{III}(aq) ion occurs, for example, in $[Cr(OH_2)_6]Cl_3$ and in the chrome alums, $MCr(SO_4)\cdot 12H_2O$. There are several stable isomers of the chloride; among these the dark green *trans*-$[CrCl_2(OH_2)_4]Cl\cdot 2H_2O$ is the commercially available salt.

The rate of exchange of water with $[Cr(OH_2)_6]^{3+}$ is extremely slow ($k = 4.5 \times 10^{-7}\ s^{-1}$ at ambient temperature). Extensive mechanistic and kinetic studies suggest that this reaction proceeds by an I_a mechanism, that is, associative interchange. The aquo ion is fairly acidic (equation 7) and the resulting hydroxo complex dimerizes to the doubly bridged $[(H_2O)_4Cr(\mu\text{-}OH)_2Cr(OH_2)_4]^{4+}$, a weakly coupled antiferromagnet. Addition of base sets off a stepwise polymerization yielding various hydroxy complexes of higher nuclearity; some of these have been isolated by ion-exchange chromatography.

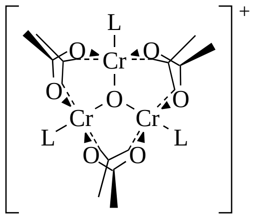
$$[Cr(OH_2)_6]^{3+} \underset{+H^+}{\overset{-H^+}{\rightleftharpoons}} [Cr(OH_2)_5(OH)]^{2+} \qquad pK_a = 4$$

$$\rightleftharpoons [(H_2O)_4Cr(\mu\text{-}OH)_2Cr(OH_2)_4]^{4+} \qquad (7)$$

Refluxing of $CrCl_3(THF)_3$ in anhydrous alcohols yielded purple insoluble solids, which were formulated as $[Cr(ROH)_nCl_3]$ adducts (R = Me, Et, *i*-Pr, *n*-Bu, *n*-hexyl). Various alkoxides of Cr^{III} have been prepared; they have been reviewed in detail.[29] Extreme steric congestion is likely to be responsible for the distorted tetrahedral coordination geometry exhibited by $Li[Cr\{OCH(t\text{-}Bu)_2\}_4]\cdot THF$.[30]

Many acetylacetonate complexes and related β-diketonates of Cr^{III} have been made over the years. Many of these are rather volatile, a property that has been exploited for the separation of isomers by gas chromatography and for gas-phase structure determinations by electron diffraction. Owing to its stability and solubility in organic solvents, paramagnetic $[Cr(acac)_3]$ has been used as a relaxation agent in ^{13}C NMR spectroscopy. Electrophilic substitutions at the coordinated diketonato ring are facile, and this has been taken as an evidence of an aromatic nature.

Attempts to prepare Cr^{III} acetate typically lead to trinuclear complexes of the familiar 'basic carboxylate' type (**9**). Three acetate bridged chromium ions share one central oxide ion, and the remaining sixth coordination site of every chromium is occupied by water or other ligands. A large variety of these complexes, differing in the associated ligands, the nature of the carboxylate, the counterion, and even the oxidation state, have been prepared and their physical properties studied. Especially their magnetic exchange interactions have been the subject of much controversy.



(**9**)

Oxalate (ox, $C_2O_4^{2-}$) complexes of Cr^{III} have been known since the very beginning of coordination chemistry. Thus, the resolution of chiral $[Cr(ox)_3]^{3-}$ with strychninium counterion by Werner in 1912 produced the first optically active anionic coordination compound. There also exists a series of bis(oxalato) complexes of the type $[Cr(ox)_2X_2]^{2+/0}$, where X can be any of a variety of neutral donors (e.g. H_2O, NH_3, etc.) or anionic ligands (e.g. SCN^-, N_3^-, etc.). These compounds have been used to study the mechanism of cis/trans isomerization and racemization of optically active octahedral coordination compounds.

Several dioxygen complexes of chromium featuring superoxide (O_2^-) bound to Cr^{III} can be made by exposure of Cr^{II} precursors to O_2.[31] The first structurally characterized example of such an adduct – that is, $[Tp^{tBu,Me}Cr(pz'H)(O_2)]^+$ – interestingly features the rare 'side-on' bonding mode of the superoxide ligand.[32]

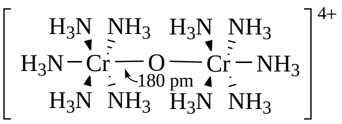
Other oxygen-based donor molecules that form Cr^{III} complexes include THF (e.g. the synthetically useful $[Cr(THF)_3Cl_3]$), urea ($[Cr\{OC(NH_2)_2\}_6]^{3+}$), sulfoxides (e.g. $[Cr(DMSO)_6]X_3$), amides (e.g. $[Cr(DMF)_6]X_3$), N-oxides, and phosphine oxides.

Introduction of sulfur ligands into the coordination sphere of aqueous Cr^{III} has been accomplished by oxidation of Cr^{II}(aq) with various sulfur-containing oxidants. There resulted a series of complexes of the composition $[Cr(SR)(H_2O)_5]^{2+}$ (R = H, alkyl, aryl). They all ultimately

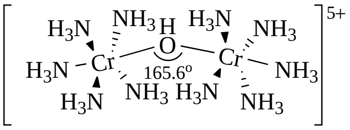
suffer substitution of the sulfur ligand by water, that is, 'aquation'. In nonaqueous media, a number of thiolato complexes ($[Cr(SR)_3]$, R = Me, Et, Ph, Bz) and thioether adducts of Cr^{III} halides ($[CrX_3(L)_3]$, X = Cl, Br; L = THT, SMe_2, SEt_2) have been prepared and characterized. There are also many complexes containing bidentate sulfur ligands such as dithiocarbamates, 1,3-dithiodiketonates, 1,2-dithiolates, and so on.

4.4.3 Nitrogen and Phosphorus Ligands

Cr^{III} complexes of ammonia and amines (both mono- and polydentate) exist in overwhelming numbers. Representatives of this class of compounds were among the first coordination compounds to be studied by Werner and his contemporaries. The early work (prior to 1970) on amine complexes has been reviewed comprehensively.[33] Typical complexes include $[CrA_6]^{3+}$ (A = NH_3, amine) and a wide variety of mixed ligand systems of the type $[CrA_{6-(n+m)}L_nX_m]^{(3-m)+}$ (L = neutral donor ligand, e.g. H_2O; X = monoanionic ligand, e.g. halide). Molecular orbital studies confirm that the $[Cr(NH_3)_6]^{3+}$ ion does not feature π-bonding with the NH_3 ligands. Because of the kinetic inertness of Cr^{III} complexes, isomers of various kinds are commonly observed and can be isolated and characterized. In neutral or basic media, mixed ammine/aquo complexes form dimers and polynuclear species with oxo and hydroxo bridges. The simplest of these are the blue 'basic rhodo' ion (**10**) and the red 'acid rhodo' complex (**11**). Complexes with two or three bridging ligands (e.g. μ-hydroxides) are also very common. The Cr^{III} ions in these complexes are invariably coupled antiferromagnetically. Much effort has been expended in trying to correlate the exchange constant J with structural parameters.[34] While it is generally accepted that the coupling in edge-bridged bioctahedra (two bridging ligands) is mediated by the bridging ligands, a direct correlation between J and the metal–metal distance of face-sharing d^3–d^3 systems (three bridging ligands) has also been proposed.[35]



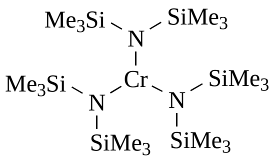
(**10**)



(**11**)

Nitrogen heterocycles also form an extensive series of Cr^{III} complexes, adding a π-bonding contribution to the metal–ligand bond. Complexes of this type include those containing pyridine and its derivatives, imidazoles, pyrazines, and pyrazoles. They are all six-coordinate octahedral species. $[Cr(bipy)_3]^{3+}$, the most oxidized member of an electron transfer series extending to $[Cr(bipy)_3]^{3-}$, is an example with a chelating ligand. A detailed study of its crystal structure and spectroscopic properties has been carried out.[36] *Porphyrin* ligands fall in this category also, and while they support chromium in the oxidation states +II to +V, Cr^{III} porphyrins are the most common ones. For example, [(TPP)CrCl] is soluble in toluene only in the presence of donor molecules, giving the expected six-coordinate [(TPP)Cr(L)Cl]. Remarkably, the sixth ligand is fairly labile and is substituted rapidly, in contrast to the typically slow ligand-substitution reactions of other Cr^{III} complexes. Finally, reports on poly(pyrazolyl)borate complexes of Cr^{III} are still relatively rare, despite the recent surge of interest in these ligands.[24]

Amide complexes of trivalent chromium constitute some of the rare exceptions from octahedral coordination. Largely because of steric constraints, there are examples of three- and four-coordinate complexes. Both $[Cr\{N(i\text{-}Pr)_2\}_3]$ and $[Cr(N\{SiMe_3)_2\}_3]$ (**12**) are monomeric in solution and in the solid state and have effective magnetic moments consistent with three unpaired electrons ($\mu_{eff} = 3.8\,\mu_B$). Their crystal structures feature trigonal planar CrN_3 moieties as well as planar $CrNR_2$ units. The latter observation, in concert with short Cr–N bonds, suggests strong ligand-to-metal π-donation. Sterically less demanding amides (NMe_2, NEt_2) lead to dimerization via bridging amido groups and thus tetrahedral coordination of Cr^{III}. The dimers disproportionate, thereby providing access to Cr^{IV} amides $[Cr(NR_2)_4]$. A four-coordinate Cr^{III} complex with the unusual trigonal monopyramidal geometry is formed by a chelating tris-amido ligand.[37]



(**12**)

The unusual solid phase $Ca_3[CrN_3]$ contains sheets of trigonal planar $[CrN_3]^{6-}$ units with short Cr–N bonds (Cr–N, 186.4, 176.6 pm). The effective magnetic moment of 1.86 μ_B implies a low-spin configuration, unprecedented for a Cr^{III} complex.[38]

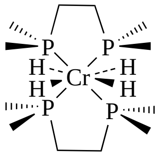
The hard Cr^{III} ion does not favor soft ligands such as phosphines and arsines. Nevertheless, phosphine adducts of the trihalides have been prepared, for example by displacement of THF from $CrCl_3(THF)_3$. Long Cr–P distances in crystallographically characterized molecules (ca. 247 pm) underscore the weakness of the bonds.

4.5 Oxidation State IV

There is no aqueous coordination chemistry of Cr^{IV}, except for unstable intermediates in reductions of Cr^{VI} species. However, the number of stable Cr^{IV} complexes prepared in nonprotic media is rapidly growing.

4.5.1 Hydrides and Halides

Hydrogenation of $[Cr(dmpe)_2(N_2)_2]$ yielded the hydride complex $[Cr(dmpe)_2H_4]$ (**13**). This unique eight-coordinate Cr^{IV} complex is diamagnetic and adopts a *Dodecahedral* structure with an average Cr–P distance of 225.5 pm and $Cr–H_{av} = 157$ pm. A more recent example is $[N(CH_2CH_2NSiMe_3)_3CrH]$.[27]



(**13**)

The fluorides CrF_4 and $CrOF_2$ were mentioned earlier (Section 3.4). The salts of the hexafluorochromate(IV) ion, that is, $[CrF_6]^{2-}$, are made by fluorinating $CrCl_3$/MCl mixtures. There are also the pentafluorochromates(IV) $M[CrF_5]$ (M = K, Rb, Cs) and the heptafluorochromates(IV) $M_3[CrF_7]$ (M = Rb, Cs). All of the above contain octahedral CrF_6 units, despite their different stoichiometries.

4.5.2 Oxygen Ligands

Besides the oxide CrO_2 and the chromates(IV) (see Section 3.3), there exists a number of Cr^{IV} alkoxides $[Cr(OR)_4]$ derived from tertiary alcohols. These are volatile blue liquids or low-melting solids with effective magnetic moments of ca. 2.8 μ_B. The crystal structure of $[Cr\{OCH(t\text{-}Bu)_2\}_4]$ has been determined and confirms the tetrahedral coordination geometry of chromium. The short Cr–O distances (177.3 pm) indicate significant ligand–metal π-donation.

4.5.3 Nitrogen Ligands

Certain Cr^{III} amides disproportionate upon heating and yield volatile Cr^{IV} derivatives of the type $[Cr(NR_2)_4]$ (R = Et, Pr). Their magnetic moments and electronic spectra are fully consistent with tetrahedral structures. Reaction with tertiary alcohols yields the tetraalkoxides described above and insertions of CO_2 or CS_2 yield Cr^{III} carbamates and dithiocarbamates, respectively.

Cr^{II} porphyrin complexes react with O_2 to form stable oxochromium(IV) species. For example, the red [(TPP)CrO] contains a five-coordinate Cr^{IV} displaced out of the porphyrin plane toward the oxygen atom (Cr–O, 157.2 pm). There are also a few Cr^{IV} scorpionates featuring terminally bound oxo ligands. The most recent of these is paramagnetic $[Tp^{tBu,Me}Cr(pz'H)(O)]$BARF (Cr–O, 160.2 pm), which abstracts weakly bound hydrogen atoms from hydrocarbons.[39]

4.6 Oxidation State V[40]

Cr^V coordination chemistry is still very rare. Reduction of Cr^{VI} species gives rise to unstable Cr^V intermediates, which can be detected by ESR spectroscopy. Stable compounds of Cr^V are found mostly with halides or oxygen-based ligands.

4.6.1 Halide Ligands

Aside from CrF_5, there is the hexafluorochromate(V) ion in the brick-red complexes $Cs[CrF_6]$ and $NO_2[CrF_6]$. The oxyhalides $CrOX_3$ (X = F, Cl) form a number of adducts with halide ions, namely, oxotetrahalochromates(V) of the composition $[CrOX_4]^-$ and oxopentahalochromates(V) of the type $[CrOX_5]^{2-}$. The crystal structure of $AsPh_4[CrOCl_4]$ shows the presence of five-coordinate chromium in a square pyramidal arrangement (Cr–O, 151.9 pm; Cr–Cl, 224.0 pm). $CrOCl_3$ also adds amines, for example, to give $[CrOCl_3(bipy)]$.

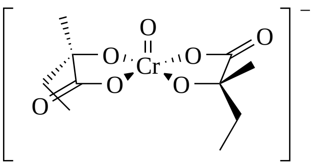
4.6.2 Oxygen Ligands

Chromate(V) was mentioned earlier. Treatment of basic $[CrO_4]^{3-}$ solutions with 30% H_2O_2 yields the moderately stable peroxide ion $[Cr(O_2)_4]^{3-}$. The crystal structure of the representative $K_3[Cr(O_2)_4]$ has been determined; the Cr^V-containing anion features side-on bound peroxide ligands (O–O, 149 pm) and a distorted dodecahedral coordination geometry. The red–brown salt is paramagnetic with $\mu_{eff} = 2.94\,\mu_B$.

The reduction of Cr^{VI} with certain tertiary α-hydroxycarboxylic acids has yielded Cr^V complexes, which are stable in aqueous solution. The structure of $K[OCr(O_2CC(Et)(Me)O)_2]$ (**14**) showed a distorted square pyramid with a short apical Cr–O double bond (155.4 pm). The facile preparation and stability of these complexes have led to their use in the study of the mechanism of oxidations involving Cr^V.[41] A similar complex containing two perfluoropinacolate ligands has also been prepared.

4.6.3 Nitrogen Ligands

Chlorination of $[Cr(N\text{-}t\text{-}Bu)_2Cl_2]$ has yielded the imido complex $[Cr(N\text{-}t\text{-}Bu)Cl_3]$, a green oil. It adds donor



(**14**)

ligands to form a series of adducts of the composition $[Cr(N\text{-}t\text{-}Bu)Cl_3(L)_2]$ (L = THF, 1/2 DME, PR_3, NCR, X^-) as well as derivatives resulting from substitution of halide.

Porphyrin ligands also allow the preparation of Cr^V complexes. For example, reaction of [(TPP)CrCl] with iodosylbenzene provides [(TPP)Cr(O)Cl], a six-coordinate complex, which is stable in solution for several hours. Its reaction with alkenes involves oxygen atom transfer and yields alcohols and epoxides.[42] Another Cr^V porphyrin complex is the nitride [(TPP)CrN]. A crystal-structure determination has confirmed the square pyramidal structure with a very short bond distance to the apical nitrido ligand (Cr–N, 156.5 pm).

Cr^{III} salen also reacts with iodosylbenzene and yields cationic Cr^V oxo complexes. These catalyze oxygen atom transfer to alkenes.[43]

4.7 Oxidation State VI

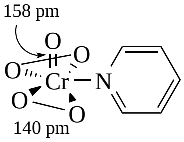
The extremely oxidizing nature of Cr^{VI} makes its coordination chemistry rather limited, as most potential ligands suffer oxidation by the metal and reduce it to a lower oxidation state. For the same reason, various forms of Cr^{VI} serve an important role as oxidants in organic chemistry. Most Cr^{VI} compounds contain halide and oxygen ligands.

4.7.1 Halide and Oxygen Ligands

With the fluoride CrF_6 still in doubt (see Section 3.4), the only certain Cr^{VI} halo complexes are the oxyhalides. The neutral compounds are listed in Table 5. A large number of chromyl compounds (CrO_2X_2) are known, in which X can be a wide variety of anionic groups, for example, NO_3, ClO_4, FSO_3, OAc, N_3, O_2CR, and so on. The structure of $CrO_2(NO_3)_2$ has been determined by electron diffraction; it was described as a severely distorted octahedron with two single bonds and two partial bonds to NO_3-type oxygens.[44] Chromyl compounds generally hydrolyze rapidly to chromate and the corresponding acid.

CrO_3 adds pyridine to yield $[CrO_3(py)]$ and $[CrO_3(py)_2]$. With alcohols it forms chromate esters, $CrO_2(OR)_2$. Some of these are unstable, for example $CrO_2(OSiMe_3)_2$ has been reported to explode upon distillation, but $CrO_2(OCPh_3)_2$ has been structurally characterized by X-ray diffraction. Addition of halide ion to CrO_3 yields the trioxohalochromates $[CrO_3X]^-$ (X = F, Cl), and $[CrO_4F]^-$ and $[CrO_2F_4]^{2-}$ have also been described.

Reaction of acidic dichromate solutions with H_2O_2 produces a blue compound, which can be extracted into ether. Upon coordination of various donors complexes of the composition $[CrO(O_2)_2(L)]$ (L = H_2O, py (**15**), Et_2O, etc.) can be isolated. These six-coordinate molecules adopt roughly pentagonal pyramidal structures and contain two side-on bound peroxide ligands. Deprotonation of $[CrO(O_2)_2(OH_2)]$ yields the ion $[CrO(O_2)_2(OH)]^-$, which may be isolated in the form of violet explosive salts. Related to the latter are the blue peroxohalochromates, $Ph_3AsMe[CrO(O_2)_2X]$ (X = Cl, Br).



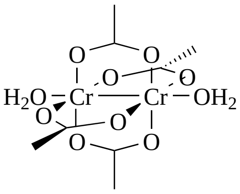
(**15**)

4.7.2 Nitrogen Ligands

Imido ligands can substitute for oxo ligands in Cr^{VI} complexes. Thus reaction of CrO_3 with $NH(t\text{-}Bu)(SiMe_3)$ yields $[Cr(N\text{-}t\text{-}Bu)_2(OSiMe_3)_2]$. Similarly, $[Cr(N\text{-}t\text{-}Bu)_2Cl_2]$, $[Cr(N\text{-}t\text{-}Bu)_2(NH\text{-}t\text{-}Bu)_2]$, and even the chromate analog $Li_2[Cr(N\text{-}t\text{-}Bu)_4]$ have been prepared.[45] $[Cr(N\text{-}t\text{-}Bu)_2Cl_2]$ even forms five-coordinate adducts with phosphine ligands; the crystal structure of $[Cr(N\text{-}t\text{-}Bu)_2Cl_2(PMe_2Ph)]$ revealed a trigonal bipyramidal molecule with the phosphine (Cr–P, 239.2 pm) and one chloride in the axial positions. Clearly, nitrogen to chromium π-donation strongly attenuates the oxidizing character of Cr^{VI}.

5 Cr–Cr BONDS[46]

The properties of chromium(II) acetate hydrate, which was first reported in 1844, set it apart from conventional Cr^{II} coordination compounds. Its red color, near diamagnetism (the weak residual paramagnetism corresponding to $\mu_{eff} = 0.3-0.7\,\mu_B$ is usually attributed to Cr^{III} impurities), and the binuclear structure (**16**) all raise the issue of metal–metal bonding. Cotton *et al.* have prepared and structurally characterized a large number of related molecules, containing carboxylates or other binucleating ligands. While the carboxylate dimers are almost always axially ligated, judicious choice of bridging ligands yields molecules featuring five-coordinate Cr^{II} (including the other chromium atom). The Cr–Cr distances cover a wide range from 183 to 255 pm, depending on the nature of the bridging ligands and the presence of axial ligands. On the basis of these observations, a quadruple bond between the Cr^{II} atoms (consisting of one σ, two degenerate π, and one δ contribution) has been assigned to these dimers.



(**16**)

The Cr–Cr distances depend primarily on the presence or absence of axial ligands. Without the latter, Cr–Cr distances below 190 pm are observed and this has led to the designation of 'supershort' Cr–Cr bonds. An electron diffraction study of unligated $[Cr_2(OAc)_4]$ in the gas phase showed a Cr–Cr distance of 196 pm, contrasting with distances in excess of 230 pm for ligated carboxylates in the solid state. The only unligated carboxylate dimer to be crystallographically characterized is $[Cr(O_2C\text{-}2,4,6\text{-}^iPr_3C_6H_2)_4]$, with a Cr–Cr distance of 197 pm.[47] The metal–metal distances generally decrease with increasing basicity of the bridging ligand, and, in the presence of axial ligands, the Cr–Cr distances decrease with increasing donor strength of the ligand. Thus, there is a roughly inverse correlation between the Cr–Cr and Cr–L distances of a series of adducts of the type $[Cr_2(O_2CR)_4(L)_2]$. There is an even better inverse correlation, however, between the Cr–Cr distance and the 'pyramidality' of the CrX_4 units, that is, the Cr–Cr–X angle, where X=O of carboxylate, and so on. *Extended Hückel Molecular Orbital Theory* suggests a strengthening of the σ- and π-components of the metal–metal bond as a reason for this effect.[48] In an attempt to compare metal–metal bonds to other covalent bonds, Cotton has introduced the 'formal shortness ratio' (FSR). The FSR for $[Cr_2(2\text{-MeO-5-MeC}_6H_3)_4]$, the compound with the shortest known metal–metal distance, is 0.767, which is even shorter than the FSR for N_2 (0.786).

The photoelectron spectra of Cr–Cr bonded dimers exhibit valence electron ionization energies as low as 6.70 eV, presumably because of electron ejection from the δ-molecular orbital. However, the ionizations from the different M–M bonding MOs cannot always be resolved, and their energies remain uncertain. The electronic spectra exhibit their lowest energy transition at ca. 20 000 cm^{-1}, and this has been assigned to the $\delta \rightarrow \delta^*$ transition. The earlier assignment of the M–M stretching mode of $[Cr_2(mhp)_4]$ at 556 cm^{-1} has been questioned and is now believed to occur at 340 or 400 cm^{-1}.[49] The dissociation constant for $[Cr_2(OAc)_4(OH_2)_2]$ into monomeric Cr^{II} complexes has been measured in acetic acid/water mixtures; K_D ranged from 7×10^{-7} M ($[H_2O] = 8.32$ M) to 4.5×10^{-5} M (pure water).[50]

While the short Cr–Cr distances themselves are unambiguous, the strength of the attendant metal–metal bond has been the subject of some debate. It now seems that the earlier estimate of the bond dissociation energy of a Cr–Cr quadruple bond of 205 kJ mol^{-1} is probably unrealistically high. Indeed, it has been suggested that 'Cr–Cr quadruple bonds may in fact be just artifacts of the bridging ability of the ligands, able to impose both a dinuclear structure and close proximity between the two metals'.[51] However, there exists at least one example of a macrocyclic Cr^{II} complex that has no bridging ligands and clearly features a Cr–Cr bond (Cr–Cr, 209.6 pm, $\mu_{eff} = 0.7\,\mu_B$).[52] There are also several organometallic Cr^{II} (and even Cr^{III}) derivatives that exhibit short Cr–Cr contacts and low effective magnetic moments (*see* ***Chromium: Organometallic Chemistry***). Thus, metal–metal bonding does occur in chromium chemistry, but it is clearly of less consequence than for the heavier elements of this group (Mo, W).

1 INTRODUCTION

The organometallic chemistry of chromium originated with a pair of early discoveries implying the intermediacy of organochromium compounds. In 1866, Berthelot[1] found that acetylene was reduced to ethylene by salts of chromium(II). Forty eight years later, in 1914 Bennett and Turner[2] reported the coupling of aryl groups derived from *Grignard Reagents* in the presence of chromium(III). It was not until 1957, however, that Anet and Leblanc[3] prepared the first pure σ-bonded organochromium compound, $[PhCH_2Cr(H_2O)_5]^{2+}$, and Herwig and Zeiss[4] synthesized $Ph_3Cr(THF)_3$.

Organochromium species containing π-bonded ligands were first prepared by Hein as early as 1919, but were not definitively characterized for another 35 years. Hein[5] reported on the reaction of PhMgBr with $CrCl_3$ to give 'Chromorganoverbindungen'; this synthesis was reproduced by Zeiss and Tsutsui[6] in 1954, at which time they identified the products as bis(arene)chromium cations. Shortly thereafter, Fischer and Hafner[7] published their route to neutral bis(benzene)chromium. This early work has been chronicled, most recently by Seyferth.[8]

The diverse chemistry of chromium carbonyl complexes has its origin in the discovery of $Cr(CO)_6$ in 1926 by Job and Cassal.[9] Early developments in this area included the preparation of the (η^6-arene)$Cr(CO)_3$ family of organometallics by Nicholls and Whiting in 1959,[10] the synthesis of the first structurally characterized carbene complex by Fischer and Maasböl (1965),[11,12] and a subsequent report from Fischer's laboratory describing *trans*-halogeno(phenylcarbyne)tetracarbonylchromium.[13]

Finally, the history of the chromium–carbon bond would not be complete without mention of the first homoleptic tetraalkyl, $Cr(CH_2SiMe_3)_4$, prepared by Wilkinson and his colleagues in 1970.[14] By this time, organochromium chemistry had become firmly established in the landscape of organometallic chemistry, and since then a vast array of molecules in oxidation states ranging from −IV to +VI has been reported in the chemical literature. Today, organochromium chemistry remains an area of vigorous research, as chemists seek more stereoselective (arene)chromium reagents, more efficient polymerization catalysts, and novel molecules in unusual oxidation states. This article summarizes the relevant chemistry, with emphasis on recent developments of interest. It is organized by the increasing formal oxidation state of the metal. Di- and polynuclear compounds are not explicitly covered here, but can be found in ***Dinuclear Organometallic Cluster Complexes*** and ***Polynuclear Organometallic Cluster Complexes***. A book devoted solely to the organometallic chemistry of chromium was published in 1975.[15] More recent comprehensive reviews are available,[16,17] and synthetic procedures have been summarized very recently.[18,19]

2 HIGHLY REDUCED CHROMIUM ORGANOMETALLICS

The most familiar compounds containing chromium in negative oxidation states are the binary carbonyl anions, also called carbonylmetallates.[20] $[Cr(CO)_5]^{2-}$ has been known for some time, having been first prepared via alkali metal reduction of $Cr(CO)_6$ in liquid ammonia.[21] Refinements of this basic methodology[22,23] have allowed for quantitative synthesis. The monomeric binary carbonyl anion $[Cr(CO)_5]^-$ can be generated electrochemically; its lifetime, however, is only a few seconds.[24] A remarkable 'superreduced' carbonylmetallate, $[Cr(CO)_4]^{4-}$, is obtained cleanly and in high yield from the reduction of the (tetracarbonyl)chromium(0) complex of tetramethylethylenediamine (equation 1).[25] The success of this reaction is attributed to 'reductive labilization', whereby preferential loss of the poorest acceptor ligand occurs upon reduction.

$$(TMEDA)Cr(CO)_4 + 4Na \xrightarrow{NH_3(l)} Na_4(Cr(CO)_4 + TMEDA \quad (1)$$

$[Cr(CO)_5]^{2-}$ is a light yellow, extremely air-sensitive powder. *Back Bonding* to the carbonyls is extensive here, and is reflected in the median value of υ_{CO}, 1750 cm^{-1}.[23] This dianion is a strong base, a good nucleophile, and a powerful reducing agent (equations 2–4).[23,26,27]

$$2[Cr(CO)_5]^{2-} + 3H_2O \longrightarrow [HCr_2(CO)_{10}]^- + H_2 + 3OH^- \quad (2)$$

$$[Cr(CO)_5]^{2-} + CN^- + 2H_2O \longrightarrow [Cr(CO)_5CN]^- + 2OH^- + H_2 \quad (3)$$

$$[Cr(CO)_5]^{2-} + Cl_2CS \longrightarrow 2Cl^- + Cr(CO)_5(CS) \quad (4)$$

Yellow pyrophoric $[Cr(CO)_4]^{4-}$ gives an IR spectrum consistent with its structure and with a *Formal Oxidation State* of −4: the most intense carbonyl band appears at 1462 cm^{-1}. Reaction with three equivalents of Ph_3SnCl in two steps yields $[(Ph_3Sn)_3Cr(CO)_4]^-$, the first seven-coordinate chromium compound with exclusively monodentate ligands. More efficient is the synthesis of $[(Ph_3Sn)_2Cr(CO)_4]^{2-}$ from $(TMEDA)Cr(CO)_4$ and Ph_3SnLi, followed by addition of Ph_3SnCl. These moderately air-sensitive organometallics can be isolated as their Et_4N^+ salts. A single-crystal X-ray study of the tris(triphenyltin) anion confirmed the presence of heptacoordinate chromium.[28] The tetraanion also reacts with NH_4Cl to give $Cr(CO)_4(NH_3)_2$ (rather than the anticipated $[H_3Cr(CO)_4]^-$), and with excess MeCN to give $[H_2Cr(CO)_8]^{2-}$. Further information on the reactivity of these carbonylmetallates and their derivatives can be found in a review article describing these compounds.[29]

Substituted compounds of chromium in negative oxidation states are also known. Two apparent examples are $[(\eta^6\text{-}C_6H_6)Cr(CO)_3]^{2-}$ and $[(bipy)Cr(CO)_4]^-$.[30,31] An EPR spectrum of the latter compound, however, indicated that the unpaired electron resides within the aromatic ring; this result implies that chromium is actually in the zero oxidation state, bound to $(bipy)^-$.[23] Finally, potassium reduction of $Cr(\eta^6\text{-}C_6H_6)_2$ yielded the corresponding radical anion $[Cr(\eta^6\text{-}C_6H_6)_2]^-$, a Cr(-I) compound without any carbonyl ligands, which was characterized by ESR spectroscopy.[32]

3 CHROMIUM(0) ORGANOMETALLICS

This section highlights some of the significant features of chromium(0) carbonyls and of the chemistry of this oxidation state. Further information can be found in the articles ***Carbonyl Complexes of the Transition Metals*** and ***Organic Synthesis using Transition Metal Carbonyl Complexes***, and in the review literature.[15,16]

3.1 Chromium Hexacarbonyl

This colorless, volatile, and air-stable solid is the starting material for synthesis of many Cr^0 derivatives. Commercially available, it is seldom synthesized; however, *Reductive Carbonylation* (e.g. equation 5) gives higher yields and is more reliable than other methods. $Cr(CO)_6$ melts at 130 °C, sublimes at room temperature in vacuo, and dissolves slightly in organic solvents. It exhibits perfect octahedral symmetry, as determined by electron and neutron diffraction and X-ray crystallography. The IR spectrum of this material in CCl_4 shows a single sharp band at 1984 cm^{-1}.

$$CrCl_3 + xsCO + LiAlH_4 \xrightarrow{Et_2O} Cr(CO)_6 \quad (5)$$

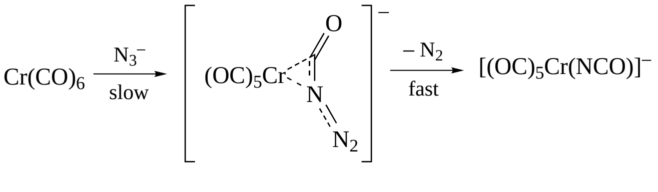
$$Cr(CO)_6 \xrightarrow{h\nu} Cr(CO)_5 + CO \quad (6)$$

Chromium hexacarbonyl is extremely photolabile (equation 6); therefore photochemical substitution is an efficient means of preparing derivatives.[33] Oxidation of the Cr^0 center requires nitric or sulfuric acid, or chlorine. Alternatively, some ligands induce complete carbonyl dissociation with concomitant oxidation, for example, acetylacetonate. Chemical reduction with alkali or alkaline-earth metals or electrochemical reduction proceeds in two-electron steps with loss of two CO molecules to first give $[Cr_2(CO)_{10}]^{2-}$ and then $[Cr(CO)_5]^{2-}$. Nucleophilic attack at CO generates a number of stable (Nu = R) and unstable (Nu = N_3, OH, H, NEt_2) products. The stable $[(OC)_5CrCOR]^-$ ion is a carbene precursor.

3.2 Substituted Chromium(0) Carbonyls Without Carbon Ligands[34]

The derivatives of chromium hexacarbonyl, $Cr(CO)_{6-x}(L)_x$, make up the single largest class of organochromium compounds, and a substantial number of these are Cr^0 compounds as well. The most common synthetic route involves direct reaction of $Cr(CO)_6$ and x L, but displacement of a weakly bound ligand from a carbonyl derivative is also frequently employed. Carbonyl dissociation is usually promoted with heating or UV irradiation.

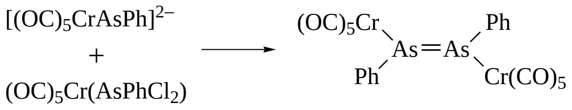
The rare chromium carbonyl fluoride $[Cr(CO)_5F]^-$ can be prepared oxidatively or by substitution; it is stable in air for short periods. Protonation of $[Cr(CO)_5]^{2-}$ with methanol yields the carbonyl hydride $[HCr(CO)_5]^-$,[35] isolable as the Et_4N^+ or Ph_4As^+ salt. Its hydride resonance in the ^1H NMR spectrum is located at −7.0 ppm. Since σ-donor nitrogen ligands lack the acceptor ability of CO, an ability that minimizes the buildup of electron density on chromium trisubstitution is the maximum extent of reaction observed, for example, between $Cr(CO)_6$ and NH_3. Nucleophilic attack of an azide at a carbonyl carbon of $Cr(CO)_6$ gives an isocyanate following a Curtius-type degradation (Scheme 1). (Ammine)pentacarbonylchromium undergoes a condensation reaction with acetone in the presence of a drying agent to give the (ketimine)pentacarbonyl compound.



Scheme 1

$Cr(CO)_5(THF)$, an O-donor derivative, is synthetically useful as a source of the unsaturated fragment $Cr(CO)_5$, as the weakly bound cyclic ether is easily dissociated or displaced.[36] By contrast, phosphines (PR_3), phosphites ($P(OR)_3$), phosphorus halides (PX_3), phosphorus amines ($P(NR_2)_3$), phosphinites ($PR_2(OR)$), and phosphonites ($PR(OR)_2$) are σ-donor/π-acceptor ligands that readily substitute for THF, forming stable derivatives. The better π-acceptors, $P(OR)_3$ and PF_3, can form the homoleptic compounds $Cr\{P(OR)_3\}_6$ and $Cr(PF_3)_6$. A vast number of Cr^0 complexes containing carbonyl and phosphorus ligands can be found in the literature;[37,38] the reader is referred to these sources for information on specific complexes, syntheses, and reactions. Forcing conditions are necessary to form carbonyl compounds of the remaining group 15 ligands. As with the phosphorus derivatives, polydentate ligands and unusual compounds have been reported, for example, Scheme 2. An X-ray crystallographic structure revealed very short As=Cr bonds in this molecule, that is, 2.38 Å.

The nitrosonium ion[39] and the alkyl- and aryldiazonium ions[40] are π-acceptor ligands that are isoelectronic with carbon monoxide. Other π-acceptors are characterized by the α-diimine moiety; these include the stabilizing ligands bipy, phen, and terpy. Mononitrosyl complexes of chromium(0) have been known for some time (Scheme 3);[41] recently renewed interest in (nitrosyl)chromium species has led to the development of routes to $(\eta^5\text{-}C_5H_5)Cr(NO)_2X$ ($X = CH_2SiMe_3$, Cl, Me, FPF_5) and $[(\eta^5\text{-}C_5H_5)Cr(NO)_2L]^+$ ($L = PPh_3$, NCR, CNR, py, H_2NAr). A recent review of organometallic metal-NO complexes, including chromium compounds, is available.[42] The first thionitrosyl complex has been prepared using the novel reagent $N_3S_3Cl_3$ with $[(\eta^5\text{-}C_5H_5)Cr(CO)_3]^-$.[43] On the basis of CO stretching frequencies, it is likely that NS is even superior to NO as a π-acceptor. Other Cr^0 complexes containing sulfur, as well as selenium and tellurium ligands, have been described.[16,17]



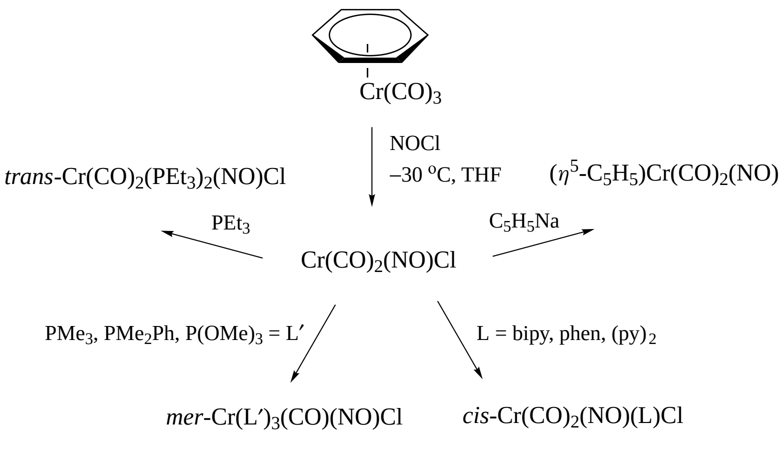
Scheme 2

3.3 Substituted Chromium(0) Carbonyls with σ-donor Carbon Ligands

Among the types of complexes found here are formyl, acyl, alkyl, and aryl carbonyls, carbonyl cyanides,[44] carbonyl isocyanides and acetylides,[45] and thiocarbonyl and selenocarbonyl complexes.[46] Of the greatest significance, however, are the chromium carbenes, for example, $(CO)_5Cr{=}C(OR)R'$. This chemistry has been thoroughly reviewed;[47] nevertheless, these compounds will be briefly discussed here.

The first carbene compound to be well characterized was prepared in 1966 and was one of many *Fischer-Type Carbene Complexes* to be reported (see equation 7). Fischer carbenes are characterized by heteroatom substituents at the carbene carbon, stabilization by a low-valent metal center, and a partial positive charge at the carbene carbon. In contrast, *Schrock-Type Carbene Complexes*, or alkylidenes,[48] that have alkyl substituents, are found on metal centers in higher oxidation states, and are nucleophilic at carbon. Many Fischer carbenes are known for chromium, whereas chromium alkylidenes are much less common. Monohalocarbenes of chromium, for example, $(OC)_5Cr{=}C(F)NEt_2$, have also been extensively investigated.[49] Two carbene reactions of note for their application to organic synthesis are the cycloaddition of alkenes with carbene complexes and the reaction of aromatic carbenes with alkynes to yield complexed naphthols (the ‘Dötz reaction’).[50]

$$Cr(CO)_6 \xrightarrow{PhLi} [(OC)_5C{=}C(O)Ph]^- \xrightarrow{MeI} (OC)_5Cr{=}C(OMe)Ph \quad (7)$$



Scheme 3

4 CHROMIUM(I) ORGANOMETALLICS

4.1 Carbonyl Compounds of Chromium(I)

Almost all of the organochromium(I) compounds to be discussed in this section have a *Seventeen Electron Configuration*; that is, they are electron-deficient metallaradicals. In view of the π-acidity of the CO ligand, one would expect the more stable carbonyl species to possess one or more σ-donor ligands to compensate for the electron deficiency at chromium and the acceptor nature of the carbonyls. By this argument, $Cr(CO)_6{}^+$,[51] produced electrochemically from $Cr(CO)_6$, should be among the least stable examples of a chromium(I) carbonyl; in fact, it has a half-life of only seconds at room temperature. Pentacarbonyl halides, $Cr(CO)_5X$ ($X = F$, Cl, Br, I),[52] can be obtained via electrochemical oxidation of the corresponding anions; oxidative cleavage of $[Cr_2(CO)_{10}]^{2-}$ by I_2 constitutes an alternative route to the iodide, which in the solid state decomposes only slowly at 25 °C. The iodide also serves as the starting material for syntheses of other Cr^I derivatives (see equations 8 and 9). By contrast, the fluoride has a lifetime of minutes when in solution at ambient temperature.

$$Cr(CO)_5I + CN^- \longrightarrow Cr(CO)_5CN + I^- \quad (8)$$

$$Cr(CO)_5I + 4NH_3 \longrightarrow [Cr(CO)_2(NH_3)_4]I + 3CO \quad (9)$$

Tetracarbonyl cations $[Cr(CO)_4(L_2)]^+$, where L_2 represents arylphosphines, alkyl, or aryl phosphites, or a bidentate ligand with phosphorus or arsenic donor atoms, have been produced by both chemical and electrochemical means. However, only one of these complexes, namely, *trans*-$[Cr(CO)_4(PPh_3)_2]^+$, is stable enough to be isolated as the perchlorate salt.[53] Exposure to light and moisture produces *trans*-$Cr(CO)_4(PPh_3)_2$ via disproportionation. Just as easily isolated, but somewhat less sensitive, are the $[Cr(CO)_3(PR_3)_3]^+$ cations.[54] Oxidation with a silver ion or NO^+ converts the *fac*-($R_3 = Me_2Ph$, $(OMe)_3$) and *mer*-($R_3 = (OMe)_3$, $(OMe)_2Ph$, $(OPh)_3$) complexes into Cr^I products with mer structures. Light and heat promote the formation of reduced *mer*-$Cr(CO)_3(PR_3)_3$. These tetra(carbonyl) and tri(carbonyl) cations have been the subject of ESR spectroscopy and theoretical study.[55]

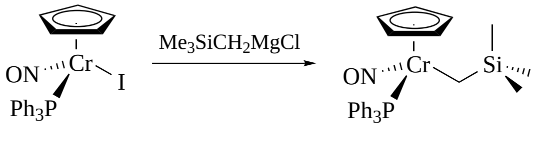
Tricarbonyl complexes of the tridentate ligand hydridotris(1-pyrazolyl)borate (Tp) and its 3,5-dimethyl analogue (Tp*), as well as of tetrakis(1-pyrazolyl)borate (Tp′), have been reported recently.[56] Each is prepared from the corresponding anion by oxidation with a ferricinium ion. Ligand substitution on $TpCr(CO)_3$ yields a phosphine derivative, $TpCr(CO)_2(PMe_3)$. Interestingly, $TpCr(CO)_3$ does not react with other, larger phosphines, while $Tp^*Cr(CO)_3$ is evidently too sterically hindered to undergo phosphine substitution at all. Although all four compounds are readily oxidized, they can be stored for several days at room temperature if kept under an inert atmosphere. EPR spectra of the Tp and Tp* tricarbonyls have been obtained at 5 K. The extremely low temperature was necessary in order to lower the C_{3v} symmetry of the chromium centers, breaking the associated orbital degeneracies so that spectral resonances could be observed. Not unexpectedly, the EPR spectra of the $Tp'Cr(CO)_3$ and $TpCr(CO)_2(PMe_3)$ complexes could be obtained at much higher temperatures (120 and 225 K respectively) because of their relatively lower symmetries.

The oxidation of substituted dicarbonyl complexes of chromium(I) featuring the bidentate ligands dppm and dppe has been examined. Chromium(0) starting materials, $Cr(CO)_2(dppm)_2$ and $Cr(CO)_2(dppe)_2$, both with cis carbonyl configurations, were oxidized to trans cations $[Cr(CO)_2(dppm)_2]^+$ and $[Cr(CO)_2(dppe)_2]^+$; chemical and electrochemical methods were employed. Chemical oxidation of the dppm compound proved more facile than that of the dppe analogue; this had been predicted on the basis of electrochemical studies. The dicarbonyl hydride, $[Cr^{II}(CO)_2(dppm)_2H]^+$, was isolated from the oxidation reaction of $[Cr(CO)_2(dppm)_2]$ with $O_2/HClO_4$, while the same reaction conditions oxidized the neutral dppe complex to the cation.

4.2 Cyclopentadienyl Compounds of Chromium(I)

Most of the (cyclopentadienyl)chromium(I) compounds found in the literature are of three types: nitrosyl complexes, both neutral and cationic, unsymmetrical sandwich complexes, and carbonyl complexes. Representative nitrosyl-containing molecules include $(\eta^5\text{-}C_5H_5)Cr(NO)(L)Cl$ (L = py, PR_3, $AsPh_3$, CNR, etc.), $(\eta^5\text{-}C_5H_5)Cr(NO)(PPh_3)CH_2SiMe_3$, $[(\eta^5\text{-}C_5H_5)Cr(NO)(L_2)]$ PF_6 (L_2 = bipy, phen), and $[(\eta^5\text{-}C_5H_5)Cr(NO)(NCMe)_2]$ PF_6.[42] Although structurally and electronically similar, the two neutral compounds are prepared via dissimilar routes; this is also true of the cations. The chlorodinitrosyl complex $(\eta^5\text{-}C_5H_5)Cr(NO)_2Cl$ undergoes ligand substitution with strong Lewis bases to form the Cr^I mononitrosyls with liberation of NO. On the other hand, mononitrosyl $(\eta^5\text{-}C_5H_5)Cr(NO)(PPh_3)I$, a chromium(I) nitrosyl itself, serves as the synthetic precursor for the (trimethylsilyl)methyl species; ligand exchange being effected with Me_3SiCH_2MgCl (Scheme 4).

Noteworthy is the fact that these neutral nitrosyls, including the precursor iodide, are chiral by virtue of having four unique ligands bound to chromium. Reaction of bipy or phen with $[(\eta^5\text{-}C_5H_5)Cr(NO)_2(MeCN)]PF_6$ at 100 °C results in displacement of MeCN and one NO



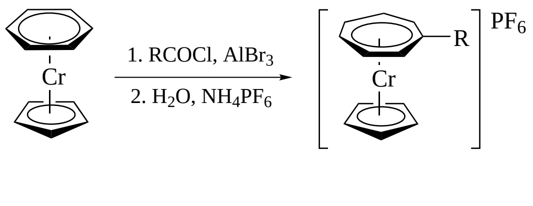
Scheme 4

group by the incoming bidentate ligand. Finally, cleavage of a nitrosyl iodide dimer, $[(\eta^5\text{-}C_5H_5)Cr(NO)I]_2$, with $AgPF_6$ in MeCN affords the nitrosylbis(acetonitrile) cation. These four compounds exhibit a range of stabilities. $[(\eta^5\text{-}C_5H_5)Cr(NO)_2L_2]$ PF_6 is extremely robust, while the bis(acetonitrile) cation and the chloronitrosyl complex can be handled briefly in air as solids. Magnetic moments are appropriate for d^5 low-spin systems: $1.47–1.96\,\mu_B$ (spin-only value $= 1.73\,\mu_B$). Structure determinations carried out on $(\eta^5\text{-}C_5H_5)Cr(NO)(PPh_3)CH_2SiMe_3$ and on $[(\eta^5\text{-}C_5H_5)Cr(NO)(NCCH_3)_2]PF_6$ revealed a three-legged *Piano Stool Structure* for both with no geometric distortions attributable to the effects of the unpaired electron in these metallaradicals. Studies of the reactivity of the trimethylsilylmethyl cation provided routes to two novel compounds. Treatment with NO, NO^+, and $2HSnPh_3$ led to isolation of $(\eta^5\text{-}C_5H_5)Cr(NO)_2CH_2SiMe_3$, $[(\eta^5\text{-}C_5H_5)Cr(NO)_2(PPh_3)]PF_6$, and $(\eta^5\text{-}C_5H_5)Cr(NO)(PPh_3)(SnPh_3)H$ (see Section 5.2).

Among the 17-electron species are those in which the *Cyclopentadienyl* ligand and a cyclic triene or arene form an unsymmetrical sandwich complex. The most familiar example, $(\eta^5\text{-}C_5H_5)Cr(\eta^6\text{-}C_6H_6)$,[57] is synthesized from $CrCl_3$, either C_5H_5MgBr or NaC_5H_5, and PhMgBr. Very reactive, it does not undergo Friedel–Crafts acylation but rather a ring expansion (Scheme 5), yielding $[(\eta^5\text{-}C_5H_5)Cr(\eta^7\text{-}C_7H_6R)]^+$. In the presence of cycloheptatriene and $AlCl_3$ or azulene and $BF_3{\cdot}Me_2O$, arene replacement occurs to give $[\eta^5\text{-}C_5H_5)Cr(\eta^7\text{-}C_7H_7)]^+$ and $[(\eta^5\text{-}C_5H_5)Cr(\eta^7\text{-azulenium})]^+$, respectively. Its permethylated analogue, $(\eta^5\text{-}C_5Me_5)Cr(\eta^6\text{-}C_6Me_6)$, has been obtained from the thermal reaction of dimeric $[(\eta^5\text{-}C_5Me_5)Cr(\mu\text{-Cl})Me]_2$ and excess 2-butyne.[58] Photolysis of a mixture of $(\eta^5\text{-}C_5H_5)CrCl_2{\cdot}THF$, i-PrMgBr, and cycloheptatriene yields the $(\eta^6\text{-}C_7H_8)$ sandwich; air oxidation converts this to the cationic cycloheptatrienyl complex. Substitution of 1,3,5-cyclooctatriene or cyclooctatetraene in this preparation gives the analogous $(\eta^6\text{-}C_8H_{10})$ and $(\eta^6\text{-}C_8H_8)$ products. The latter can be protonated and reacted with R^- (R = H, Me), forming $(\eta^5\text{-}C_5H_5)Cr(7\text{-R-1,3,5-cyclooctatriene})$.

Recent interest in metal-centered radicals[59,60] has prompted numerous studies of the 17-electron monomers $(\eta^5\text{-}C_5H_5)Cr(CO)_3$ and $(\eta^5\text{-}C_5Me_5)Cr(CO)_3$, present to various extents at ambient temperature via dissociation of the parent dimers (e. g. equation 10).[61]

$$[(\eta^5\text{-}C_5H_5)Cr(CO)_3]_2 \rightleftharpoons 2(\eta^5\text{-}C_5H_5Cr(CO)_3) \qquad (10)$$



Scheme 5

That the chemistry of $[(\eta^5\text{-}C_5H_5)Cr(CO)_3]_2$ reflects the reactivity of the monomer can be seen in the products of atom abstraction, ligand substitution, and disproportionation reactions. A number of phosphine derivatives have been prepared; however, only $(\eta^5\text{-}C_5H_5)Cr(CO)_2PPh_3$ was sufficiently robust to be isolated in a crystalline form and fully characterized. In addition, dppm, dppe, and dppb gave stable disproportionation products. A comparative study of the analogous $(\eta^5\text{-}C_5Me_5)$ dimer and monomer revealed a longer, weaker Cr–Cr bond than is present in the cyclopentadienyl dimer;[62] reactivity toward t-BuNC and smaller phosphines (e.g. PMe_3 and $P(OMe)_3$), yielding very air sensitive, thermally labile derivatives, and participation in atom abstraction reactions to form labile halo, hydrido, alkyl, and tributyltin compounds of $(\eta^5\text{-}C_5Me_5)Cr(CO)_3$. Crystal-structure determinations have been carried out on $(\eta^5\text{-}C_5Me_5)Cr(CO)_2PPh_3$ and on $(\eta^5\text{-}C_5Me_5)Cr(CO)_2PMe_3$. Both exhibit monomeric three-legged piano-stool structures. The unusually small OC–Cr–CO bond angles, 80.9 °C and 79.9 °C, respectively, contrast with the approximate value of 90 °C for similar *Eighteen Electron Compounds* and are believed to represent a deformation associated with location of the electron 'hole' between the carbonyl ligands.

4.3 Arene, Bis(Arene), and Other π-ligand Compounds of Chromium(I)

Monoarene complexes of the form $[(\eta^6\text{-}C_6R_6)Cr(CO)_2L]^+$ (R = H, Me; L = CO, PR_3) may be prepared from the corresponding 18-electron species via chemical or electrochemical oxidation. The (benzene)tricarbonyl chromium cation is of limited stability; however, substituted arene complexes, for example, $[(\text{hexaethylbenzene})Cr(CO)_3]^+$, exhibit appreciable lifetimes on the cyclic voltammetric timescale.[63] Substantially more robust are the dicarbonyl cations $[(\eta^6\text{-}C_6Me_6)Cr(CO)_2L]^+$ (L = PPh_3, $PMePh_2$, PMe_2Ph), $[(\eta^6\text{-biphenyl})Cr(CO)_2PPh_3]^+$, and $[(\eta^6\text{-}C_6Me_6)Cr(CO)_2(RC{\equiv}CR)]^+$ (R = Ph, 4-MeOC_6H_4).

Unlike bis(benzene)chromium itself, the bis(benzene)chromium cation and its numerous substituted analogues are air stable as solids and in solution. Three of these compounds, $[(\eta^6\text{-benzene})_2Cr]^+$, $[(\eta^6\text{-benzene})(\eta^6\text{-biphenyl})Cr]^+$, and $[(\eta^6\text{-biphenyl})_2Cr]^+$, were isolated by Hein during his historic work with 'Chromorganoverbindungen' in 1919.[5] Crystal structures feature eclipsed arene rings, and magnetic moments lie within the range $1.70–1.80\,\mu_B$.[15] These cations are derived from oxidation of $(\eta^6\text{-arene})_2Cr$. Alkyl and aryl halides, RX, oxidize bis(arene) complexes with the formation of R·, which subsequently abstracts hydrogen, disproportionates, or dimerizes. Halogen oxidation is also effective in some cases. Most reactions of $[(\eta^6\text{-arene})_2Cr]^+$ are reductive in nature or decompose the molecule. Acid-promoted and oxidative routes to the free arene are also known.

5 CHROMIUM(II) ORGANOMETALLICS

5.1 Mono-, Di-, and Poly(organo)chromium(II) Compounds

Significantly fewer complexes of these types are known for chromium(II) than for chromium(III). Solvated species are of the general formula $R_nCrCl_{2-n}S_x$ and can be prepared directly from CrX_2 or $CrX_2(THF)_2$ (X = Cl, Br) and one or two equivalents of Grignard reagents. Only two mono(organo) compounds, (1-naphthyl)CrBr(THF) and its 1-(2-methyl)naphthyl analog, have been prepared in this manner. The only other $RCrClS_x$ complex, a mesityl chloride, was obtained via ligand exchange between solvated bis(mesityl)chromium and $CrCl_2$.

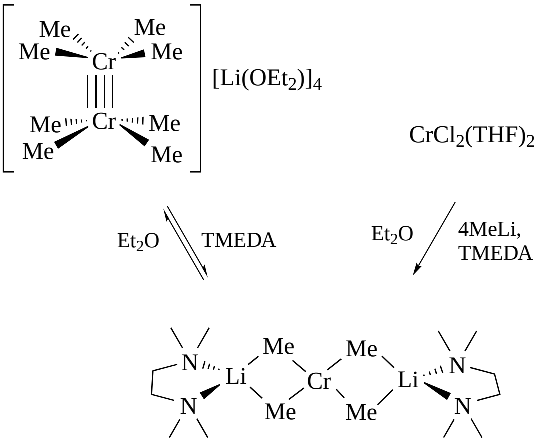
In contrast, numerous examples of R_2CrS_x have been synthesized by the Grignard route, for example, $(mesityl)_2CrS_x$ (S_x = $(THF)_3$ or (THF)(bipy)), $(Ph)_2Cr(bipy)_2$, and $(o\text{-anisyl})_2Cr(bipy)_2$. One finds that substitution of an N- or P-donor ligand for THF in these molecules stabilizes them considerably. For example, $(Ph)_2Cr(THF)_n$ is an unstable brown solution at temperatures of −30 °C and above, whereas the bipy solvate is an isolable blue solid. Alternatives to the Grignard route include reaction with lithium reagents (equation 11) or thermal transformations of tri(organo)chromium(III) species and metal poly(organo)chromates (equation 12).

$$CrCl_2(THF)_2 \xrightarrow[-70\,^{\circ}C]{2PhLi} Ph_2Cr(THF)_n \xrightarrow{2bipy} Ph_2Cr(bipy)_2 \quad (11)$$

$$Ph_2Cr^{III}(CHPh_2)(THF)_n \xrightarrow[bipy]{\Delta,\ THF} Ph_2Cr^{II}(bipy)_2 + Ph_2CH\bullet \quad (12)$$

Chromium(II) polyorganochromates, M_2CrR_4, exist as monomers and as dimers; the latter are discussed in ***Dinuclear Organometallic Cluster Complexes***. Reaction of appropriate lithium reagents with $CrBr_2(THF)_2$ yields the three complexes $Li_2[Cr(N\text{-methylpyrrolyl})_4](THF)_3$, $Li_2[CrPh_4](THF)_4$, and $Li_2[Cr(mesityl)_4](THF)_4$. The tetraphenyl compound may also be prepared from PhLi and $(Ph)_2CHCr(Ph)_2(THF)_n$. Reversible cleavage of the chromium−chromium quadruple bond of $[Cr_2Me_8][Li(L)]_4$ (L = THF, Et_2O) gives the high-spin species Li_2CrMe_4.[64] Cleavage is achieved by replacing the Lewis base coordinated to the lithium with TMEDA. Alternatively, the compound can be synthesized from $CrCl_2(THF)_2$ and four equivalents of MeLi in Et_2O with an excess of TMEDA present (Scheme 6). Analogous complexes $(TMEDA)CrR_2$ (R = CH_2Ph, CH_2CMe_3, $CH_2C(Ph)Me_2$) have been prepared as well.[65]

As a rule, these compounds are very sensitive to oxygen and water. The solvated compounds tend to lose solvent molecules in vacuo. Magnetic measurements reveal the presence of high-spin and low-spin Cr^{II} species within this group. $(Mesityl)_2Cr(THF)_3$ has an associated magnetic moment of 4.82 μ_B, the spin-only value for a system with four unpaired electrons being 4.9 μ_B. These values can be compared with the value of 3.22 μ_B for $(Ph)_2Cr(bipy)_2$, which is indicative of a system with only two electrons unpaired (spin-only value = 2.8 μ_B). Little is known about the chemistry of these organochromium(II) compounds. Most have been shown to react with $HgCl_2$ to give RHgCl and Hg_2Cl_2, and to undergo the same Cr–C bond cleavage in the presence of I_2. Hydrolysis and oxidation are two other reactions reported for some complexes.



Scheme 6

5.2 Chromium(II) Hydrides

The majority of compounds in this family can be described by the formula $(\eta^5\text{-}C_5R_5)CrL_1L_2L_3H$, where R = H or Me and L_1-L_3 represent some combination of three carbonyl and/or phosphine ligands (*see* ***Hydride Complexes of the Transition Metals***). The most familiar hydride, $(\eta^5\text{-}C_5H_5)Cr(CO)_3H$, is obtained from the reaction of chromocene with CO and H_2. Addition of cyclopentadiene to $(MeCN)_3Cr(CO)_3$ also affords the desired product, as does the synthesis from $Cr(CO)_6$ and a metal cyclopentadienide followed by protonation. A weak acid, this thermally unstable species readily loses a molecule of hydrogen en route to reversible formation of the dimer $[(\eta^5\text{-}C_5H_5)Cr(CO)_3]_2$. Reactions include carboxylation in the presence of $BF_3{\cdot}Me_2O$ to give $[(\eta^5\text{-}C_5H_5)Cr(CO)_4]BF_4$ and preparation of compounds containing chromium−metal bonds. This hydride is also known to be an active catalyst for the hydrogenation of conjugated dienes, for example, isoprene; however, the $(\eta^6\text{-arene})Cr(CO)_3$ system exhibits far greater stereoselectivity.

The $(\eta^5\text{-}C_5Me_5)$ analogue of $(\eta^5\text{-}C_5H_5)Cr(CO)_3H$ was first identified in 1983,[66] but no details of its preparation or characterization were mentioned. A subsequent report described several synthetic routes: from $[(\eta^5\text{-}C_5Me_5)Cr(CO)_2]_2$ and moist $LiPF_6$ in CH_2Cl_2 or H_2O in toluene, from treatment of $[(\eta^5\text{-}C_5Me_5)Cr(CO)_3]Na$ with acetic acid, and from

$(MeCN)_3Cr(CO)_3$ and C_5Me_5H.[67] It is also formed in the reaction of $(\eta^5\text{-}C_5Me_5)Cr(CO)_3$ with H_2S, the other products being $(\eta^5\text{-}C_5Me_5)Cr(CO)_3SH$ and $[(\eta^5\text{-}C_5Me_5)Cr(CO)_2]_2(\mu\text{-}S)$.[68] $(\eta^5\text{-}C_5Me_5)Cr(CO)_3H$ is a sublimable, air-sensitive crystalline solid. Solutions turn dark red when exposed to air or O_2, indicative of the presence of an unidentified transient species, which decomposes in the absence of O_2.

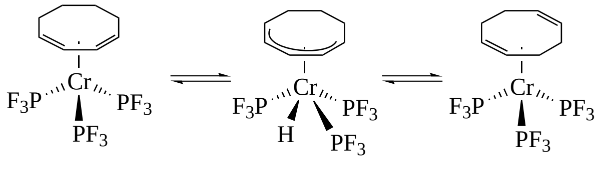
The hydride $(\eta^5\text{-}C_5H_5)Cr(P(OMe)_3)_3H$ has been prepared quantitatively from $(\eta^5\text{-}C_5H_5)CrCl_2(THF)$, $NaBH_4$, and excess $P(OMe)_3$. Treatment of this product with CO results in a single substitution, and $(\eta^5\text{-}C_5H_5)Cr(P(OMe)_3)_2(CO)H$ forms. Reaction with CCl_4 oxidizes the chromium center, giving $(\eta^5\text{-}C_5H_5)CrCl_2(P(OMe)_3)$. Nitrosylation yields one of two products, monomeric $(\eta^5\text{-}C_5H_5)Cr(P(OMe)_3)_2NO$ or the hydride-bridged dimer $\{(\eta^5\text{-}C_5H_5)Cr(NO)_2\}_2(\mu_2\text{-}H)$.

The substituted hydride $(\eta^5\text{-}C_5R_5)Cr(CO)_2(CDPP)H$ (R = H, Me; CDPP = cyclohexyldiphenylphosphine) was one of several products formed following substitution of phosphine for carbonyl in the 17-electron moiety $(\eta^5\text{-}C_5R_5)Cr(CO)_3$. This complex could also be synthesized by refluxing the chromium tricarbonyl dimer and CDPP in ethanol. Crystallographic analysis revealed a four-legged piano-stool structure with cis carbonyl ligands.

The first hydrido nitrosyl compound to be isolated, $(\eta^5\text{-}C_5H_5)Cr(NO)(PPh_3)(SnPh_3)H$, was derived from $(\eta^5\text{-}C_5H_5)Cr(NO)(PPh_3)(CH_2SiMe_3)$ and two equivalents of $HSnPh_3$. Its chemistry is yet to be investigated.

Other Cr^{II} hydrides of interest include $(\eta^5\text{-}C_8H_{11})Cr(PF_3)_3H$ and $(\eta^6\text{-}C_6H_6)Cr(CO)_2(SiCl_3)H$. The former complex was obtained in 2% yield upon cocondensation of chromium vapor, cyclooctadiene, and PF_3; its structure was verified crystallographically.[69] Although the hydridic hydrogen was not located, its ^1H NMR signal was observed. Of mechanistic significance is the fact that this molecule is structurally equivalent to an intermediate in the interconversion of (1,3-) and (1,5-cyclooctadiene)$Cr(PF_3)_3$ by the π-allylhydrido mechanism (Scheme 7). Preparation of the latter involves UV irradiation of a mixture of $(\eta^6\text{-}C_6H_6)Cr(CO)_3$ and $HSiCl_3$; IR spectral evidence indicates a distorted square-pyramidal structure with an apical arene ligand and cis carbonyls.

In this context, the tetranuclear hydride clusters $[(\eta^5\text{-}C_5Me_5)Cr(\mu\text{-}H)]_4$ and $[(\eta^5\text{-}C_5Me_4Et)Cr(\mu\text{-}H)]_4$ should be mentioned; they adopt a cubane-type structure and exhibit antiferromagnetic coupling between the Cr^{II} centers.[70]



Scheme 7

Interestingly, the isotopomers $(\eta^5\text{-}C_5Me_4Et)_4Cr_4(\mu\text{-}H)_x(\text{m-}D)_{4-x}$ exhibit extremely large isotope effects on the ^{13}C NMR chemical shifts of the cyclopentadienyl ligands ($\Delta\delta = 0.37-3.06$ ppm per H/D substitution). This effect has been used to measure the barrier for the exchange of the hydride ligands ($\Delta G^\ddagger = 12$ kcal mol^{-1}).[71] Further addition at H_2 at high pressure produced the hydride cluster $(\eta^5\text{-}C_5Me_4Et)_4Cr_4(\mu\text{-}H)_7$, which was structurally characterized by neutron diffraction. This mixed-valent ($Cr^{III}{}_3Cr^{II}$) molecule has a spin state of $S = 7/2$.[72]

5.3 Carbonyl Compounds of Chromium(II)

This section describes chromium(II) species with two or more carbon monoxide ligands; (cyclopentadienyl)chromium carbonyls are presented separately (Section 5.4). An unusual seven-coordinate cation, $[Cr(CO)_2(diars)_2X]^+$ (X = Br, I), was prepared via oxidation of the precursor $Cr(CO)_2(diars)_2$ with X_2. This complex is an 18-electron, diamagnetic halide salt. An excess of X_2 does not oxidize it to Cr^{III}; instead, only the trihalide salt is isolated. $[Cr(CO)_4(SnPh_3)_3]^-$, a heptacoordinate anion, is the product of the reaction of *cis*-$[Cr(CO)_4(SnPh_3)_2]^{2-}$ with one equivalent of $SnPh_3Cl$. The first thermally stable chromium carbonyl species with seven monodentate ligands, it is subject to loss of a triphenylstannyl group via reduction or bond heterolysis. Electrochemical oxidation of $Cr(CO)_5X$ (X = Cl, Br, I) generated the halopentacarbonyl cations $[Cr(CO)_5X]^+$ at $-75\,°C$. The room-temperature instability of these species, as well as the potentials required for their formation, were shown to account for the inability to produce $[Cr(CO)_5X]^+$ previously by chemical means. Finally, a bis(trichlorosilyl) complex, $(\eta^6\text{-}C_6H_6)Cr(CO)_2(SiCl_3)_2$, was obtained from the photolysis of $(\eta^6\text{-}C_6H_6)Cr(CO)_3$ in the presence of excess $HSiCl_3$.

5.4 (η^5-cyclopentadienyl)chromium(II) Carbonyl Compounds

Chromium compounds of this type feature one to four carbonyls and one or more ancillary ligands, as seen, for example, in $(\eta^5\text{-}C_5H_5)Cr(CO)_2(\eta^3\text{-allyl})$. A general synthesis for allyl complexes of this type, including the aforementioned parent complex has just been published.[73] Alternatively, the reaction of butadiene with $[(\eta^5\text{-}C_5H_5)Cr(CO)_3]_2$ in the presence of mercury yields the $\eta^3\text{-}C_4H_7$ crotyl derivative in a photolytic preparation. $(\eta^5\text{-}C_5H_5)Cr(CO)_2(\eta^3\text{-}C_5H_7)$ forms as a by-product of the reaction of $(\eta^5\text{-}C_5H_5)_2Cr$ with CO and H_2 to give $(\eta^5\text{-}C_5H_5)Cr(CO)_3H$. The latter two allyls were initially formulated as $(\eta^4\text{-cyclopentadiene})Cr^0(CO)_2(\eta^4\text{-diene})$ (diene = C_4H_6, C_5H_6), but their true structures were later established by ^1H NMR studies. Photolysis of solutions containing $(\eta^5\text{-}C_5H_5)Cr(CO)_3Me$ and PR_3 (R = Ph, OMe) leads to isolation of $(\eta^5\text{-}C_5H_5)Cr(CO)_2(PPh_3)Me$, $(\eta^5\text{-}C_5H_5)Cr(CO)_2(PPh_3)COMe$,

and (η^5-C_5H_5)Cr(CO)(P(OMe)$_3$)$_2$Me as air-sensitive crystalline solids. Trimethyl phosphite complexes analogous to the two obtained with PPh_3 can be prepared using one equivalent of the reagent; these are sufficiently robust to undergo spectroscopic characterization, but too unstable to separate and crystallize. The acetyl species are thought to form from the attack of a photochemically activated methyl group on a *cis*-CO ligand. Other (dicarbonyl)phosphine compounds that have been reported include *trans*-(η^5-C_5H_5)Cr(CO)$_2$(PMe$_2$Ph)(PCl$_2$)[74] and (η^5-C_5H_5)Cr(CO)$_2$(PR$_3$)Et (R = OMe, OEt).

Chromium(II) compounds of the form (η^5-C_5H_5)Cr(CO)$_3$X are numerous. The ligand X may be a halide or alkyl, or may be derived from a main-group or transition-series element. Table 1 lists some of these molecules and their syntheses. As a rule, these seven-coordinate complexes exhibit greater thermal instability and air sensitivity than their molybdenum and tungsten congeners. Most will decompose at ambient temperature, even in an inert atmosphere, and rapidly if exposed to oxygen. The compounds (η^5-C_5H_5)Cr(CO)$_3$X (X = (triars)Cu, η^1-$CH_2CH{=}CH_2$, CH_2Ph, CH_2CN, CH_2CO_2Et, or CH(CO$_2$Me)$_2$) were all identified in solution on the basis of spectral data, but were too unstable to be isolated. Similar properties were observed for (η^5-C_5Me_5)Cr(CO)$_3$X (X = I, Br, Cl, Me, Bn, η^1-C_3H_5, or SnBu$_3$). The examples in Table 1, however, are all stable solids, and most are crystalline.

The tetracarbonyl cation [(η^5-C_5H_5)Cr(CO)$_4$]$^+$ is the product of the reaction of (η^5-C_5H_5)Cr(CO)$_3$H with CO in the presence of $BF_3{\cdot}Me_2O$. The moisture-sensitive product is isolated as the tetrafluoroborate salt.

5.5 Chromocene

Chromocene, bis(η^5-cyclopentadienyl)chromium, is most easily prepared by reacting a halide of chromium(II) with NaC_5H_5.[19] Other less efficient methods, for example, pyrolysis and vapor-phase reaction, are described elsewhere. Chromocene is a volatile and reactive solid with a magnetic moment of 3.27 μ_B. Comparison of this value with the spin-only value, 2.83 μ_B, suggests the presence of a significant orbital contribution. An electron diffraction study favors eclipsed cyclopentadienyl rings in (η^5-C_5H_5)$_2$Cr (D_{5d} symmetry); however, a staggered configuration (D_{5h} symmetry) remains plausible, particularly in view of the low-barrier-to-ring rotation (<3.8 kJ mol^{-1}).

The chromocene molecule undergoes reaction with a wide variety of substrates; these processes have been recently summarized.[75] Transformations of note include the exchange of cyclopentadienyl rings between (η^5-C_5H_5)$_2$Cr and Li(C_5D_5), providing a straightforward synthesis of the deuterated compound, the reaction with cold deoxygenated HBF_4 to form [(η^5-C_5H_5)Cr(OH$_2$)$_3$]BF$_4$, and the elimination of one aromatic ring with the cleavage of a second in the generation of binuclear [(η^5-C_5H_5)Cr]$_2$(μ_2,η^4,η^4-C_8H_8) from chromocene and $Na_2C_8H_8$.

While not catalytically active itself, chromocene deposited on silica yields a highly active catalyst, known as the Union Carbide catalyst, for the polymerization of ethylene.[76] It is thought that (η^5-C_5H_5)Cr moieties on the silica surface constitute the active sites for polyethylene synthesis. This catalyst's high hydrogen response allows for the synthesis of polymers having a wide range of molecular weights via adjustment of the hydrogen-to-ethylene ratio. For a given ratio, however, a relatively narrow molecular weight distribution is obtained. In spite of vigorous research spanning 30 years,[77–79] many other features of this catalytic reaction, for example, the mechanism of initiation and the oxidation state of the active chromium species, remain controversial, and so studies of the chromocene–silica system and of potential model compounds continue.

5.6 Derivatives and Analogs of Chromocene

The substituted derivatives (η^5-C_5H_5)$_2$CrL$_n$ are generated from the direct reaction of chromocene with L. In

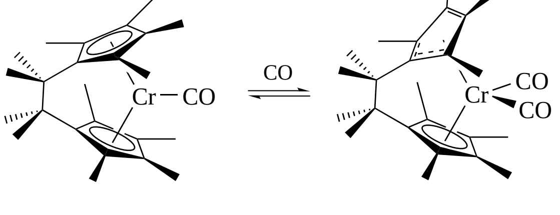
Table 1 Tricarbonyl derivatives (η^5-C_5H_5)Cr(CO)$_3$X

X	Synthesis	Comments
X (X = Br, I)	Hg[(η^5-C_5H_5)Cr(CO)$_3$]$_2$ + X_2	Cl_2 gives product with no CO ligands
R (R = Me, Et)	[(η^5-C_5H_5)Cr(CO)$_3$]$^-$ + RI	Identity of Et compound questioned
CH_2CO_2Me	[(η^5-C_5H_5)Cr(CO)$_3$]$_2$ + $BrCH_2CO_2Me$	
PCl_2	[(η^5-C_5H_5)Cr(CO)$_3$]$^-$ + PCl_3	Conversion to P(=S)Cl$_2$ compound increases stability
PO(CMe$_2$)$_2$O (ring)	[(η^5-C_5H_5)Cr(CO)$_3$]$^-$ + ClPO(CMe$_2$)$_2$O (ring)	Dioxaphospholane ligand
$AsMe_2$	[(η^5-C_5H_5)Cr(CO)$_3$]$^-$ + Me_2AsCl	Quite stable; As can be quaternized with MeI
SiH_3	[(η^5-C_5H_5)Cr(CO)$_3$]$^-$ + H_3SiBr	No solvent used; first silyl complex of this type
$SnMe_3$	(η^5-C_5H_5)Cr(CO)$_3$H + Me_3SnNMe_2	CO atmosphere
	(CH_3CN)$_3$Cr(CO)$_3$ + (η^5-C_5H_5)SnMe$_3$	CO atmosphere
MPh_3 (M = Ge, Sn, Pb)	[(η^5-C_5H_5)Cr(CO)$_3$]$^-$ + Ph_3MCl	Stability: Pb<Ge, Sn
$AuPPh_3$	(η^5-C_5H_5)Cr(CO)$_3$H + Ph_3PAuCl	Diamagnetic
HgX (X = Cl, Br, I)	Hg[(η^5-C_5H_5)Cr(CO)$_3$]$_2$ + HgX_2	

this way, compounds with L_n = CO, $(NH_3)_4$, $(NH_3)_9$, and (η^2-$F_3CC{\equiv}CCF_3$) have been prepared.[75] None of these adducts, however, persist at temperatures greater than −20 °C. Thermally stable aminates, (η^5-$C_5H_5)_2Cr(RNH_2)_x$ (R = Et, Pr, Bu, $CH_2{=}CHCH_2$; x = 4.5−5.5), form at 25 °C upon exposure of chromocene to the vapors of primary linear amines; like the carbonylation and ammoniations just mentioned, this reaction is reversible. The first irreversible adduct formation was observed with an N-heterocyclic carbene, to give (η^5-C_5H_5)Cr(η^1-C(NAr)$_2C_2H_2$)(η^1-C_5H_5).[80] Other examples of thermally stable, irreversibly formed derivatives of this type contain an ansa-chromocene ligands. This tetramethylethylene-bridged chromocene carbonyl complex, $[Me_4C_2(C_5H_4)]_2Cr(CO)$, is the product of the reaction of the bis-Grignard reagent $Me_4C_2(C_5H_4MgCl)_2{\cdot}4THF$ with $CrCl_2{\cdot}THF$ in a CO atmosphere.[81] While extremely air sensitive, this substance is sufficiently robust to be sublimed at 60−70 °C. Similarly, adducts of the type [*trans*-1,2-(3,4-$(CH_3O)_2C_6H_3)_2C_2H_2${η^5-C_5H_4}$_2$]Cr(L) (L = CO, CNR) and Me_2Si(η^5-$C_5Me_4)_2$Cr(CO) have been reported.[82,83] At elevated CO pressures, $[Me_4C_2(C_5H_4)]_2Cr(CO)$ and (η^5-$C_5H_5)_2$Cr(CO) react reversibly to give dicarbonyl species with concomitant $\eta^5 \rightarrow \eta^3$ slippage of one of the cyclopentadienyl rings (Scheme 8). Surprisingly, even a ligand-free ansa-chromocene, namely, Me_2Si(η^5-$C_5Me_4)_2$Cr, has now been prepared and structurally characterized.[84]

The known chromocene analogues feature substituted cyclopentadienyl rings and/or other anionic ligands with pentahapto coordination. (η^5-$C_5Me_5)_2$Cr is efficiently prepared from $[C_5Me_5]Na$ and $Cr_2(OAc)_4$.[85] This volatile, air-sensitive solid is an extremely potent reducing agent ($E_{>1/2}$ = −1.04 V), forming mildly air-sensitive [(η^5-$C_5Me_5)_2Cr]^+$ in the presence of water, ammonium ion, or ferricinium ion. By contrast, chromocene is inert to water and decomposed by [(η^5-$C_5H_5)_2Fe]^+$; chromocinium salts are extremely air sensitive, even pyrophoric (see Section 6.9). Complexes with monosubstituted and perdeuterated cyclopentadienyl rings have also been reported. Octaisopropylchromocene undergoes a low-spin/high-spin transition with increasing temperature.[86]

Structurally similar to and isoelectronic with chromocene are (η^5-indenyl)$_2$Cr (now known to have a dinuclear structure)[87] (η^5-fluorenyl)$_2$Cr, and [η^5-(9-methyl)fluorenyl]$_2$Cr, (η^5-$C_8H_{11})_2$Cr, {[(3)-1,6-$C_2B_{10}H_{12}]_2$ Cr}$^{2-}$, (η^5-pentadienyl)$_2$Cr, and (η^5-C_5R_5)Cr(η^5-pentadienyl) (R = H, Me). Control of the spin state by sterically enforced rotational orientation of the ligands has been noted in substituted bis(indenyl)chromium complexes.[88] Supported indenyl, fluorenyl, and pentadienyl derivatives function as Union Carbide-type catalysts, catalyzing the polymerization of ethylene. Oxidation of the air-stable bis(metallocarborane)chromium by chemical or electrochemical means yields the stable Cr^{III} anion. Bis(pentadienyl) compounds undergo 'naked metal' reactions analogous to those of Ni(allyl)$_2$, yielding homoleptic bisphosphines and isocyanides. By contrast, the half-open chromocenes, whose pentadienyl ligands adopt the η^5-S (sickle) coordination mode, form 18-electron adducts with CO, PF_3, RNC, $PPhMe_2$, and other two-electron donor ligands.[89]



Scheme 8

5.7 Miscellaneous Compounds of Chromium(II)

The CrR_2 fragment figures prominently in this group of molecules. A thermally stable complex formulated as $Cr(CH_2SiMe_3)_2$ was obtained from the interaction of Me_3SiCH_2Li with excess $CrCl_2$ or $CrCl_3$. Its true tetrameric structure, $Cr_4(CH_2SiMe_3)_8$, was later revealed by X-ray crystallography.[90] Treatment of *trans*-$CrCl_2(dmpe)_2$ with two equivalents of MeLi yields the 16-electron trans dimethyl complex, $CrMe_2(dmpe)_2$.[91] Related (dialkyl)bisphosphine compounds with a rare square-planar geometry, *cis*-CrR_2(dippe) (R = Me_3CCH_2, Me_3SiCH_2, or 1,3,5-$Me_3C_6H_2$; dippe = 1,2-bis(diisopropylphosphinoethane)) are synthesized by alkylation of dimeric $[CrCl_2(dippe)]_2$. An X-ray study showed extremely long Cr–P bonds in these molecules, a consequence of their high-spin d^4 chromium centers (μ = 4.9 μ_B), the trans influence of R, and the steric requirements of the R groups and phosphine. All of these dmpe and dippe products are air and moisture sensitive; in spite of their electron-deficient configuration, none are agostic (*see Agostic Bonding*). As ethylene polymerization catalysts, the dippe compounds demonstrate little activity, which may imply that low-valent Cr^{II} centers are not the active sites in chromium-based catalytic processes.

(η^5-C_5Me_5)Cr(dmpe)Me is derived from the chemical reduction of its Cr^{III} analogue with Na/Hg. Air sensitive but thermally stable, its magnetic moment, 2.79 μ_B, is compatible with a low-spin d^4 configuration.[92] Attempts to perform similar chemistry on [(η^5-C_5Me_5)Cr(dmpe)R]$^+$ (R = Et, other alkyls) were unsuccessful. This Cr^{II} complex reacted with ethylene at room temperature, but facile β-elimination prevented the formation of a polymer. That its isostructural Cr^{III} analog polymerized ethylene at 90 °C implies that chromium(III) is the more suitable oxidation state for catalysis, at least in this system. Reaction of the ethylene polymerization catalyst [(η^5-C_5Me_5)CrMe(THF)$_2$]BPh_4 with styrene gave (η^5-C_5Me_5)Cr(η^6-Ph-BPh_3), a Cr^{II} sandwich compound incorporating one of the rings of the 'noninteracting' BPh_4^- counterion.

Alkylation of the dinuclear chloride precursor [(η^5-C_5Me_5)Cr(μ-Cl)]$_2$ yields a series of alkyl bridged chromium(II) alkyls of the constitution [(η^5-C_5Me_5)Cr(μ-R)]$_2$

(R = Me, Et, *n*-Bu, CH_2SiMe_3, Ph). They feature short Cr–Cr distances (~2.26 Å), low effective magnetic moments, and attenuated reactivity, all consistent with strong metal–metal bonding.[93] Steric saturation of chromium with a sterically encumbered tris(pyrazolyl)borate ligand (i. e. $Tp^{t\text{-Bu,Me}}$ = hydrotris(3-*tert*-butyl-5-methylpyrazolyl)borate), on the other hand, facilitates the preparation of mononuclear, coordinatively unsaturated alkyls. $Tp^{t\text{-Bu,Me}}CrR$ (R = Cl, Et, Ph, CH_2SiMe_3) adopt cis divacant octahedral structures and high-spin configurations with four unpaired electrons.[94] Notably, these four-coordinate 12-electron species do not react with ethylene. However, $Tp^{t\text{-Bu,Me}}CrPh$ undergoes a clean reaction with O_2, producing the paramagnetic Cr^{IV} complex $Tp^{t\text{-Bu,Me}}Cr(O)OPh$ via an observable Cr(III) superoxide intermediate.[95]

6 CHROMIUM(III) ORGANOMETALLICS

6.1 Neutral Solvated Mono(Organo)chromium(III) Compounds

Complexes in this class can be represented by the general formula $RCrCl_2S_n$, and numerous routes to their preparation are known. Reaction of a Grignard reagent or $CrR_3(THF)_n$ with $CrCl_3(THF)_3$ at the appropriate temperature gives the desired product. Organoaluminum reagents and the diphenylmethyl anion add to $CrCl_3$, giving the monoalkylated species as well. Benzyl derivatives $RC_6H_4CH_2CrCl_2(py)_3$ are generated cleanly from $RC_6H_4CH_2Cl$ (R = H, *o*-Cl, *p*-Cl) and $CrCl_2(py)_2$. Related dithiocarbamates and acetylacetonates can also be synthesized. Molecules of $RCrCl_2S_n$ typically contain a phenyl, benzyl, or an *n*-alkyl R group and THF or pyridine as solvate, but more unusual molecules such as $(C_3F_7)CrCl_2L_n$ (L_n = $(py)_3$, $(bipy)_2$, $(phen)_2$, terpy) are also known. The N-donor solvate ligands are particularly good at stabilizing the chromium–carbon bond in these otherwise unstable molecules.

These d^3 systems can be characterized by their magnetic moments, which fall in the range 3.6–4.0 μ_B (spin-only value = 3.87 μ_B), and by a sensitivity to temperature, oxygen, and moisture. They react with $HgCl_2$ to give RHgCl and Cr^{III}; thermally induced homolysis of the Cr–C bond leads to $CrCl_2$ and various organic species. $RCrCl_2(THF)_3$ (R = Me, Et, *n*-Pr, *i*-Bu) is also reported to catalyze ethylene polymerization under mild conditions.[96]

6.2 Solvated Mono(Organo)chromium(III) Aquo Cations[97,98]

The general formula $[RCr(OH_2)_5]^{2+}$ describes this group of complexes. Reaction of an alkyl halide with chromium(II) perchlorate in perchloric acid yields these pentaaquo cations; a similar synthesis employs the isomeric bromoalkylpyridinium bromides. Oxidation of Cr^{II} salts by hydroperoxides and peroxides gives cationic products, as does the hydrolysis of $RCrCl_2S_n$. Finally, the interaction of Cr^{II} and alkylbis(dimethylglyoximato)cobalt also provides $[RCr(OH_2)_5]^{2+}$. Most of these processes involve the generation of a free radical and its subsequent attack on chromium(II).

Solutions of these cations have been prepared for numerous ligands R, including $CHCl_2$, CF_3, CH_2OH, $C(Me)_2OH$, and η^5-C_5H_5, but few have been isolated as solids. Like $RCrCl_2S_n$, these compounds are temperature and oxygen sensitive. In the presence of acid or mercury(II), Cr–R bond cleavage occurs to give RH or RHgCl. Oxidative cleavage generates the aldehyde, RCHO. Reactions with metal salts, organic halides, and halogens are also known.

6.3 Solvated Di(Organo)chromium(III) Compounds

Complexes of chromium(III) bearing two alkyl ligands assume one of two forms, R_2CrClS_n or $[R_2Cr(\text{bidentate ligand})_2]^+$. Examples of the neutral species are known for R = *n*-alkyl, *i*-alkyl, and cyclohexyl, with THF as a solvate. A related species is $Cr(n\text{-alkyl})_2Cl(Me_2PCH_2)_3CMe$, in which a tripod ligand functions in the stabilizing role of solvate.[99] Preparations include reaction of a polyphenylchromate, $M_x[Cr(C_6H_5)_{x+3}]$, with $CrCl_3(THF)_3$ in DME, addition of Grignard reagent to a mixture of $CrBr_2(THF)_2$ and bidentate ligand, followed by air oxidation, and thermal rearrangement and hydrolysis of a tri(organo)chromium(III) complex, R_3Cr(bidentate ligand) (THF).

The di(organo) neutral species are oxygen and water sensitive; they react with $HgCl_2$ and I_2, and like their mono(organo) analogs they are reported to possess catalytic activity. The cations, on the other hand, are stabilized by the chelation of bipy or phen, and so are unaffected by air and water but do react with $HgCl_2$. X-ray structural analyses of several $[R_2Cr(bipy)_2]I$ complexes indicate a cis arrangement of R ligands in these octahedral molecules.

6.4 Solvated and Unsolvated Tri(Organo)chromium(III) Compounds

Compounds R_3CrS_n comprise the largest class of solvated chromium(III) organometallics. The most simple and efficient synthetic route entails the addition of Grignard or lithium reagents to $CrCl_3$. A myriad of complexes (R = alkyl, aryl, vinyl, benzyl, naphthyl, styryl, cyclohexyl, etc.) have been prepared in this way. The phenyl compound, and perhaps others, can be produced in high yield from the reaction of $Li_3[CrPh_6]$ with $CrCl_3$ in THF. Exchange of the customary THF solvate for bipy or phen yields more stable products; phosphines can also be employed here. A few R_3Cr compounds do not require solvent stabilization;

among these are $(CH_2{=}CHCH_2)_3Cr$, $(CH_2{=}C(Me)CH_2)_3Cr$, $(MeCH{=}CHCH_2)_3Cr$, (1-norcamphyl)$_3$Cr, and $[(Me_3Si)_2CH]_3Cr$.[100]

The R_3CrS_n triaryl derivatives are generally stable at room temperature, whereas their alkyl analogs must often be isolated and handled at low temperature. All undergo thermal fragmentations and rearrangements under appropriate conditions. The Cr–C bond of a triaryl complex homolyzes to give the arene and the biaryl; alternatively, a σ-to-π rearrangement occurs and bis(π-arene)chromium forms. Fragmentation via reductive dimerization to give butadienes is observed in triallyl and vinyl species. Trialkyl compounds are characterized by homolytic Cr−C bond cleavage and by α- and β-*Hydride Elimination*, the products being alkanes, alkenes, and chromium hydrides. The molecule [*t*-BuSi$(CH_2PMe_2)_3$]Cr(*n*-Bu)$_3$ demonstrates an extraordinary stability for a 15-electron trialkyl: its decomposition requires a temperature of 95 °C (Scheme 9). This resistance to β-elimination is attributed to the kinetically inert d^3 configuration and the chelating tripod phosphine ligand, the 'arms' of which are less likely to dissociate for entropic reasons.[101] While R_3Cr and R_3CrS_n do not themselves affect alkene isomerization or catalytic hydrogenation, their chromium-based fragmentation products have been shown to isomerize alkenes and act as hydrogenation catalysts. In addition, triallylchromium is known to function as a catalyst for the polymerization and oligomerization of butadiene and other unsaturated molecules.

The R_3CrS_n and R_3Cr complexes exhibit magnetic moments that are in the range expected for chromium(III): 3.53−3.98 μ_B. They react readily with $HgCl_2$ and I_2; most are sensitive to oxygen and moisture. The chemistry of these compounds with unsaturated substrates is extensive, and is described in detail elsewhere.

6.5 Lithium and Sodium Poly(Organo)chromates

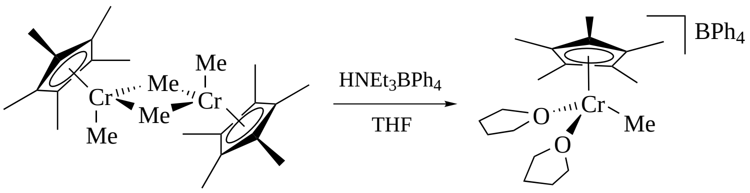
Representatives of this class of chromium(III) complexes can be described by the general formula $M_n[CrR_{n+3}]$ ($n = 1-3$). Hexaorganochromium compounds are prepared from an appropriate lithium reagent and $CrCl_3$ (stoichiometric ratio >6:1). Two other pathways are available for synthesis of the hexaphenylchromate: reaction of stoichiometric PhLi with $CrBr_3$, $CrCl_3(py)_3$, or $Cr(acac)_3$, and treatment of Cr^{II} salts with a significant excess of the lithium reagent. $M_2[CrR_5]$ is apparently only known for R = Ph; a steric strain in $M_3[CrPh_6]$ causes the extrusion of MPh to leave this pentaphenylchromate. Solvents like THF or DME facilitate the process. Treatment of $CrCl_3(THF)_3$ with PhNa in ether constitutes a formal synthesis. Tetra(organo)chromates $M[CrR_4]$ are also known for R = aryl and are obtained from the reaction of $CrCl_2$, CrR_2, or $CrCl_3$ with RLi. Penta- and hexaphenylchromates will also combine with $CrCl_3$ to give tetraphenylchromates if DME is available to stabilize the products. The first structurally characterized representative is $Li(THF)_4[Cr(C_6Cl_5)_4]$. It adopts a pseudooctahedral geometry, including two Cr–Cl interactions besides the four covalent Cr–C bonds.[74]

Of these three types of poly(organo)chromate anions, only the hexaorgano species tolerates a variety of ligand types bound to chromium. Hexamethylchromate has been reported,[102] as well as an unusual spirocyclic compound, $Li_3[Cr(1,4\text{-}C_4H_8)_3]\ (Et_2O)_{2.5}$. Notable polyaryls include the tris(2,2′-biphenyl) compound and the hydride $Li_3[CrH(Ph)_5](Et_2O)_3$. Collectively, poly(organo)chromates are thermally stable, but exceedingly sensitive to oxygen, water, and protic media. An exception is found in the tetra(organo)chromates, which tend to form chromium(II) dimers with loss of R−R. Both Cr^{II} and Cr^{III} species are formed in the reactions of these compounds, which include fragmentation and ligand replacement.

X-ray crystal structures of $Li_3[CrMe_6](dioxane)_3$ and of $Na_2[CrPh_5](Et_2O)_3(THF)$ have been determined. The latter is a distorted trigonal bipyramid; the former is octahedral, with a remarkably long Cr–C bond distances (average = 2.300(15) Å).

6.6 Solvated Mono(η^5-cyclopentadienyl)chromium Compounds

These solvent-stabilized half-sandwich complexes, of the general formula $(\eta^5\text{-}C_5H_5)CrX_2S$, are customarily prepared by the addition of S (S = THF, dioxane, Ph_3P) to '$(\eta^5\text{-}C_5H_5)CrX_2$' (X = Br, I) or $[(\eta^5\text{-}C_5H_5)_2Cr]$ $[(\eta^5\text{-}C_5H_5)CrY_3]$ (Y = Cl, Br, I, O(O=C)CF_3). The dihalide starting material is generated from the action of the appropriate allyl halide on $[(\eta^5\text{-}C_5H_5)Cr(CO)_2]_2$; the ionic complex forms upon treatment of chromocene with CCl_4, CF_3CO_2H, or HX. Pyridine-solvated compounds are easily prepared in one step from chromocene and pyridinium tribromide or iodide. Reaction of the hydride



Scheme 9

(η^5-C_5H_5)CrH{P(OMe)$_3$}$_3$ with CCl_4 yields the phosphite-stabilized compound (η^5-C_5H_5)$CrCl_2${P(OMe)$_3$}. Analogous THF-solvated (η^5-C_5Me_5)CrX_2S species have been reported for X = Cl, Br, and I; however, their syntheses differ significantly. Besides solvent ligand exchange, two other reactions of these air-sensitive organometallics have been studied. (η^5-C_5R_5)CrX_2(THF) (R = H, X = Br, I; R = Me, X = Cl, Br, I) dimerizes upon heating to give [(η^5-C_5R_5)CrX_2]$_2$. Finally, the hydride (η^5-C_5H_5)CrH{P(OMe)$_3$}$_3$, the starting material for the preparation of (η^5-C_5H_5)$CrCl_2${P(OMe)$_3$} (see above), is itself obtained from (η^5-C_5H_5)$CrCl_2$(THF), $NaBH_4$, and P(OMe)$_3$.

6.7 Miscellaneous Unsolvated Mono(η^5-cyclopentadienyl)chromium Compounds

The unsolvated form of the dichloride described in the previous section may be synthesized from chromocene and hexachlorocyclopentadiene or gaseous HCl,[103] whereas the bromide is best obtained by removal of the solvate from (η^5-C_5H_5)CrX_2(THF) in vacuo. The iodide is only available as crude '(η^5-C_5H_5)CrI_2' from the reaction of C_3H_5I with [(η^5-C_5H_5)Cr(CO)$_2$]$_2$. Trichloride anions, [(η^5-C_5R_5)CrX_3]$^-$ (R = H, X = Cl, Br, I; R = Me, X = I), result when HX is added to (η_5-C_5R_5)$_2$Cr, followed by NH_4X. The lithium salt of the trichloro anion has been crystallographically characterized. Treatment of Cr(acac)$_3$ with C_5H_5MgBr leads to formation of (η^5-C_5H_5)CrBr(acac).

An unprecedented insertion of nitrile into the chromium–alkyl bonds of dimers [(η^5-C_5Me_5)Cr(μ-Cl)R]$_2$ led to the formation of the mononuclear β-diketiminato species (η^5-C_5Me_5)Cr{[HNC(R)]$_2$CR$'$}Cl (R = Me, Et; R$'$ = H, Me).[104] This unusual reactivity has been attributed to the relatively high oxidation state and coordinative unsaturation of the starting dimers and intermediates. Similar to the β-diketiminato complex in structure are (η^5-C_5Me_5)Cr{[OC(Me)$_2$]$_2$CH$_2$}py, featuring a chelating bis(alkoxide) ligand, and (η^5-C_5Me_5)Cr[OC(Me)$_2$CHC(Me)O]py, whose bidentate ligand is a doubly deprotonated β-hydroxy ketone.[105] These molecules are the products of the reactions of (η^5-C_5Me_5)Cr(R)$_2$py (R = Me or O-*t*-Bu, respectively) with acetone.

6.8 Mono(η^5-cyclopentadienyl)chromium Alkyl Compounds

This class of organometallics originates from chemistry of the chromium–carbon bond developed only within the last two decades.[105,106] Illustrative of this fact is the observation that a comprehensive reference published in 1982 makes no mention of compounds of chromium(III) bearing both cyclopentadienyl and alkyl ligands.[16] Within this class are found mono-, di-, and trialkyl complexes of (η^5-C_5H_5) and (η^5-C_5Me_5); these will be examined in turn. Much of the interest in these compounds centers on their role as catalysts for the polymerization, oligomerization, and selective trimerization of ethylene.

Monoalkyls of the form (η^5-C_5R_5)Cr(R$'$)(L)Cl (R = H, R$'$ = Me or Et, L = py, PPh$_3$, Cl$^-$; R = Me, R$'$ = Me or Et, L = py, PMe$_3$, 3,5-lutidine) are prepared by cleavage of the dimers [(η^5-C_5R_5)Cr(R$'$)(μ-Cl)]$_2$ with the appropriate nucleophile, L. Cationic monoalkyls, [(η^5-C_5Me_5)CrL_2R]X (L = py, PMe$_3$, THF, MeCN, 3,5-lutidine; L$_2$ = dmpe, dppe, bipy; R = Me, Et), are derived from the same pentamethylcyclopentadienyl dimer or from (η^5-C_5Me_5)Cr(R$'$)(L)Cl upon treatment with $TlPF_6$ in the presence of L. An alternative preparation of the bis(THF)(methyl) cation involves protonation of [(η^5-C_5Me_5)Cr(Me)(μ-Me)]$_2$ with $HNEt_3BPh_4$ in THF (Scheme 9).

Monomers and dimers can also serve as starting materials for the synthesis of the dialkyls (η^5-C_5R_5)Cr(R$'_2$)L (R = H, R$'$ = Me, Bn, CH_2SiMe_3, L = PMe$_3$, PEt$_3$; R = Me, R$'$ = Me, L = PMe$_3$, py, THF). Treatment of (η^5-C_5R_5)$CrCl_2$(PR$_3$) with two equivalents of alkyllithium or a Grignard reagent gives the desired product, as does the cleavage of [(η^5-C_5Me_5)Cr(Me)(μ-Cl)]$_2$ with alkyllithium in the presence of L. (η^5-C_5Me_5)Cr(Me)$_2$py can also be obtained from the addition of py to dimeric [(η^5-C_5Me_5)Cr(Me)(μ-Me)]$_2$.

A particular subset of these ligated dialkyls are those in which the ligand is tethered to the cyclopentadienyl ligand. Thus, chromacyclopentane and cycloheptane derivatives stabilized by the (η^5;η^1-$Me_4C_5CH_2CH_2NMe_2$) ligand have been prepared and their reactivity supports the intermediacy of such metallacycles in the catalytic trimerization of ethylene.[107] A variety of donor-ligand-substituted cyclopentadienylchromium(III) complexes with amino and phosphino substituents has been prepared and screened for an ethylene polymerization activity.[108,109]

Two other interesting cyclopentadienyl alkyls are (η^5-C_5Me_5)Cr(CH_2SiMe_3)$_2$ and [(η^5-C_5Me_5)$_2$Cr$_2$(η^1-CH_2Ph)(μ-η^3 : η^6-CH_2Ph)]. The former is an unusual 13-electron species whose coordinative unsaturation makes it an extremely effective catalyst for ethylene polymerization, and which exhibits a rich thermal decomposition chemistry.[110] The latter, a mixed-valent complex exhibits ferromagnetic coupling between the two chromium atoms and is a catalyst for the polymerization of ethylene as well.[111]

Compounds in this class are characterized by thermal stability, crystallinity, and sensitivity to air and moisture. Most possess 15-electron configurations and pseudooctahedral coordination spheres. The isolation of ethyl derivatives demonstrates that β-elimination is not facile in these Cr^{III} alkyls.[105] Also, evidence for agostic interactions is lacking. While the reactivity of the neutral complexes is limited to ligand exchange, alkylation, and dimer formation, cationic [(η^5-C_5Me_5)CrL_2R]X is recognized as an efficient ethylene polymerization catalyst, particularly where L = THF, R = Me,

and X = BPh_4. The PF_6^- analog is equally reactive; however, it is prone to decomposition by abstraction of fluoride from the counterion and chloride from the CH_2Cl_2 solvent, yielding polynuclear chromium complexes held together by fluoride bridges. The most reactive of these cationic alkyls is the exceedingly labile $[(\eta^5\text{-}C_5Me_5)Cr(OEt_2)_2CH_2SiMe_3][B(3,6\text{-}(CF_3)_2C_6H_3)_4]$;[112] it even oligomerizes propene, despite the well-established selectivity of CpCr-catalysts for insertion of ethylene over α-olefins.[113]

6.9 Chromocinium Derivatives and Analogs

The chromocinium ion, $[(\eta^5\text{-}C_5H_5)_2Cr]^+$, results from the oxidation of chromocene by chemical or electrochemical means. Allyl iodide is an efficient oxidant; however, the pyrophoric iodide product is best converted to the BPh_4^- salt or the reineckate, $[Cr(SCN)_4(NH_3)_2]^-$, for ease of handling. In addition, the reactions of $[(\eta^5\text{-}C_5H_5)Cr(CO)_3]_2$ with CCl_4 or HX (X = Br, I) and with chromocene generate the ion as $[(\eta^5\text{-}C_5H_5)_2Cr][(\eta^5\text{-}C_5H_5)CrX_3]$ and $[(\eta^5\text{-}C_5H_5)Cr][(\eta^5\text{-}C_5H_5)Cr(CO)_3]$, respectively. Treatment of $CrBr_3$ with C_5H_5Li gives $(\eta^5\text{-}C_5H_5)_2CrBr$. Electrochemical oxidation occurs reversibly with a half-wave potential of −0.67 V. Chromocinium prepared by this route is stable in solution as the PF_6^- salt.

The decamethylchromocinium ion, $[(\eta^5\text{-}C_5Me_5)_2Cr]^+$, has been isolated as the iodide from chromocene and HI. Further reaction with HI forms the salt of the complex anion $[(\eta^5\text{-}C_5Me_5)_2Cr][(\eta^5\text{-}C_5Me_5)CrI_3]$.

There exist analogs of the chromocinium ion in which the cyclopentadienyl rings are partly or wholly replaced by dianionic carborane ligands. Dicarbollide ions $[(3)\text{-}1,2\text{-}C_2B_9H_9R_2]^{2-}$ ($R_2 = H_2$, HMe, Me_2, HPh) and $[(3)\text{-}1,7\text{-}C_2B_9H_{11}]^{2-}$ react with $CrCl_3$ to give $\{[(3)\text{-}1,2\text{-}C_2B_9H_9R_2]_2Cr\}^-$ and $\{[(3)\text{-}1,7\text{-}C_2B_9H_{11}]_2Cr\}^-$. If the reaction is carried out in the presence of $C_5H_5^-$, one obtains the neutral mixed-sandwich complexes $(\eta^5\text{-}C_5H_5)Cr[(3)\text{-}1,2\text{-}C_2B_9H_9R_2]$ and $(\eta^5\text{-}C_5H_5)Cr[(3)\text{-}1,7\text{-}C_2B_9H_{11}]$. The chromium(III) metallacarborane $[(1,6\text{-}C_2B_{10}H_{12})_2Cr]$ has been prepared by chemical (Ag^+, H_2O_2) or electrochemical oxidation of its Cr^{II} precursor. These dicarbollyl derivatives of Cr^{III} are stable in air and can be recrystallized from aqueous solutions, and are unaffected by acid. They do, however, decompose in the presence of an aqueous base. Electrochemical data indicate that reduction is not reversible in these complexes. A crystal-structure determination has been carried out on the cesium salt of $\{[(3)\text{-}1,2\text{-}C_2B_9H_9(Me)_2]_2Cr\}^-$. Related to these sandwich compounds is trianionic $[(B_{10}H_{10}CH)_2Cr]^{3-}$, which exhibits similar properties and reactivity.

6.10 Other Chromium(III) Organometallics

The search for chromium-based olefin polymerization catalysts has led to the exploration of chromium alkyls with a wide variety of ancillary ligands other than cyclopentadienyls.[114] For example, N,N'-disubstituted β-diketiminato (i.e. 'nacnac') complexes of chromium have been alkylated and shown to catalyze ethylene polymerization.[115,116] Specifically, the cationic complex $[(2,6\text{-}i\text{-}PrPh)_2nacnacCr(OEt_2)Me][B(3,6\text{-}(CF_3)_2C_6H_3)_4]$ catalyzes the polymerization of ethylene in the absence of any activators or cocatalysts and produces polyethylene of extremely narrow polydispersity.[117] Another set of ligands used to stabilize Cr^{III} alkyls are the N-substituted 1,3,5-triazacyclohexanes, for example, in $\{(i\text{-}Pr)_3N_3(CH_2)_3\}Cr(CH_2SiMe_3)_2Cl$.[118] Oxidation of square-planar Cr^{II} precursors containing a tridentate aminophosphine ligand with alkyl halides gives alkyls of the type $Cr(R)X[N(SiMe_2CH_2PPh_2)_2]$ and $Cr(R)X[N(SiMe_2CH_2PPh_2)_2]$ (R = Me, CH_2SiMe_3; X = Cl, Br, I). These compounds are unusual examples of five-coordinate Cr^{III} complexes.[119]

7 CHROMIUM(IV) ORGANOMETALLICS

7.1 Tetraorganochromium Compounds

The majority of chromium(IV) organometallics belong to the family of homoleptic tetraalkyls and tetraaryls. These compounds are generally prepared by one of two synthetic routes. In the first, the chromium(III) precursor $CrCl_3(THF)_3$ is reacted with four equivalents of alkyl- or aryllithium. If the reaction is performed in pentane or ether, a disproportionation reaction occurs and the tetrasubstituted product forms directly. In THF, however, the reaction yields $Li[CrR_4]$, which gives CrR_4 upon oxidation; substitution of Grignard reagents for alkyllithiums gives comparable results in some cases. Direct conversion to CrR_4 also occurs via the second route, in which $Cr(O\text{-}t\text{-}Bu)_4$ and four equivalents of alkyllithium are combined in pentane.

Table 2 lists representative homoleptic tetraalkyls and aryls. Like all σ-bonded transition metal alkyls, these compounds are subject to decomposition via a variety of routes. The absence of β-hydrogen atoms in many of these molecules, however, eliminates potential decomposition pathways involving β-hydride eliminations, thereby enhancing the thermal stability of these species. In other tetraalkyls, β-hydrogens are present but geometric or steric factors impede the concerted elimination or abstraction process. An obvious example is tetrakis(l-norbornyl)chromium, which will not eliminate to give the bridgehead alkene. In spite of these sources of stabilization, chromium–carbon bond homolysis remains a feasible fragmentation pathway.

General features of each molecule in Table 2 include a magnetic moment of 2.6–3.0 μ_B, appropriate for a Cr^{IV} complex with two unpaired electrons, and tetrahedral coordination; the crystal structures of $Cr(CH_2SiMe_3)_4$ and $Cr(CH_2CMe_3)_4$

Table 2 Homoleptic tetra(organo)chromium(IV) compounds

Compound	Preparation[a]	Comments
$Cr(CH_2SiMe_3)_4$	1, 2	Purple–red crystals; thermally stable
$CrMe_4$	3	Maroon oil; stable at −78 °C
Cr(1-norbornyl)$_4$	1	Red–brown crystals; thermally stable
Cr(*t*-Bu)$_4$	1, 3	Dark red crystals; thermally stable
Cr(mesityl)$_4$	4	Dark brown crystals; thermally stable
Cr(cyclohexyl)$_4$	2	Dark red crystals; thermally stable
$Cr(C(Ph){=}CMe_2)_4$	1	Green crystals; thermally stable
Cr(*n*-Bu)$_4$	3	Red solution; stable at 0 °C

[a]Key to preparation: 1 = $CrCl_3(THF)_3 + 4RLi$, 2 = $CrCl_3(THF)_3 + 4RMgX$, 3 = Cr(O-*t*-Bu)$_4$ + 4RLi, 4 = (a) $Ar_3Cr + ArLi$, (b) air oxidation.

have recently been determined.[120] As a rule, these compounds show limited reactivity, and this is particularly the case for those in which the metal center is effectively shielded by bulky alkyl groups. However, supported tetraalkyls, for example, $Cr(CH_2SiMe_3)_4$ or $Cr(CH_2CMe_3)_4$ on an inorganic oxide carrier, function as very active catalysts for ethylene polymerization. A detailed 'surface organometallic' study of the reaction of these two compounds with silica showed the formation of surface bound bis(alkyl)chromium fragments, for example, $(\equiv SiO)_2Cr(CH_2CMe_3)_2$, which was transformed into alkylidene $(\equiv SiO)_2Cr(=CHCMe_3)$ upon heating. The latter species initiated the polymerization of ethylene.[121]

7.2 Chromium Carbonyl Carbynes[122]

An attempt to replace the methoxy group of $(CO)_5Cr(=C(Ph)OMe)$ with a halide (from BX_3) led to the unanticipated formation of the first carbyne complex (*see Carbyne Complexes*). This synthetic method, cleavage of a carbene substituent by a Lewis acid, remains a good general route to these organometallics. Initially, the Lewis acid coordinates strongly to an oxygen-, nitrogen-, or sulfur-containing group present on the carbene. The weakened carbene carbon–heteroatom bond then breaks, and a transient halocarbene intermediate forms. This decomposes to a cationic carbyne whose halide counterion displaces the trans carbonyl to yield the neutral product. However, if the carbene is substituted in the trans position with a good σ-donor such as a phosphine, the cationic carbyne species is charge stabilized and can be isolated.

Crystal-structure determinations performed on chromium carbonyl carbynes indicate an average Cr–C bond length of 1.70 Å, ca. 0.2 Å shorter than the average Cr–C(carbonyl) distance. An exception is seen in $X(CO)_4Cr{\equiv}C\text{-}NR_2$, in which the Cr–C bond is somewhat longer and the C–N bond somewhat shorter than expected. These findings are consistent with the presence of some double bond character. The Cr≡C–R bond angle is customarily very close to linear, but structures bent up to 12° are known. Chromium carbonyl carbynes are frequently employed as starting materials for the synthesis of carbenes inaccessible by standard routes. Other reactions include carbonyl substitution and oxidative decomposition, thermal coupling of carbynes to yield alkynes, and transfer of carbyne ligands to cobalt to form (μ_3-methylidyne)nonacarbonyl tricobalt complexes.

7.3 Chromocene Derivatives and Other Compounds of Chromium(IV)

A series of reports[123] describes a number of substituted chromocene derivatives obtained from the oxidative addition of sulfur, selenium, and halogen reagents to $(\eta^5\text{-}C_5H_5)_2Cr$. Air-stable $(\eta^5\text{-}C_5H_5)_2Cr(NCY)(YCN)$ and $(\eta^5\text{-}C_5H_5)_2Cr(CN)(NCY)$ (Y = S, Se) were produced in the reactions of chromocene with $(YNC)_2$ and $Y(CN)_2$ respectively. Addition of HN_3 and CNN_3 to $(\eta^5\text{-}C_5H_5)_2Cr$ gave rise to $(\eta^5\text{-}C_5H_5)_2Cr(N_3)_2$ with release of H_2, and to $(\eta^5\text{-}C_5H_5)_2Cr(CN)(N_3)$, while treatment of $(\eta^5\text{-}C_5H_5)_2Cr$ with IX (X = Cl, Br) gave $(\eta^5\text{-}C_5H_5)_2CrIX$. Notably, none of these compounds have been structurally characterized.

There are now also some ansa-chromocene derivatives that feature tetravalent chromium. The first of these was the diamagnetic hydride $[Me_4C_2(\eta^5\text{-}C_5H_4)_2Cr(CO)H][B(3,5\text{-}(CF_3)_2C_6H_3)_4]$[124] that was observed as a metastable intermediate in the protonation of $Me_4C_2(C_5H_4)_2Cr(CO)$. More recently, the stable cyanide $[Me_4C_2(\eta^5\text{-}C_5H_4)\{\eta^5\text{-}C_5H_3B(C_6F_5)_3\}Cr(CN)CNXyl]$ has been structurally characterized.[125]

A triamidoamine ligand $((N_3N)^{3-} = ((Me_3SiNCH_2CH_2)_3N)^{3-})$ has facilitated the preparation of a new class of chromium(IV) organometallics. Alkyls $(N_3N)CrR$ (R = Me, *n*-Bu) as well as the hydride $(N_3N)CrH$ have been characterized by X-ray diffraction.[126] The five-coordinate molecules adopt high-spin d^2 configuration.

Other chromium(IV) organometallics include $K_3[Cr(O_2)_2(CN)_3]$ and 1,1′-*commo*-$Cr[(2,3\text{-}SiMe_3)_2\text{-}2,3\text{-}C_2B_4H_4]_2$. The latter is a diamagnetic carborane sandwich complex. Diamagnetism has also been claimed for the compounds $(\eta^5\text{-}C_5Me_5)Cr(Cl)(Br)Me$ and $(\eta^5\text{-}C_5Me_5)Cr(OPh)_2Me$.

8 CHROMIUM(V) ORGANOMETALLICS

Few organochromium compounds possessing the d^1 configuration are known. (η^5-C_5Me_5)$CrOBr_2$ was obtained from the reaction of [(η^5-C_5Me_5)Cr(Br)(μ-Br)]$_2$ with O_2.[127] Its cyclopentadienyl analog was synthesized from chromocene and Br_2 followed by O_2. These compounds possess the expected piano-stool geometry and are metastable, reverting easily to the starting materials. The electrophilic oxygen ligand of (η^5-C_5Me_5)$CrOBr_2$ is, however, readily transferred to phosphines; catalytic oxygenation occurs in the presence of O_2 and excess phosphine. (η^5-C_5H_5)$CrOBr_2$ is even more reactive, transferring its oxygen to both phosphines and sulfides (equation 13).

$$2(\eta^5\text{-}C_5Me_5)Cr(O)Br_2 \xrightarrow{PR_3} [(\eta^5\text{-}C_5Me_5)Cr(Br)(\mu\text{-}Br)]_2 + 2O{=}PR_3 \quad (13)$$

The corresponding chloro derivatives, that is, Cp*$CrOCl_2$ and Cp$CrOCl_2$, were reported more recently.[128] Both were prepared by oxidation of Cr(III) precursors with O_2, and they too engage in O-atom transfer chemistry; Cp$CrOCl_2$ is particularly noteworthy for transferring oxygen to a variety of olefins. These reactions feature a change of spin state along the reaction pathway, and the corresponding potential energy surfaces and their 'minimum energy crossing point' (MECP) have been characterized computationally.

The first oxoalkyl of chromium(V), (η^5-C_5Me_5)CrO(Me)$_2$, was prepared via oxygen transfer from trimethylamine *N*-oxide to the Cr^{III} precursor (η^5-C_5Me_5)Cr(py)Me_2.[129] Its effective magnetic moment at 285 K, 1.76 μ_B, is consistent with the presence of pentavalent chromium. At ambient temperature and pressure, this complex does not function as an ethylene polymerization catalyst; however, it does react with the starting material to give the Cr^{IV} dimer [(η^5-C_5Me_5)Cr(Me)$_2$]$_2$(μ_2-O). Another chromium(V) alkyl, namely, dinuclear [Cp*Cr(O)Me]$_2$(μ-O), was produced by the reaction of [Cp*Cr(μ-Me)]$_2$ with O_2.

9 CHROMIUM(VI) ORGANOMETALLICS

The majority of d^0 organochromium species feature a bis(imido)chromium moiety. The compounds Cr(=N-*t*-Bu)$_2$(Ar)$_2$ (Ar = mesityl, 2,6-xylyl), prepared from Cr(=N-*t*-Bu)$_2$(OSiMe$_3$)$_2$ and two equivalents of the appropriate Grignard reagent, were the first organometallic complexes of chromium(VI) to appear in the literature.[129] Their stability has been attributed to the steric protection afforded to the metal center and amido nitrogens by the aromatic ligands' ortho methyl groups. The dimesityl compound does, however, undergo *CO Insertion* to give the unusual bis-acyl Cr(=N-*t*-Bu)$_2$(COC$_6$H$_2$Me$_3$)$_2$; this thermally eliminates the amide HN(*t*-Bu)COC$_6$H$_2$Me$_3$. *t*-Butyl isocyanide also inserts into the chromium–carbon bond of the mesityl complex, but only a single insertion is observed, and Cr(=N-*t*-Bu)$_2${η^2-[*t*-BuN=C(C$_6$H$_2$Me$_3$)]}(C$_6$H$_2$Me$_3$) is formed. An η^2-aminoacyl is also the product of the reaction between Cr(=N-*t*-Bu)$_2$Cl$_2$(*t*-BuNC) and methyllithium. Presumably, methyl replaces one of the chlorides, then migrates to the isocyanide carbon to give Cr(=N-*t*-Bu)$_2${[η^2-[*t*-BuN=C(Me)]}Cl].

The first report of a chromium(VI) alkyl described the synthesis of Cr(=N-*t*-Bu)$_2$R$_2$ (R = CH$_2$SiMe$_3$, CH$_2$CMe$_3$, CH$_2$CMe$_2$Ph) via alkylation of Cr(=N-*t*-Bu)$_2$X$_2$ (X = Cl, Br) with RMgCl or R$_2$Zn.[130] Although coordinatively unsaturated, these complexes do not bind a fifth ligand, nor is there evidence for agostic interactions between the alkyl α-methylene groups and chromium. They also do not react to form alkylidenes. Novel monomeric cyclopentadienyl compounds of chromium(VI), (η^5-C_5H_5)Cr(=N-*t*-Bu)$_2$X (X = Br, Cl), were prepared from Cr(=N-*t*-Bu)$_2$(py)X$_2$ and Mg(η^5-C_5H_5)$_2$(THF)$_{2.5}$. These halides could be alkylated to give (η^5-C_5H_5)Cr(=N-*t*-Bu)$_2$R (R = Me, CH$_2$SiMe$_3$, CH$_2$CMe$_3$, CH$_2$CMe$_2$Ph).

The analogous arylimido species Cr(=N-2,6-*i*-PrC$_6$H$_3$)$_2$Cl$_2$ gives rise to the structurally characterized dialkyl Cr(=N-2,6-*i*-PrC$_6$H$_3$)$_2$(CH$_2$CMe$_3$)$_2$. The latter undergoes α-elimination and generates Cr(VI) alkylidenes of the type Cr(=N-2,6-*i*-PrC$_6$H$_3$)$_2$(=CHMe$_3$)(L) (L = THF, PMe$_3$).[131] Surprisingly, these alkylidenes do not react with alkenes.

Treatment of several of the imido alkyls described above with borate activators (e. g. [Ph$_3$C][B(C$_6$F$_5$)$_4$] or [PhNMe$_2$H][B(C$_6$F$_5$)$_4$]) generated ethylene polymerization catalysts.[132] However, the hexavalent nature of the active catalysts has been questioned based on density functional calculations on model systems.[133]

A monomeric oxoalkyl of chromium(VI), (η^5-C_5Me_5)CrO$_2$Me, has been obtained from the oxidation of (η^5-C_5Me_5)Cr(py)Me$_2$ with O_2.[134] In C_6D_6 solution, it slowly decomposes over a period of weeks; in addition, it fails to polymerize ethylene or undergo methanolysis of the chromium–carbon bond. (η^5-C_5Me_5)CrO$_2$Me does, however, oxidize PPh$_3$ with concomitant formation of the chromium(V) dimer [(η^5-C_5Me_5)Cr(O)(Me)]$_2$(μ_2-O). Another set of formally hexavalent cyclopentadienyl chromium compounds are aminocarbyne complexes like [(η^5-C_5H_5)Cr(≡C*i*-Pr$_2$)(Br)(CN*t*-Bu)$_2$] PF$_6$ and [(η^5-C_5Me_5)Cr(≡C*i*-Pr$_2$)(CN*t*-Bu)$_3$](PF$_6$)$_2$.[135]

Finally, the nitrido alkyl NCr(CH$_2$SiMe$_2$Ph)(N*i*-Pr$_2$)$_2$ has been structurally characterized,[136] and the related dialkyl NCr(CH$_2$SiMe$_3$)$_2$(N*i*-Pr$_2$) has been shown to insert *tert*-butylisonitrile.[137]

Glossary

Base-off: nucleotide function not coordinated to a cobalt center in a complete corrin
Base-on: nucleotide function coordinated to a cobalt center in a complete corrin
Complete corrin: a cobamide with an appended nucleotide base
Ileum: last part of the small intestine
Incomplete corrin: a cobyrinic acid derivative lacking a nucleotide base
Pernicious anemia: microscopic abnormalities of blood and bone marrow correlating with B_{12}-deficiency

1 INTRODUCTION

Vitamin B_{12} (**1**) was discovered some 55 years ago as the (extrinsic) 'antipernicious anemia factor,' important for human and animal metabolism.[1] The cobalt complex (**1**) was structurally characterized by X-ray analysis in the laboratory of D.C. Hodgkin.[2,3] In these studies, the unique buildup of the 'tetrapyrrolic' corrin ligand and the intramolecularly coordinating 'pseudo-nucleotide' function of the vitamin were discovered.[2]

The unusual nature of the red cobalt complex (**1**) induced considerable activity in the field of coordination chemistry: vitamin B_{12} derivatives were found to represent unique examples of kinetically labile Co^{III} complexes, the analysis of whose 'model type' coordination chemistry itself proved to be of particular value.[4] Interestingly, for the transition metal cobalt, no other cofactor function has been clearly established, except for that in the B_{12}-derivatives.[5]

The complex and novel structure of the corrin ligand prompted a series of early investigations of its chemistry,[4,6] and the partial synthesis of vitamin B_{12} was achieved from the B_{12}-degradation product cobyric acid (**2**)[6] (Figure 1; for the nomenclature of the B_{12}-derivatives, see Kräutler[7]).

About 40 years ago, coenzyme B_{12} (adenosylcobalamin, (**3**)) was discovered by Barker *et al.*, and its organometallic nature was revealed by X-ray analysis in the laboratory of D. C. Hodgkin.[2,3] The partial syntheses of the coenzyme (**3**), of methylcobalamin (**4**), and of other organometallic B_{12}-derivatives from vitamin B_{12} were rapidly developed by Smith *et al.* and Bernhauer *et al.*; later on, methylcobalamin (**4**) was also found in human serum.[6]

The unmatched complex structure of the 'low-molecular weight' natural product vitamin B_{12} posed a challenge to synthetic chemistry, which was met in the early 1970s by Eschenmoser[8] and by Woodward[9] and their coworkers. The biosynthesis of the structure of natural cobalt-corrins is no less intricate[10,11] and facets of its pathways still remain to be uncovered (see section 2.3).

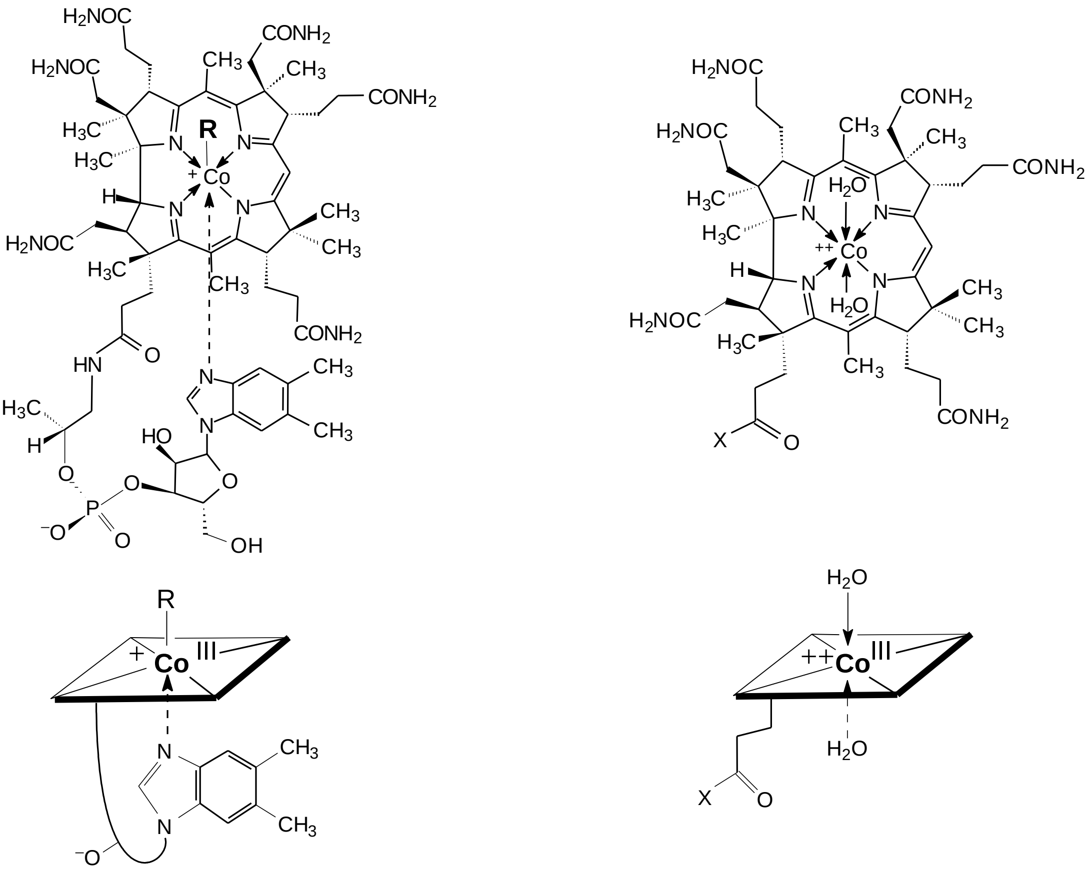
The metabolically important functions of the B_{12}-derivatives are directly concerned either with enzymatically controlled organometallic reactions involving protein-bound adenosylcobamides (such as coenzyme B_{12}, (**3**)), or methyl-Co^{III}-corrinoids (such as methylcobalamin, (**4**)), or with enzyme-controlled redox reactions. Studies on the underlying biologically relevant organometallic chemistry of the B_{12}-coenzymes in homogeneous (protic) solution, as well as the characterization of the enzymatic processes themselves have attracted considerable interest.[12–14]

Subsequent to the original quest for vitamin B_{12} (**1**), driven by medicinal purposes mainly, further investigations on the natural corrinoids laid bare the central roles of the B_{12}-coenzymes in the metabolism of microorganisms, in particular.[6,7] These 'primitive' organisms uniquely possess the capacity to build up the complex B_{12} structure in nature,[10,11,13,14] in which they may vary the constitution of the nucleotide function in a species-specific way (Figure 2).[6,13] The cobalt-corrins, in turn, have been proposed to be structural and functional remnants of 'early' (primitive) forms of life,[15] where presumably, central metabolic processes could rely considerably on organometallic chemistry at cobalt and nickel centers.[5]

2 B_{12} COENZYMES

The coenzyme B_{12} molecule consists of several unique structural units: the corrin ligand, the intramolecularly coordinating nucleotide function, the corrin-bound Co^{III}-ion, and the organometallically bound 5′-deoxyadenosyl ligand (Figure 3).[3] The cyanide derivative, vitamin B_{12} (**1**), is an isolation artifact that appears not to have a physiological role itself.[15]

Coenzyme B_{12} (**3**) and vitamin B_{12} (**1**) are thus representatives of the nucleotide-containing 'complete corrins'. Removal



R = CN; cyanocobalamin (vitamin B_{12}, **1**)
R = 5′-adenosyl; adenosylcobalamin (coenzyme B_{12}, **3**)
R = CH_3; methylcobalamin (**4**)

X = OH; diaqua-Co^{III}-cobyric acid (**2**)

of the nucleotide function leads to 'incomplete corrins', such as the cobinamides (Figure 1).

2.1 Structure and Bonding in Corrins

2.1.1 *Co^{III}-corrins*

Early structural investigations have been concerned mostly with the (diamagnetic) Co^{III}-corrins.[2,3] Throughout, the corrin-bound Co^{III} center (a d^6 ion) is found to carry two axial ligands (pseudooctahedral hexacoordination); the existence[16] of (diamagnetic) five-coordinate alkyl-Co^{III}-corrins lacks convincing experimental support. In the base-on form of the complete corrins, the 'lower' axial position (α-position) is occupied by the nucleotide base. The sixth ligand, for example, a methyl group in methylcobalamin (**4**), then sits in the 'upper' position (β-position).

The corrins are related to the natural porphyrins by both their structure[17] and their biosynthesis.[10,11] Besides its linearly conjugated chromophoric system that comprises the four inner nitrogen centers, the corrin ligand exhibits a uniquely functionalized periphery and a saturated and direct trans junction between the two 'western' reduced pyrrole rings; the (15-membered inner ring of the) corrin ligand provides a coordination hole smaller than that of the (16-membered inner ring of the) porphyrins[17] and is inherently nonplanar (Figure 3).[2,3]

The remarkable 'nucleotide loop', which contains an unusual α-configured nucleotide function, forms a nearly strain-free 19-membered ring[17] to allow for coordination of the nucleotide base to the lower side of the corrin-bound metal center (base-on forms).[2,3] Protonation at the nitrogen atom of the nucleotide base (in some cases, mere solvolysis) leads to the base-off form (Figure 4).

The β-ligands in natural corrinoid cofactors are either organometallically bound 5′-adenosyl or methyl groups, or else an aquo or a cyano ligand is found in the isolation forms (where the latter two may be artifacts of the isolation conditions).[15]

The corrin ligand and the basic motif of the nucleotide chain are widely conserved structural units in the natural corrins. Norpseudovitamin B_{12} (**8**) is the first example of a natural corrinoid with a modified isopropanolamine linker: it is (the isolation form of) the cofactor of perchloroethene-dehalogenase in an obligate anaerobe.[20] The nucleotide bases (a 5,6-dimethylbenzimidazole in the cobalamins) of natural complete corrins from different bacterial sources also exhibit variability in their constitution (Figure 2).[13]

Most of the X-ray analytical studies on Co^{III}-corrins were concerned with the bonding of the axial ligands and their effect on (1) the lengths of the axial (Co–N)- and (Co–ligand)-bonds, as well as on (2) the extent of nonplanarity of the corrin ligand:[3] the latter structural feature has been called the 'upwards-folding of the corrin – ligand', which is represented by the angle between the planes through the inner atoms of the northern and of the southern ligand halves.[3,21] This 'upwards-folding of the corrin ligand' was proposed to be a biologically relevant, particular ability of the corrin ligand to respond to the steric demands of the axial ligands[22] (but see below). Data of incomplete Co^{III}-corrins[3] indeed point to lesser nonplanarity of the corrin ring in the absence of a coordinating bulky base. The 'folding of the corrin ligand' also is smaller (11.7°) in Coα-imidazolyl-Coβ-cyanocobamide than in vitamin B_{12} (17.7°), in support of the proposed mechanical effect of the steric bulk of the nucleotide base.[2,3,23]

2.1.2 *Co^{II}-corrins*

For the paramagnetic (low-spin) Co^{II}-corrins, all available evidence points to a predominantly pentacoordinated Co^{II}-center.[4] The X-ray structures of two paramagnetic Co^{II}-corrins confirmed this to be the case in the crystal[3,24,25] and two-dimensional EPR-spectroscopy, in frozen solution.[26] In the crystal, the structure of Co^{II}-cobalamin (B_{12r}, (**5**)) was found to differ little from that of the 'complete' corrin moiety of alkyl-Co^{III}-cobalamins, such as coenzyme B_{12} (**3**) and methylcobalamin (**4**)[3,27,28] (Figure 3). In particular, the 'folding' of the corrin ligand (16.3° in (**5**)), as well as the positioning of the nucleotide base with respect to the corrin ligand, were found to be surprisingly similar in the three structures (folding in (**3**): 13.3°; in (**4**): 15.8°).[27] A complex of Co^{II}-cobalamin with molecular oxygen, shown to form in preparations of corrinoid enzymes upon exposure to air, could also be formed reversibly in the crystal, where it was studied by X-ray analysis.[29]

2.1.3 *Co^{I}-corrins*

So far, for the highly oxygen-sensitive Co^{I}-forms of cobalt-corrinoids (such as Co^{I}-cobalamin, (**6**)), information from X-ray analysis on their three-dimensional structure is not available. However, in these strongly nucleophilic,[30] highly reduced[19] cobalt complexes, the diamagnetic Co^{I}-center (a d^8 metal ion, isoelectronic with a Ni^{II}-ion) presumably is ligated by the corrin ligand only, in a tetracoordinated, nearly square-planar fashion.[4,19,31] As a consequence, the Co^{I}-forms of complete corrins would have to be base-off, that is, the nucleotide function would not be attached to the central cobalt ion.

2.2 Spectroscopy

Qualitative information on the structure of the colored corrinoids in solution can be extracted rapidly from UV/Vis and CD spectra; most of the spectroscopic features can be rationalized nowadays by comparison with theoretically calculated spectra.[4,32] For more precise constitutional information, some of the newly developed methods of mass spectrometry allow the analysis even of the involatile B_{12}-derivatives.[33] Modern one-and two-dimensional proton, carbon, nitrogen, and phosphorus NMR spectroscopy has proven a powerful instrument for the delineation of the structure of diamagnetic cobalt-corrins in solution.[34–36] ESR-spectroscopy has given important information on paramagnetic corrinoid Co^{II}-complexes,[26,37] whether in frozen solutions or bound in corrinoid enzymes. X-ray adsorption fine spectroscopy (EXAFS) spectroscopy and vibrational (IR and Raman) spectroscopy are other spectroscopic techniques used more frequently now in the B_{12} field.[38,39]

2.3 Synthesis and Biosynthesis of Corrins

The preparation of corrins[8] and the total synthesis of vitamin B_{12} was achieved in the 1970s in the laboratories of Eschenmoser[8] and Woodward[9] as a climax in synthetic chemistry. Indeed, once made accessible by laboratory synthesis, the corrin ring structure proved to be accessible on various oxidation levels by an array of ring closure reactions conceived for their possible biosynthetic model

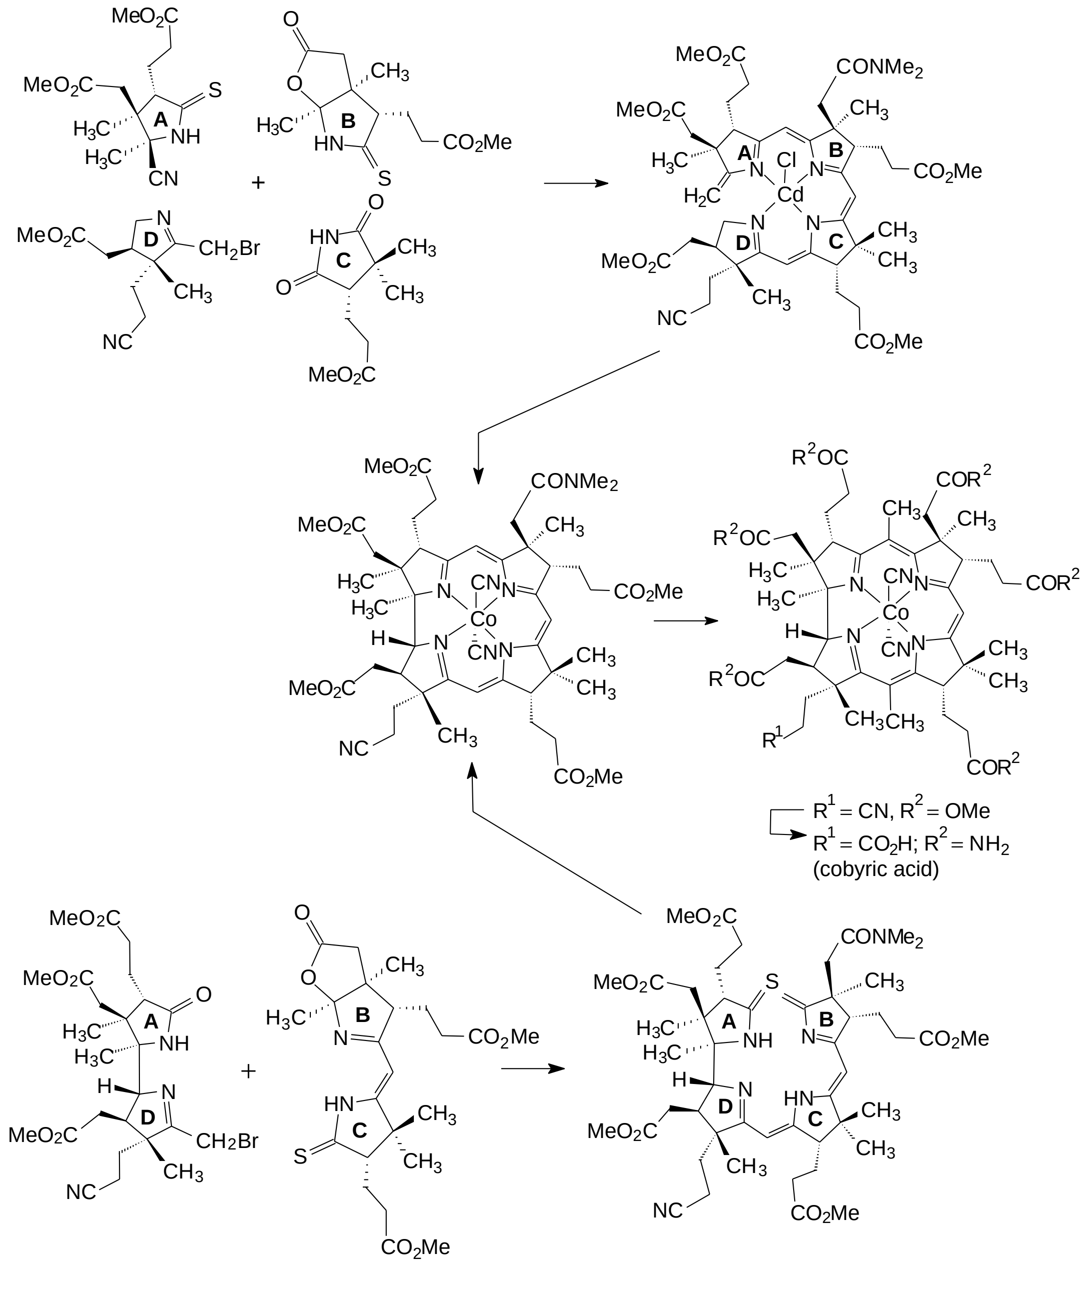

Figure 5 Outline of the total synthesis of cobyric acid (Figure 1) on the way to vitamin B_{12}: top: the ETH approach via an A/D ring closure of the corrin ring system; bottom: the Harvard/ETH approach via an A/B ring closure

character.[8,17] For the unique preparative conquest of the vitamin B_{12}-structure by abiotic synthesis,[8,9] the B_{12}-precursor cobyric acid (**2**) was first synthesized specifically (Figure 5) and then the attachment of the nucleotide chain was carried out by methods known from earlier work.[6,7] More recently, the regiospecific attachment of the nucleotide chain to an undifferentiated cobyrinate was also achieved in the laboratory of Eschenmoser, in support of his proposal of a ‘preenzymatic’ pathway to the B_{12}-structure.[17] For the insertion of cobalt into the corrin ligand, several methods are known, based on Co^{II} chemistry;[4] the removal of a cobalt ion from an intact natural corrinoid so far has not been successful.[40]

The natural corrinoids are made exclusively by microorganisms, which are also exploited on a large scale for the industrial production of vitamin B_{12}.[6,41] The biosynthesis of the corrin ligand branches off from that of the other porphinoids at their common tetrapyrrolic intermediate, uroporphyrinogen III, and has been studied both in aerobic and in anaerobic microorganisms[10,11] (Figure 6). The ‘corrin pathway’ separates with the sequential incorporation of (some of) the seven

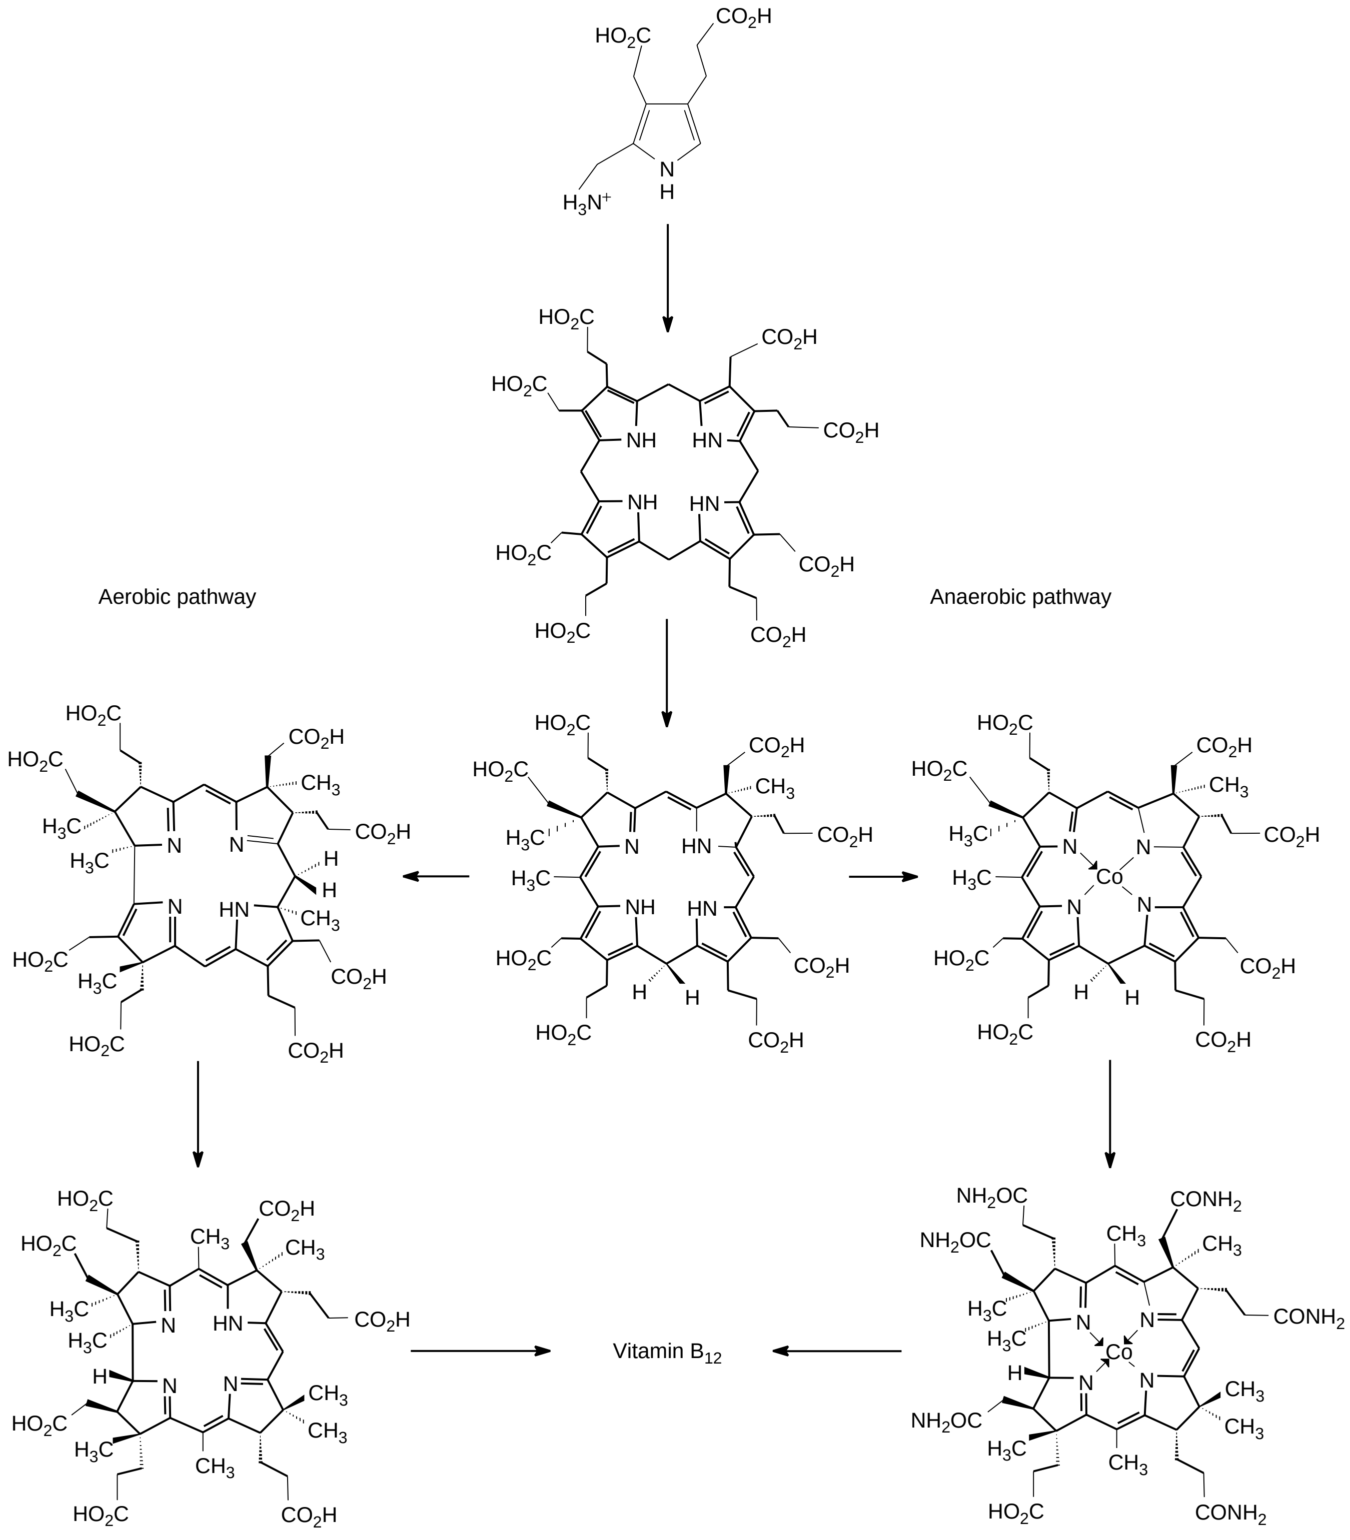

Figure 6 Outline and some central intermediates in the two main known pathways of the biosynthesis of vitamin B_{12}, the 'aerobic path' (left) and the 'anaerobic path' (right)

'extra' methyl groups into the reduced ligand. In the 'aerobic pathway,'[10,42] the metal-free hydrogenocobyrinic acid is produced first. The biological insertion of the cobalt ion thus occurs at a 'late' stage of a partially amidated form to lead to the 'incomplete' corrinoid cobyric acid, eventually. The nucleotide loop is finally built, starting with cobalt-adenosylated cobyric acid (5′-adenosylcobyrate).[6,43] In the 'anaerobic pathway', enzymatic insertion of the cobalt ion takes place much earlier, at the stage of the 'dimethylated' factor III. The bound cobalt ion is believed to assist the ring contraction and redox steps encountered in this biosynthetic path to cobyric acid.[11,44]

2.4 Organometallic B_{12} Derivatives

Most metabolic functions of the corrinoids are associated with their capacity for organometallic chemistry,[12–14] discovered together with the structure of coenzyme B_{12}.[2,3] The standard procedures for the synthesis of organometallic B_{12}-derivatives involve the alkylation of the corresponding highly nucleophilic Co^{I}-corrins with alkyl halides, alkyl tosylates, and so on.[19,45] In less well-investigated ways, organocorrinoids also can be prepared by the reaction of the radicaloid Co^{II}-corrins with radicals[46,47] or by alkylation with nucleophilic alkylating agents of the electrophilic Co^{III}-corrins.[48]

The 'super-nucleophilic' Co^{I}-corrins[19,30] can be prepared in situ by electrochemical or chemical reduction of B_{12};[4,19] the alkylation reaction is carried out in deoxygenated (aqueous or nonaqueous) solution. In general, the alkylation occurs with high diastereoselectivity on one side, at the 'upper' β-face.[6,49] Friedrich and coworkers noticed the formation of a second set of organocorrinoids, suggested to be the isomeric structures with the alkyl group bound at the 'lower' α-face. The organocorrinoids with a β-alkyl group are thermodynamically preferred in aqueous media.[6] The selective formation of organocorrins with an α-alkyl group thus has to be interpreted in terms of a kinetically controlled alkylation reaction.[4,48–50]

Two major mechanisms have to be taken into consideration for the alkylation of Co^{I}-corrins.[4,45,48–51] The 'classical' mechanism of a bimolecular nucleophilic substitution reaction at carbon (the Co^{I}-corrin acts as a nucleophile) leads to β-alkylated Co^{III}-corrins with high diastereoselectivity.[49] Secondly, an electron transfer-induced radical process (where the Co^{I}-corrin acts as a one-electron reducing agent) may also lead to cobalt alkylation. The observed formation of incomplete α-alkylated Co^{III}-corrins under kinetically controlled conditions has been proposed to occur via this path.[46,49] The high nucleophilic reactivity of Co^{I}-corrins and their diastereoselective nucleophilic reaction on the ('upper') β-face are not increased by the nucleotide function on the ('lower') α-face; rather they appear to be an inherent reactivity of the corrin-bound tetracoordinate Co^{I}-center.[46,52] Among the organometallic B_{12} derivatives prepared to date, neopentylcobalamin, benzylcobalamin, and dimethylmalonylcobalamin have particularly weak Co–C bonds and have served as models for thermally labile, homolytically cleaving organocobalamins.[53–55]

The major biosynthetic paths for the formation of adenosylcobamides (such as (**3**)) and of methylcobamides (such as (**4**)) proceed stereospecifically by alkylation (via nucleophilic attack) of enzyme-bound Co^{I}-cobamides with adenosine-5′-triphosphate (ATP) and with N^5-methyltetra-hydropterins or S-adenosylmethionine (SAM), respectively.[56,57]

Organocorrinoids are sensitive to visible light and can be photochemically dealkylated (typically via Co^{II}-corrins and alkyl radicals).[58,59] One-electron reduction of alkyl-Co^{III}-corrins produces short-lived alkyl-Co^{II}-corrins that rapidly cleave their organometallic bond with an alternative formation of Co^{I}-corrin and alkyl radical fragments or of Co^{II}-corrin and an alkyl anion.[19,51,60] However, electrochemical reduction of organo-Co^{III}-corrins in general occurs with a more negative half-wave potential than the reduction of Co^{II}-corrins (to Co^{I}-corrins); for this reason, the alkyl-Co^{III}-corrins can be prepared from and are in general stable in the presence of Co^{I}-corrins.[19,51]

2.4.1 *Coenzyme B_{12}*

The original crystal structure of coenzyme B_{12} was reexamined by X-ray (and neutron) diffraction analysis[3,27] and by NMR spectroscopy.[61] These latter spectroscopic investigations indicate that the organometallically bound deoxyadenosyl group of the coenzyme molecule is not conformationally fixed, but exists in (at least) two conformations around the Co–C bond. The lengths of the bonds to the two axially coordinated ligand atoms (Co–C $= 2.00$ Å; Co–N $= 2.24$ Å)[3,27] are longer than in the other organocobalamins studied by X-ray analysis.[2] The angle Co–Cα–Cβ ($= 124.4°$) is unusually large for a saturated carbon, possibly the indication of steric strain in this organometallic B_{12} derivative.[2]

The nucleotide base can be acidolytically decoordinated ($pK_a = 3.67$)[18] with relative ease. More slowly (and under more acidic conditions), the organometallically bound deoxyadenosyl group is cleaved by heterolytic decomposition.[62,63]

The strength of the Co–C bond of coenzyme B_{12} (**3**) has been estimated in the laboratories of Halpern[12] and of Finke[64,65] to be ca. 30 kcal mol^{-1} from a series of kinetic analyses of its thermal decomposition in aqueous and nonaqueous solutions. The original estimates for the homolytic (Co–C)-bond dissociation energy were 26 ± 2 kcal mol^{-1};[12] and 30 ± 2 kcal mol^{-1}.[64] Complications in these investigations were caused by (1) the presence of the base-off form of (**3**) and (2) cage effects had to be taken into account for the quantitative analysis of such bond-dissociation processes.[65,66]

In some cases, the base-on forms of organocobalamins decompose considerably faster than their (protonated) base-off forms or the corresponding (incomplete)

organocobinamides,[53–55] and this was considered to be valid in a more general sense.[64] However, the thermal decomposition of 5′-adenosyl-cobinamide at 110 °C in water at pH 7 ($k = 1.2 \times 10^{-5}\,s^{-1}$) is only 20 times slower than the decomposition of the coenzyme (**3**) ($k = 2.6 \times 10^{-4}\,s^{-1}$)[67] under the same conditions. Contribution of the nucleotide coordination to the activation of coenzyme B_{12} toward homolysis of the Co–C bond should, therefore, be correspondingly small. Indeed, on the basis of available thermodynamic data concerning the nucleotide coordination in the coenzyme (**3**) and in the homolysis product Co^{II}-cobalamin (**5**), the homolytic bond strength of the cobinamide was estimated earlier to be only ca. 0.7 kcal mol^{-1} higher than that of coenzyme B_{12}.[68]

2.4.2 *Methylcobalamin and Other Methyl-Co^{III}-corrins*

The structure of methylcobalamin (**4**) is available from X-ray analysis and NMR spectroscopy.[3,28,34,69] Both axial bonds (Co–C = 1.99 Å and Co–N = 2.19 Å) are shorter in methylcobalamin than in coenzyme B_{12}. The 'upwards-folding' is stronger than in coenzyme B_{12} (15.8° vs. 13.3°).[3] The homolytic (Co–C)-bond dissociation energy of methylcobalamin (**4**) has been estimated from the kinetics of its thermal decomposition at elevated temperature to be ca. 37 ± 3 kcal mol^{-1}.[60] Not unexpectedly, the Co–C bond of (**4**) is considerably more resistant to homolysis than that of coenzyme B_{12}.

The cobalt-bound methyl group of (**4**) is not readily removed by acid. Treatment of (**4**) with acid in aqueous solution leads to proteolytic decoordination of the nucleotide base ($pK_a = 2.9$).[18] The cobalt-bound methyl group of methyl-Co^{III}-corrins can be abstracted (1) by nucleophiles, such as thiol(ate)s,[54,70,71] (2) by radicaloid species, such as other Co^{II}-corrins,[68] or (3) by electrophilic species, such as Hg^{II}-ions.[72] A reversible and rapid methyl-group transfer occurs in deoxygenated aqueous solution between methyl-Co^{III}-corrins and Co^{I}-corrins.[15] From the pair, methyl-Co^{III}-cobinamide and Co^{I}-cobalamin (**6**), methylcobalamin (**4**) and Co^{I}-cobinamide are generated and prevail at equilibrium. Accordingly, the nucleotide coordination in (**4**) stabilizes it against abstraction of the cobalt-bound methyl group by nucleophiles (by ca. 4 kcal mol^{-1}; ca. 17 kJ mol^{-1}),[15,68] whereas it activates (**4**) for the abstraction of the cobalt-bound methyl group by electrophiles.[73] In addition, as a result of methyl-group transfer equilibria between (**4**) and incomplete Co^{II}-corrins, the nucleotide coordination was found to hardly influence (thermodynamically) the homolytic bond strength of the Co–C bond in (**4**).[15,45,68] The reversible methyl-group transfer reaction between methylcobalamin (**4**) and Co^{II}-cobinamide, to give Co^{II}-cobalamin and Coβ-methyl cobinamide respectively, and the reverse reaction were studied at temperatures between 5 and 60 °C in deoxygenated aqueous solutions, and the equilibrium was characterized ($K(20\,°C) = 0.56$, $\Delta H_0 = 2.5 \pm 0.5$ kcal mol^{-1}, and $\Delta S_0 = 7.1 \pm 0.1$ kcal mol^{-1}; Figure 7).[68]

In view of the coordination pattern in protein-bound methylcobalamin (see below), the thermodynamic studies on the effect of the coordination of the dimethylbenzimidazole base to the α-side of the cobalt center on the homolytic and heterolytic (Coβ-C)-bond dissociation energy in (**4**) (thermodynamic effect of the trans ligand or 'trans influence') were extended to corresponding investigations with Coβ-methyl-imidazolylcobamides, such as (**9**), where imidazole replaces the dimethylbenzimidazole: these studies showed this change of the nature of the axial base to have little effect on the two relevant bond-dissociation energies of the corresponding methylcobamide.[74]

2.5 B_{12} Coenzymes as Enzyme-bound Cofactors

2.5.1 *Coenzyme B_{12} and Adenosylcobamides as Cofactors*

The biologically relevant reactivity of coenzyme B_{12} is associated with the homolysis of its Co–C bond, as well as with the recombination of the products of homolysis (Figure 8).[12,15] The remarkable structural similarity between the corrinoid homolysis fragment Co^{II}-cobalamin and the Co^{III}-corrin part of coenzyme B_{12} contributes to lowering

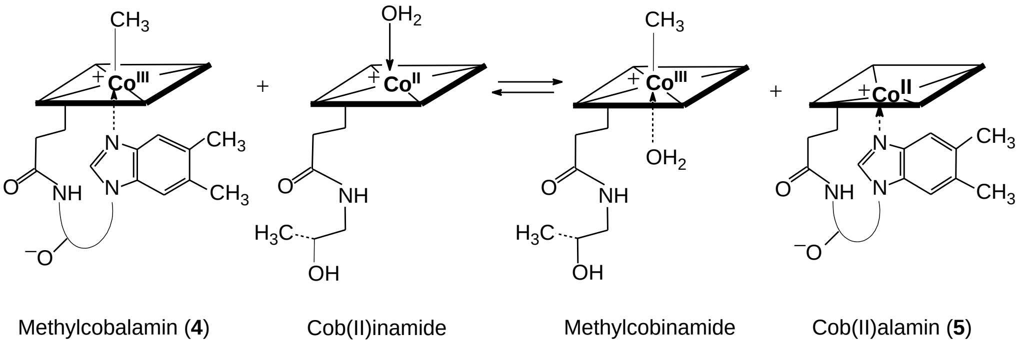

Figure 7 Schematic representation of the methyl-group equilibrium between methylcobalamin (**4**), Co^{II}-cobinamide, Co^{II}-cobalamin (**5**), and Coβ-methylcobinamide

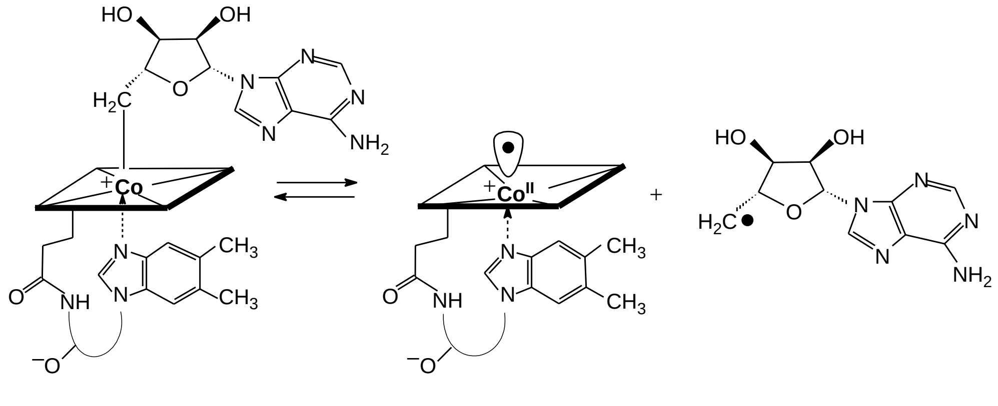

Figure 8 Illustration depicting the reversible homolysis of the Co–C bond, the biologically relevant reactivity of coenzyme B_{12} (**3**)

the activation barrier in both directions (and recombination occurs at (nearly) diffusion-controlled rates in homogeneous solution[58,59]).[25]

The role of coenzyme B_{12} as cofactor of enzymatic rearrangement reactions requires the (reversible) formation of the 5′-adenosyl radical by homolysis of the organometallic bond of (**3**) (estimated bond-dissociation energy ca. 30 kcal mol^{-1};[12,72]) to be accelerated there by a factor of $10^{12\pm1}$.[65,75]

In spite of the available crystallographic information on a series of coenzyme B_{12}-dependent enzymes (see below),[13,14] the 'activation' of the protein-bound coenzyme B_{12} toward (Co–C)-bond homolysis is still an unsolved matter.[76,77] The replacement of the dimethylbenzimidazole base by an imidazole, as observed in some (but not all) coenzyme B_{12}-dependent enzymes,[13,14] appears not to be a major factor contributing to the rate enhancement of the (Co–C)-bond homolysis. The presently available structural data on coenzyme B_{12}-dependent enzymes support the general validity of the 'mechanochemical model' (see below).[12–14] However, instead of an 'upwards conformational distortion' of the corrin ring,[12,22,78] or of a movement of the benzimidazole base toward the corrin ring,[79] 'strong binding of the separated Co^{II}-corrin and adenosyl fragments to the protein'[25] may enhance protein and substrate induced separation of the homolysis fragments and labilize the organometallic bond of the bound coenzyme B_{12}.[15] X-ray analysis of Co^{II}-cobalamin (**5**) was instrumental in contributing to this problem, as it indicated a little structural difference between this Co^{II}-corrin and the Co^{III}-cobamide-moiety of coenzyme B_{12}.[25]

2.5.2 *Methylcobalamin and Methylcobamides*

The cofactor role of the methylcorrinoids is based on enzymatic methyl-group transfer reactions. Formation of a methylcorrin by the methylation of an enzyme-bound Co^{I}-corrin and its subsequent demethylation by thiol(ate)s or other nucleophiles appear to be the two crucial steps of the known catalytic cycles. Heterolytic formation and cleavage of the Co^{III}-methyl bond in nucleophilic substitution reactions can be considered to be the main biologically relevant reactivity of the methylcorrinoids, such as methylcobalamin (**4**).[13,14,57] In such heterolytic reactions, the arrangement of the nucleotide loop with respect to the metal center could be inferred to change considerably the reactivity in methyl-group transfer reactions (as coordination would be intact in the methyl-Co^{III}-corrin,[46] but absent in the Co^{I}-corrins;[22,56] Figure 9): A weakening of the nucleotide coordination by interaction with a protein thus destabilizes the more oxidized state of the methyl-Co^{III}-corrinoid (with respect to that of the Co^{I}-corrin) and, in turn, activates the demethylation of the methyl-Co^{III}-corrin by a nucleophile.[80]

Similar to the situation with coenzyme B_{12}-dependent enzymes, recent pioneering crystallographic studies on methionine synthase have considerably clarified the structural aspects of enzymatic methyl-group transfer, involving protein-bound 'complete' methylcorrinoids.[57] There the coordinating

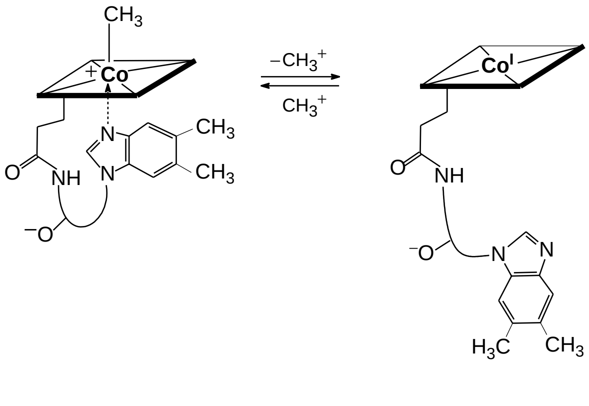

Figure 9 Symbolic illustration depicting the major structural changes occurring in heterolytic Co-demethylation and Co-methylation reactions of the cobalamins (**4**) and (**6**)

nucleotide was first recognized to be replaced by a histidine (to give a 'center' form of the bound (**4**)).[81,82] While the axial base coordination clearly helps to 'tune' the strength of the Co–C bond in heterolytic reactions of protein-bound methylcorrinoids,[13,57,68] the better dynamic binding of the center form of (**4**) in methionine synthase appears to be another important and necessary contributor to this enzyme's catalytic capacity, by allowing it access to the required modular structural changes.[68,83]

2.5.3 Co^{II}-cobalamin and Co^{II}-cobamides

The pertinent structural data indicate the arrangement of the nucleotide loop to change little with respect to the metal center in homolytic (Co–C)-bond dissociation reactions, but to vary considerably in one-electron redox reactions involving Co^{II}- and Co^{I}-corrins.[19] In a protein, weakening of the nucleotide coordination thus destabilizes the more oxidized state of the Co^{II}-corrinoid with respect to that of the Co^{I}-corrin and, in turn, activates its reduction to a Co^{I}-corrin by a one-electron reducing agent. In several cobalamin-dependent methyltransferases (see below), the nucleotide coordination is noticeably weakened (or inhibited) by the interactions of the bound corrin with the apoenzyme, and 'tuning' of the reactivity of the protein-bound corrinoid cofactors by control of the intramolecular nucleotide coordination was shown to be relevant.[57,84]

In dehalogenating enzymes of anaerobic microorganisms, corrinoid cofactors have a newly discovered further role in the redox catalysis of the energy conserving dehalogenation of chloro(hydro)carbon compounds ('dehalorespiration'), and the specific redox properties of the protein-bound unusual corrinoids are of particular current interest.[20,85]

3 B_{12} ENZYMES

Aside from the B_{12}-binding and transporting proteins, three major classes of corrinoid enzymes are known: methyltransferases, coenzyme B_{12} utilizing enzymes, and corrinoid dehalogenases. The coenzyme B_{12} utilizing enzymes can be classified further as carbon skeleton mutases, dehydratases, deaminases, and ribonucleotide reductase. Members of all classes of the B_{12}-enzymes are important in microorganisms. In human and animal metabolism B_{12}-binding proteins, the methyl transferase methionine synthase and methylmalonyl-CoA-mutase (MMCM) play essential roles.[13,14,45]

3.1 B_{12}-binding Proteins

B_{12}-binding (and B_{12}-transporting) proteins are important in human, animal, and bacterial metabolism, where they function as extracellular, membrane-bound, and intracellular proteins.[6,86,87] Lack of the B_{12}-binding (extracellular) protein 'intrinsic factor' and, as a consequence, a disorder in the uptake of vitamin B_{12}-derivatives from the nutrition, is recognized to be the most widely distributed cause for 'pernicious anemia'.[88,89]

The human B_{12}-binder intrinsic factor is a glycoprotein of ca. 44 kDa, with a high binding constant (in 1:1 complexes) for vitamin B_{12} (**1**) and other cobalamins. The intrinsic factor is secreted by cells of the gastric mucosa and specifically binds cobalamins and carries them to the ileum. There the ileum receptor protein accepts the corrinoid from the intrinsic factor complex and transports it further across the intestinal epithelial absorptive cell.[86,88] The cobalamins then appear to be bound to transcobalamin II and transported in the blood in this way to membrane-bound transcobalamin/corrin receptor proteins of the specific cells.[6,86,87]

3.2 Methyltransferases

The catalysis of the transfer of a methyl group is an important role of enzyme-bound vitamin B_{12} derivatives in human, animal, and bacterial metabolism.[13,14] The known enzyme-controlled methyl group-transfer reactions are key steps in the cobamide-dependent methylations of homocysteine to methionine, in the metabolic formation of methane from other C_1-compounds in methanogenic bacteria, and in the fixation of carbon dioxide via the acetyl coenzyme A pathway of some bacterial autotrophs (Figure 10).[13,14]

The catalytically active, protein-bound corrinoids involved in such enzymatic methyl-group transfer steps are Co^{I}-corrins (such as Co^{I}-cobalamin, (**6**)) and methyl-Co^{III}-corrins (such as methylcobalamin, (**4**)), which are now indicated to be 'base-off' in these enzymes, that is, with the nucleotide base uncoordinated.[57,84]

3.2.1 Methionine Synthase

The cobalamin-dependent formation of methionine by methylation of homocysteine is an important enzymatic process in human, animal, and bacterial metabolisms.[13,14,57] The catalysis of the methyl-group transfer and the role of enzyme-bound cobalt-corrinoids in cobalamin-dependent methionine synthase have been well studied for the enzyme from *Escherichia coli*.[57] (Figure 11). This cobalamin-dependent methionine synthase consists of a single polypeptide chain (about 123 kDa) and binds methylcobalamin in a center form.[81,82] Catalysis of the methyl transport occurs with a maximum turnover of ca. $20\,s^{-1}$, by an 'ordered sequential mechanism' involving two steps mainly: (1) From bound methylcobalamin, the cobalt-bound methyl group is abstracted by the thiol of homocysteine, with formation of methionine and of an enzyme-bound Co^{I}-cobalamin. (2) This highly nucleophilic enzyme-bound Co^{I}-corrin then abstracts the methyl group of (mono- or polyglutamate forms of)

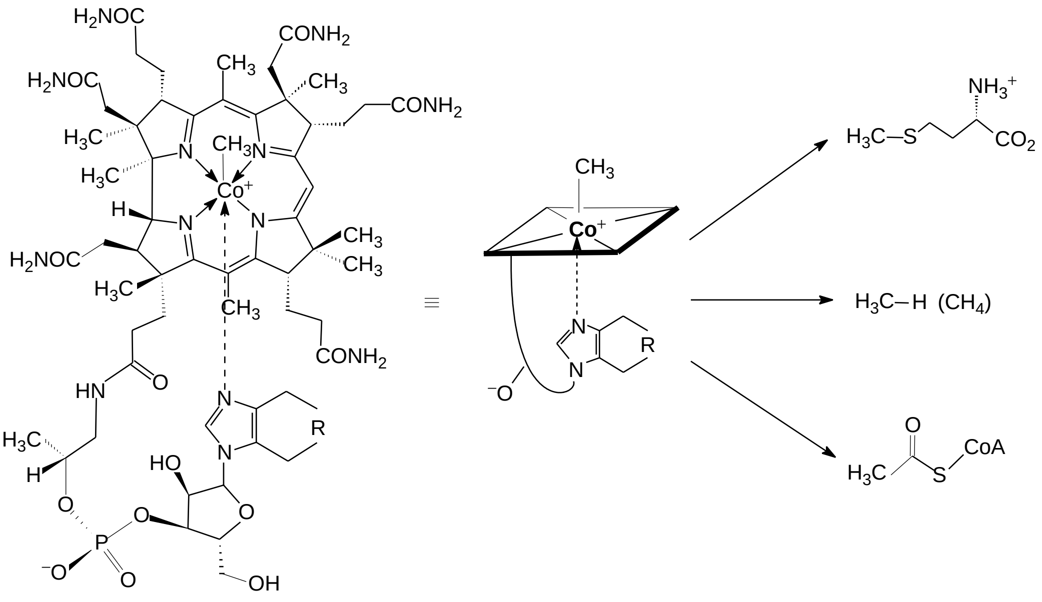

Figure 10 Methylcorrinoids as the source of a methyl group in the biosynthesis of methionine from homocysteine (top), of methane (middle), and of the acetyl group of acetyl coenzyme A (bottom)

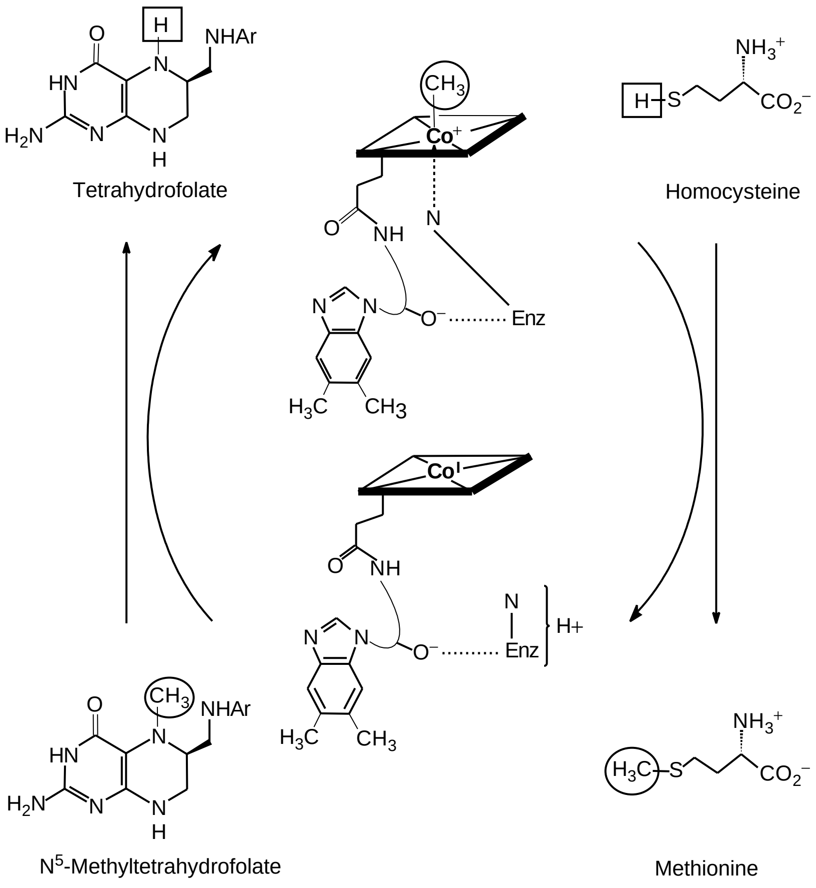

Figure 11 Schematic illustration of the cobalamin-dependent enzymatic biosynthesis of methionine via methyl-group transfer from N^5-methyltetrahydrofolate to homocysteine

N^5-protonated N^5-methyltetrahydrofolate to reconstitute the bound methyl-Co^{III}-corrinoid. The transfer of the methyl group takes place with overall retention of configuration (indicating two nucleophilic substitutions, each with stereochemical inversion), formally involving the transfer of a methyl cation.[57]

The half-wave potential for the enzyme-bound Co^{II}/Co^{I}-cobalamin couple of the methionine synthase from *E. coli* at 526 mV versus SHE is about 80 mV lower than that of the Co^{II}/Co^{I}-cobalamin couple in neutral aqueous solution.[19] Access to the catalytic cycle of the enzyme by one-electron reduction of Co^{II}-cobalamin (and reactivation upon occasional adventitious formation of Co^{II}-cobalamin) is indicated to be accomplished by a unique mechanism. The (thermodynamically unfavorable) reduction with intermediate formation of the enzyme-bound Co^{I}-cobalamin is driven by a rapid methylation of the highly reduced Co^{I}-center of the reduced corrin with *S*-adenosylmethionine.[57] The modular nature of methionine synthase allows for the control of the methyl-group transfer processes by modulating and alternating conformational equilibria.[57,90,91]

3.2.2 *Corrinoid Enzymes in Bacterial Acetate Metabolism*

In bacterial metabolism, corrinoids related to methylcobalamin hold an essential position also as functional intermediates in autotrophic fixation of carbon dioxide via acetyl coenzyme A.[84,90] In Wood's group, the acetogen *Clostridium thermoaceticum* was analyzed particularly thoroughly for this new way of carbon dioxide fixation,[90,92] but the latter was found to operate also in a variety of other acetogenic, as well as in methanogenic, sulfur-metabolizing, and sulfate-reducing bacteria.[93] In the course of the assembly of acetyl coenzyme A from carbon dioxide in the carbon monoxide dehydrogenase/acetyl coenzyme A synthase complex, the cobalt-bound methyl group of a methylcorrinoid and carbon monoxide (from the reduction of carbon dioxide) combine to give the acetyl group of acetyl coenzyme A.[90] The function of the enzyme-bound corrinoid concerns the catalysis of a methyl-group transfer via two nucleophilic substitution steps from an N^5-methyltetrahydropterin to the as yet unidentified nucleophilic acceptor on the acetyl coenzyme A synthase subunit. The acetyl group is then assembled from the two C_1 fragments and without direct cooperation of a corrinoid (carbonylation of an enzyme-bound methyl-Co^{III}-corrinoid[94] has been shown to be highly unlikely).[90] The available crystal structures of the carbon monoxide dehydrogenase/acetyl coenzyme A synthase complex[95,96] indicate either a nickel[96] or a copper-center[95] at the active site cluster.

In acetate-catabolizing methanogens, enzyme-bound methylcorrinoids are also indicated to serve as intermediates in methyl-group transport. There, methane and carbon dioxide are formed from acetic acid (via acetyl coenzyme A, whose acetyl group is split into carbon monoxide and a corrin-bound methyl group). Accordingly, the methyl-group transport in this path of acetate degradation would have to work in the reverse sense, compared to the situation in the bacterial assembly of acetyl coenzyme A.[97,98]

3.2.3 *Corrinoid Enzymes in Bacterial Methanogenesis*

In other forms of bacterial methanogenesis, methyl-Co^{III}-corrinoids also perform an essential function as cofactors in enzymatic methyl-group transfer. Previously, enzyme-bound methyl-Co^{III}-corrinoids were suspected to directly provide access to methane (via protonation of their cobalt-bound methyl group).[99] Nowadays, the methyl-Co^{III}-corrinoids are recognized to act more indirectly in methanogenesis, as intermediates in methyl-group transport. The role of the terminal methyl-carrier in the formation of methane in methanogens is assigned to the porphinoid nickel complex coenzyme F430,[100] structurally characterized in Eschenmoser's group.[101] Enzyme-bound corrinoids are found, for example, to serve as methyl-group carriers between an N^5-methyltetrahydropterin and the thiol coenzyme M (i.e. in a function related to their role in the methylation of homocysteine to methionine; see Figure 11).[102]

3.3 Coenzyme B_{12} Utilizing Enzymes

About 10 coenzyme B_{12}-dependent enzymes are now known (reviewed in References 13,14, and 76 see Table 1): four carbon skeleton mutases (methylmalonyl-CoA mutase (MMCM),[103] glutamate mutase (GM),[104,105] methylene glutarate mutase (MGM),[104] isobutyryl-CoA mutase (ICM)[106]), diol dehydratase (DD),[107] glycerol dehydratase,[107] ethanolamine ammonia lyase (EAL),[108] two amino mutases,[109] and B_{12}-dependent ribonucleotide reductase.[110] The coenzyme B_{12}-dependent enzymes are unevenly distributed in the living world, and MMCM is the only enzyme that is also indispensable in human metabolism.[103]

The known coenzyme B_{12}-dependent enzymes all perform chemical transformations in enzymatic radical reactions that are difficult to achieve by typical 'organic' reactions. Homolytic cleavage of the Co–C bond of the protein-bound coenzyme B_{12} (**3**) to a 5′-deoxy-5′-adenosyl radical (**9**) and cob(II)alamin (**5**) is the entry to reversible H-abstraction reactions involving the 5′-position of the radical (**9**). Indeed, homolysis of the Co–C bond is the thermally most easily achieved transformation of coenzyme B_{12} (**3**) in neutral aqueous solution (with a homolytic (Co–C)-BDE of about 30 kcal mol^{-1};[12,65]). However, to be relevant for the observed rates of catalysis by the coenzyme B_{12}-dependent enzymes, the homolysis of the Co–C bond of the protein-bound coenzyme (**3**) needs to be accelerated by a factor of about 10^{12}, in the presence of a substrate.[12,65] Coenzyme B_{12} might then be considered, first of all, to be a structurally sophisticated, reversible source for an alkyl radical, whose Co–C bond is labilized in the protein-bound state[12] (Figure 8), and the first major task of the

Table 1 Coenzyme B_{12} catalyzed enzymatic reactions involving natural substrates

(*R*)-methylmalonyl-CoA/succinyl-CoA[103,111]	(*S*)-glutamic acid/(2*S*,3*S*)-methylaspartic acid[104,105]	2-methyleneglutarate/(*R*)-3-methylitaconate[104]	isobutyryl-CoA/*n*-butyryl-CoA[106]	D-ornithine/(2*R*,4*S*)-2,4-diaminovaleric acid[109]	D-(*α*)-lysine/2,5-diaminohexanoic acid[109]	L-(*β*)-lysine/(3*S*,5*S*)-3,5-diaminohexanoic acid[109]	1,2-propanediol/propanal (R = CH_3)[107] glycerol/3-hydroxypropanal (R = CH_2OH)[107]	ethanolamine/acetaldehyde[108]	ribonucleotide/2′-deoxyribonucleotide[110,112]	 B = nucleotide base, X = diphosphate or triphosphate group

enzyme concerns the 'activation' of coenzyme B_{12} (**3**) and the reversible generation of the 5′-deoxy-5′-adenosyl radical (**9**).

The coenzyme B_{12}-dependent enzymes all rely upon the reactivity of bound organic radicals that are formed (directly or indirectly) by a H-atom abstraction by the 5′-deoxy-5′-adenosyl radical (**9**). In these enzymatic reactions, the radical (**9**) is the established reactive partner in the proper enzymatic radical reaction, so that AdoCbl (**3**) should be looked at as a 'precatalyst' (or catalyst precursor[15]). Tight control of the reactivity and correct mutual orientation of (**9**) and of the substrate for H-atom transfer must be advantageous,[113] but means of (further) activation of the catalyst (**9**) by the protein environment can hardly be recognized. A similar situation presumably also prevails in other enzymatic radical reactions involving protein-bound (**9**) not derived from AdoCbl (**3**)[109] or peptidic radicals.[110] Organometallic B_{12} species, in which (the putative) organic radicals are bound to the corrin-bound cobalt center via a Co–C_β bond, are now considered unlikely as (kinetically competent) intermediates in the rearrangements catalyzed by B_{12}-dependent enzymes.

3.3.1 Carbon Skeleton Mutases

In the four known carbon skeleton rearrangement reactions catalyzed by coenzyme B_{12}-dependent mutases, two vicinal groups (a hydrogen atom and an organic substituent) exchange their positions in a (pseudo)intramolecular fashion.[76] The B_{12} cofactor is bound in a 'base-off/His-on' constitution and at an interface between two modules, called the B_{12}-binding and the substrate activating domains (or subunits). Indeed, the B_{12}-binding domains in MMCM and MGM (and even of MetH) and the B_{12}-binding subunits in GM and ICM exhibit considerable mutual sequence homology. This homology does not extend to the other coenzyme B_{12}-dependent enzymes or to the substrate-binding domains of the carbon skeleton mutases.[114]

Methylmalonyl-CoA-mutase. MMCM interconverts *R*-methylmalonyl-CoA and succinyl-CoA in a carbon skeleton rearrangement reaction (Figure 12).[103] Binding of the substrate labilizes the Co–C bond toward homolysis (because of a decrease of the enthalpy of activation by about 16 kcal mol^{-1}) and triggers the homolysis of the Co–C bond of the bound adenosyl-corrinoid.[115] The radical (**9**) then abstracts an H atom from the methyl group of the enzyme-bound methylmalonyl-CoA. H-atom abstraction is accompanied by a large deuterium isotope effect of the (substrate) H atoms, and has been suggested to occur by tunneling and to be coupled kinetically to the homolysis step.[116] H-atom abstraction gives the 2′-methylmalon-2′-yl-CoA radical that rearranges rapidly to the succin-3-yl-CoA radical.[103] The rearrangement has been suggested to occur intramolecularly and involve the stage (formally) of a substituted cyclopropyloxyl radical, as no evidence for a fragmentation mechanism in model experiments has been seen. The radical rearrangement is also suggested to occur without noticeable participation of the bound cob(II)alamin, that is, the corrinoid is merely a 'spectator'.[117] The radical rearrangement step appears to be critically controlled by the interactions with the apoenzyme[118] and is assisted by an H-bond to His244 in the substrate activating domain of the enzyme. Mutation of His244 of MMCM reduced the rate of the rearrangement reaction by about 10^3-fold.[118] The succin-3-yl-CoA radical (resulting from the rearrangement) is suggested to reabstract an H atom from 5′-deoxyadenosine to give succinyl-CoA, and the 5′-deoxyadenosyl radical (**9**), that recombines with cob(II)alamin to give the enzyme-bound coenzyme B_{12} (**3**).

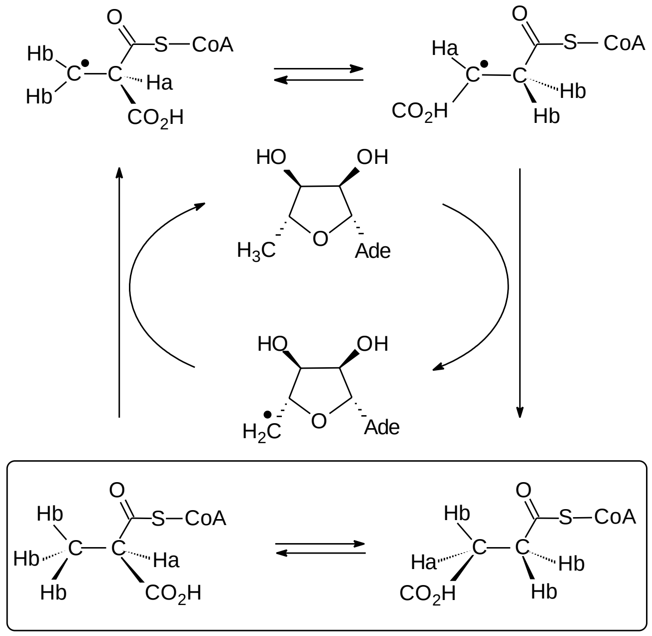

Figure 12 Illustration showing a possible mechanism of the coenzyme B_{12}-catalyzed rearrangement of (*R*)-methylmalonyl-CoA to succinyl-CoA[103]

X-ray analysis of MMCM provided the first crystal structure of a coenzyme B_{12}-dependent enzyme.[82,111,119] This study concerned the 150 kDa heterodimeric MMCM from *Propioni bacterium shermanii* and showed the B_{12} cofactor to be bound 'base-off/His-on'. The α-side of the corrin-bound cobalt center was coordinated to the histidine of a His-Asp-Lys triad as the 'regulatory' unit. The nucleotide tail of the bound corrinoid was tightly inserted into the protein, similar to the situation in MetH. The crystal structure revealed a rather 'flat' corrin ligand with a 'ligand-folding' comparable to that in the imidazolylcobamides,[23,74] without significant 'upwards conformational distortion' of the corrin. The pseudosubstrate used, dethiacoenzyme A, is bound tightly in a funnel provided by the 'substrate-binding' domain of the α-chain. A significant direct interaction between the rearranging substrate's reactive centers and the corrinoid cofactor is made unlikely by the crystal structure.[82,111,119]

MMCM was also investigated in a substrate-free form, which revealed considerable opening of the substrate-binding TIM barrel, indicating an intriguing conformational reorganization by the substrate binding.[119] In this crystal, coenzyme B_{12} (**2**) was found to be bound 'base-off/His-on' again, and to be largely intact, with the adenosine still bound to cobalt, but rotated away from its position in the crystal structure of (**3**) (above ring C of the corrin ligand) and toward a position above ring B. In a further crystal analysis of MMCM, this time with pseudosubstrates bound, the adenosyl group of the bound coenzyme AdoCbl (**3**) was again found to be repositioned (presumably with the help of the bound substrate), indicating the organometallic group to be particularly strained or to be detached from the cobalt center.[111,120] The data suggest substrate binding to assist the labilization of the Co–C bond by squeezing the adenosyl group off the cobalt-corrin.[82,120]

Glutamate mutase. GM from *Clostridium tetanomorphum* was the first enzyme discovered (around 1960) to be dependent upon a B_{12}-coenzyme. GM catalyzes the

reversible rearrangement between (S)-glutamate and (2S,3S)-3-methylaspartate (where equilibrium favors glutamate by about 10).[104,105,114,121] GM has also been studied extensively in *Clostridium cochlearium*, but other microorganisms are suspected to have enzymes with GM activity as well.[104]

The functional GM proteins from *Cl. tetanomorphum* and from *Cl. cochlearium* are homologous heterotetramers ($\varepsilon_2\sigma_2$, about 140 kDa) consisting of a pair of smaller B_{12}-binding subunits (σ) and larger substrate-binding subunits (ε), and they contain two molecules of adenosyl-cobamide.[114,121] The cofactors from the two clostridia were identified as pseudocoenzyme B_{12} (Co_β-adenosyl-adeninyl-cobamide) and adenosyl-factor A (Co_β-adenosyl-2′-methyladeninyl-cobamide),[122] but coenzyme B_{12} (**3**) also is a cofactor.[104] Binding of the substrate triggers homolysis of the Co–C bond of the adenosyl-cobamide cofactor. Similar to the situation with MMCM, H-atom abstraction and homolysis of bound AdoCbl, which give the radical (**9**), are kinetically coupled processes, and a presteady state D-isotope effect of about 30 is observed.[123] The rearrangement reaction catalyzed by GM (in the 'reverse' direction) is initiated by the abstraction of an H atom from the bound substrate, that is, from the methyl group of enzyme-bound methyl aspartate, followed by a rearrangement of the 3-methylaspart-3′-yl radical to the glutam-4-yl radical.[104,114] The radical rearrangement of GM is suggested to take place via a fragmentation/recombination mechanism that involves acrylate as a fragment.[121] The glutam-4-yl radical is then suggested to reabstract an H atom from 5′-deoxyadenosine to give the rearrangement product, (S)-glutamate, and the 5′-deoxyadenosyl radical that recombines with cob(II)alamin (**5**) to give enzyme-bound (**3**). The radicals are indicated to be bound to the protein via several H bonds. The rearrangement step appears to be critically controlled by the interactions with the apoenzyme and seems to occur without noticeable participation of the bound cob(II)alamin, that is, the corrinoid is merely a 'spectator'.[116]

Crystallographic studies with GM from *Cl. cochlearium* have provided a detailed structural picture of the enzyme, in which the corrinoid cofactor is bound 'base-off/His-on' again and at the interface between the subunits σ and ε.[105] The cobalt-coordinating histidine is part of an H-bonded 'regulatory' His-Asp-Ser triad. Detailed analysis of GM with the bound coenzyme B_{12} (**3**) revealed the position of the ribose part of the 5′-deoxyadenosyl moiety to be disordered and to be present in two conformations, related to each other by a pseudo-rotation of the furanose ring. One of these structures places the 5′-methylene group of the adenosine close to the position of the corrin-bound cobalt center, but at a distance of about 3.1 Å, and thus appears to have features expected for the direct product of the homolysis of the Co–C bond of the bound cofactor (**3**). In the other conformation, the 5′-methylene carbon is at a distance of about 4.5 Å from the metal center and is displaced toward the substrate-binding site, as if in van der Waals contact with the bound substrate. In this way, GM achieves a controlled and energetically facile transposition of the 5′-radical center from cobalt to the substrate.[105]

The solution structures of the (roughly 15 kDa) B_{12}-binding σ-subunits of GM from *Cl. tetanomorphum*[124] and of *Cl. cochlearium* were analyzed by heteronuclear NMR spectroscopy.[125] These studies provided the first structure of a cofactor-free B_{12}-binding protein and indicated the latter to be largely preorganized for B_{12}-binding and to be structured similarly in solution as in the crystal of the holo-enzyme. However, the apo-protein was seen to contain a flexible loop and a 'nascent' helix, both suggested to become structured only upon binding of the corrinoid.[126] A model for the events in binding of the 'base-off/His-on' form of the B_{12}-cofactor by the σ-subunit could be derived. According to this model, the nucleotide tail of the 'base-off' form of the adenosyl-corrinoid is trapped first and the attached nucleotide moiety stabilizes the protein. Indeed, the natural cobamide cofactors of the two clostridia are adeninyl-cobamides, such as pseudocoenzyme B_{12} (Co_β-adenosyl-adeninyl-cobamide), for which the 'base-off' form predominates in aqueous solution.[127] By contrast, in aqueous solution AdoCbl (**3**) prefers to be in the 'base-on' form (with only about 1% of the 'base-off'-form).[4,18]

Other B_{12}-dependent carbon skeleton mutases. Besides MMCM and GM, two other B_{12}-dependent carbon skeleton mutases are known. These are (1) methylene glutarate mutase (MGM), which catalyzes the reversible interconversion of 2-methylene-glutarate and R-3-methylitaconate as part of a degradative path of nicotinic acid in *Clostridium barkeri*[104,121] and (2) ICM, which catalyzes the reversible rearrangement of isobutyryl-CoA and n-butyryl-CoA, an isomerization that is relevant in the course of the biosynthesis of polyketide antibiotics.[106] This coenzyme B_{12}-dependent isomerase is observed in species of the gram-positive bacteria *Streptomyces*[106] and appears to be distributed over a wide range of microorganisms.

3.3.2 *Diol Dehydratases, Glycerol Dehydratase, and Ethanolamine Ammonia Lyase*

Diol dehydratases and glycerol dehydratase. DD and glycerol dehydratase are isofunctional enzymes that catalyze the dehydration of propane-1,2-diol, ethane-1,2-diol, and glycerol to propanal, acetaldehyde, and 3-hydroxypropanal respectively (other glycols can be dehydrated in an analogous fashion).[77,107] DD uses adenosylcobamides (such as AdoCbl, (**3**)) as cofactors and catalyzes the dehydration of 1,2-diols via a (pseudo)intramolecular H-transfer involving the 5′-position of the organometallic cofactor (for reviews see[107,128]). In contrast to the B_{12}-dependent carbon skeleton mutases, the cofactor in these dehydratases is bound in a (conventional) 'base-on' form and the protein sequence of DD lacks the diagnostic 'B_{12}-binding' (Gly-X-X-His-X-Asp)-sequence motif.[128] B_{12}-binding in a 'base-on' form was made likely by ESR-investigations of DD[129] and was finally confirmed

by X-ray analysis.[107,130] In addition, in the active site of DD of *Klebsiella oxytoca* a potassium ion is bound (together with the substrate propane-1,2-diol) to which a role as a Lewis acid in the radical rearrangement reaction has been ascribed.[130] The AdoCbl-catalyzed reaction again is based on a substrate-assisted homolysis of the Co–C bond of the corrinoid cofactor and formation of the 5′-deoxy-5′-adenosyl radical (**9**) and cob(II)alamin (**5**), as indicated by rapid kinetic studies by ESR- and UV/Vis-spectroscopic means.[128] In DD, the radical (**9**) then abstracts a H atom from the C-1 position of propane-1,2-diol, followed by 1,2-migration of the hydroxy group vicinal to the radical site (Figure 13). The migration of the hydroxyl group is suggested to be assisted by the potassium ion and by H-bonding with protic residues of the protein.[128] The (formal) product of the isomerization is a 1,1-diol (or the hydrate of the aldehyde propanal). The propanal isolated from ^{18}O-labeled (*S*)-propane-1,2-diol still is ^{18}O-labeled, while unlabeled propanal is obtained from ^{18}O-labeled (*R*)-propane-1,2-diol.[131]

The crystal structure of DD (from *Kl. oxytoca*) was solved as the complex with vitamin B_{12} (**1**) and (*S*)-propane-1,2-diol.[107,130] It showed the corrinoid to be bound at an interdomain-interface (of the B_{12}-binding β-subunit and of the substrate-binding α-subunit) and confirmed the 'base-on' nature of the bound corrinoid. The crystal structure showed the corrin-bound cobalt ion to be (largely) pentacoordinated, with an axial Co–N_{α} bond with 2.5 Å length, and the diol substrate to be ligating the potassium ion, which is situated at a distance of 11.7 Å from the cobalt center of the corrinoid.[130] The diol substrate is also bound via a tight net of H bonds to polar protein residues at an observed distance of more than 7 Å from the corrin-bound cobalt ion.[130] These observations excluded direct contacts of reaction intermediates with the cobalt center of the cofactor. Analysis of the crystal structure of DD reconstituted with the coenzyme B_{12} analogue 5-adeninyl-pentyl-cobalamin revealed the binding of an analogue of AdoCbl (**3**) to DD, in which a flexible pentamethylene unit links an adenine function to the cobalt center, similar to the ribose in the adenosyl ligand.[132] Together with earlier structure-function studies of a variety of other analogues of coenzyme B_{12} (**3**), this study supported the view of an effective adenine-binding pocket in the 'substrate binding' α-subunit. The observed binding of the adenine moiety of 5-adeninyl-pentyl-cobalamin indicates buildup of a strain in the adenosyl-cobamide cofactor as a means of activation toward homolysis of its Co–C bond.

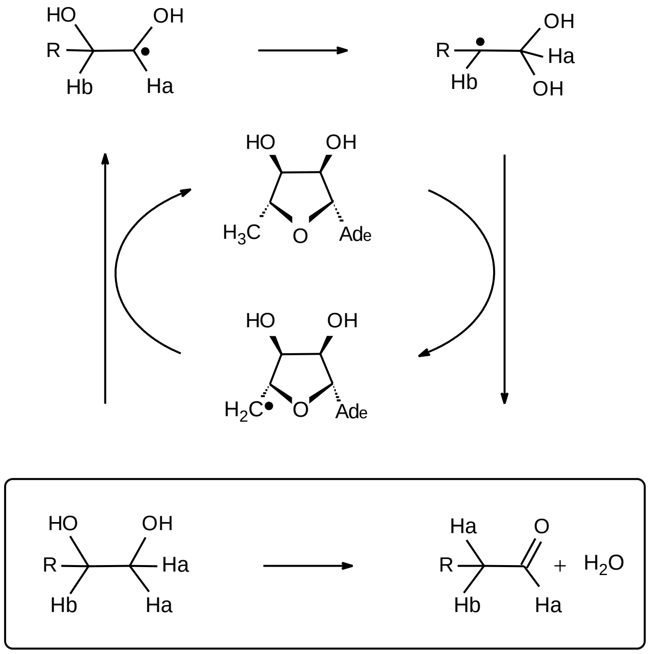

Figure 13 Illustration showing a possible mechanism of the coenzyme B_{12}-catalyzed diol dehydration

Ethanolamine ammonia lyase. EAL converts ethanolamine to acetaldehyde, with loss of ammonia.[108,133] EAL depends upon adenosylcobamides, such as coenzyme B_{12} (**3**), but a range of other adenosylcobamides are also accepted as cofactors, while cobalamins with β-ligands other than the 5′-deoxy-5′-adenosyl group (of AdoCbl) are inhibitors. Active EAL is multimeric and has an apparent molecular mass of about 560–600 kDa. Similar to the mechanism of DD, a radical mechanism is proposed for the isomerization of the vicinal amino-alcohol substrates (ethanolamine, (*R*)- and (*S*)-aminopropanol) by EAL, starting with the abstraction of an H atom from the C-1 position of the substrates.[134]

B_{12}-dependent amino mutases. Two coenzyme B_{12}-dependent amino mutases have been characterized, both of which catalyze the migration of ω-amino groups to the $(\omega - 1)$ position in diamino-acids with the help of (**2**) and pyridoxal-phosphate as cofactors:[109] (1) Ornithine-4,5-aminomutase catalyzes the migration of the terminal amino group of D-ornithine to the 4-position, to give (2*R*,4*S*)-diaminovaleric acid (Table 1). The migration of the amino group is achieved in a radical reaction, which requires the pyridoxal cofactor PLP, to assist the migration by forming a Schiff's base involving the migrating amino function. (2) D-lysine/L-β-lysine 5,6-aminomutase catalyzes the isomerization of D-lysine to 2,5-diaminohexanoic acid and of L-β-lysine to (3*S*,5*S*)-3,5-diaminohexanoic acid via a mechanism suggested to be similar to that of D-ornithine amino mutase. However, the related isomerization of L-α-lysine to L-β-lysine is catalyzed by lysine-2,3-aminomutase, which is an amino mutase that is independent of coenzyme B_{12} (**2**).[109]

3.3.3 *B_{12}-dependent Ribonucleotide Reductase*

In all organisms, the ribonucleotide reductases play essential roles in the biosynthesis of DNA by catalyzing the reduction of nucleoside di- or triphosphates to the

corresponding 2′-deoxynucleotides.[110,112] The ribonucleotide reductase (RNR) from *Lactobacillus leichmanii* belongs to the class II ribonucleotide reductases, which make use of adenosylcobamides, such as coenzyme B_{12} (**3**), to initiate the radical reaction.[112,135]

RNR uses nucleoside triphosphates (NTPs) as substrates and 2′-deoxynucleoside triphosphates (dNTPs) as allosteric effectors.[110] In RNR, the 'B_{12}-binding motif', the (Gly-X-X-His-X-Asp)-sequence, is absent and the corrinoid cofactor binds in a 'base-on'-form.[136] Homolytic (Co–C)-bond cleavage of AdoCbl (**3**) is known to be accelerated by about10^{11}-fold in RNR.[137] The free enthalpy of activation of AdoCbl, when bound to GTP-activated but substrate-free RNR, was determined to be lowered in the enzyme by about $13-15$ kcal mol^{-1}compared to the value for the homolysis of AdoCbl in aqueous solution.[137] In RNR, a protein centered thiyl radical, which is generated from the homolysis of the Co–C bond of the bound coenzyme (**3**), induces the radical reactions that formally lead to the reductive substitution by hydrogen of the 2′-hydroxyl group of the ribonucleotide. The thiyl radical then abstracts the H atom at C-3′ of the bound substrate to induce the reductive dehydration of the bound NTP to a dNTP, which involves the oxidation of the thiol groups of two cysteines (suggested to be C-119 and C-419) to a disulfide bridge.

The crystal structures of dGTP-free AdoCbl-dependent RNR in the apo-form complexed with Co_{β}-adeninylpentyl-cobalamin (a structural analog of AdoCbl (**3**), see e.g.[132]) confirmed the 'base-on' nature of the bound corrinoid, deduced from ESR data earlier.[136] In crystalline RNR, the crucial cysteine is at a distance of about 10 Å from the cobalt(II) center of the bound corrinoid, and in a region of space that is also well conserved in the three classes of RNRs.[138]

1 INTRODUCTION

'. . . we invite the attention of chemists to a class of salts which for beauty of form and color, and for abstract theoretical interest, are almost unequaled either among organic or inorganic compounds.' So wrote Wolcott Gibbs and Frederick Genth in their classic discourse 'Researches of the ammonia-cobalt bases,' published in 1856.[1] Since this time, cobalt has become arguably the most important transition metal in the development of modern coordination chemistry. The Swiss chemist Alfred Werner (1866–1919) was awarded the Nobel Prize in 1913 'in recognition of his work on the linkage of atoms in molecules by which he has thrown new light on earlier investigations and opened up new fields of research especially in inorganic chemistry' and he has often (quite correctly) been termed 'the father of modern coordination chemistry.' It is thanks to his extensive work on complexes of Co(III) that we now understand the concepts of oxidation state (*see Oxidation Number*) and coordination number (or primary and secondary valence as they were termed by Werner). His work also lies as the forefront of our understanding of inorganic stereochemistry (*see Stereochemistry*), and his studies of optically active Co(III) complexes in particular were crucial to the development of modern structural coordination chemistry. In recognition of his importance in chemistry, Co(III) am(m)ine complexes are often called *Werner complexes* (*see Werner Complexes*). Complexes of Co(III) have also been central to studies aimed at determining the mechanisms of ligand substitution (*see Ligand Substitution*) and electron transfer in coordination complexes, as exemplified in the work of the 1983 Nobel Laureate Henry Taube. In addition to the interest in its coordination complexes, cobalt finds many uses in industry, in areas as diverse as pigments, magnets, catalysts, superalloys, and batteries. ^{60}Co is an important isotope in radiotherapy, while the cobalamins constitute an important class of biological compounds. A comprehensive treatment of the chemistry of cobalt is beyond the scope of this article, and the following pages, of necessity, provide only a brief outline of some of the more interesting and important aspects of the inorganic and coordination chemistry of cobalt. The interested reader is referred to more detailed treatments of this extensive topic.[2–5]

2 THE ELEMENT

2.1 History

Cobalt ores were used by the ancient Egyptians to color glass and pottery blue, and a piece of such glass found in the tomb of Pharaoh Tutankhamen dates knowledge of cobalt to at least 1300 B.C.E. Cobalt ores were also used to color Chinese pottery from the Tang (600–900 C.E.) and Ming (1350–1650 C.E.) dynasties. Elemental cobalt was first isolated by the Swedish chemist Georg Brandt in 1735, while studying a dark blue ore obtained from a local copper mine, but it was to be another 45 years before Bergman proved that cobalt was indeed a new element. The name 'cobalt' derives

from the German word 'Kobald,' meaning 'goblin,' which appears to have been given originally by miners in Saxony; silver mines in this region contained significant amounts of the ore smaltite ($CoAs_2$), and their attempts to smelt this led to the production of foul-smelling and toxic arsenic species. Such problems were blamed on 'die Kobalde'. Espionage provided one of the earliest documented uses of cobalt compounds, with a mixture of cobalt chloride, glycerine, and water being used as an invisible ink by the Paris-based American agent Silas Deane in 1776–1777.

2.2 Abundance and Distribution

Cobalt ranks number 33 in abundance of the elements in the earth's crust, which contains on average 20-µg Co/g, although soil levels of up to 2000-µg Co/g are found in Zaire and New Zealand. Significant deposits of cobalt are found in Canada, Russia, Zambia, and Congo, with these countries accounting for approximately 65% of the current total world supply. Smaller deposits are found in Cuba, New Caledonia, and Australia. Cobalt does not exist as the free metal in nature, but occurs in approximately 200 ores, of which smaltite ($CoAs_2$), cobaltite (CoAsS), and linnaeite (Co_3S_4) are commercially important.

2.3 Isolation and Uses

Cobalt sulfide and arsenide ores are often found mixed with those of nickel and copper. The mixed ore is roasted with Na_2CO_3 and KNO_3, which removes part of the sulfur and arsenic as volatile species. The residue contains the metal oxides, as well as sulfate and arsenate, and the latter are removed by leaching with water. The metal oxide mixture is then dissolved in hot HCl or H_2SO_4, and the individual metal oxides are fractionally precipitated using $Ca(OH)_2$ and NaOCl. This process gives the mixed valent oxide Co_3O_4, which is then reduced to the metal by treatment with charcoal.

Table 1 gives data on the current world production of cobalt. In 2002, approximately 50% of cobalt produced worldwide was a by-product of nickel refining, while some 18% was obtained from refining secondary products and scrap metal. Newfound ore deposits in Australia and Africa are expected to add significantly to world production, with six new refining operations having been commissioned in these areas between 1999 and 2001. As can be seen in Table 2, the major use of cobalt is as a component of superalloys, which are designed for use at elevated temperatures.

Table 1 Current world production of cobalt (2002)[3]

Country	Mined	Refined	Approximate refined quantity (tonne)
Australia	Yes	Yes	3900
Belgium	No	Yes	1200
Botswana	Yes	–	–
Brazil	Yes	Yes	950

Feedstuffs, anodizing, recording, electrolysis, Cu electrowinning	5.1
Batteries	8.5
Tyre adhesives, soaps, driers (paint/ink)	9.0

2.4 Properties

Table 3 gives the important properties of elemental cobalt. The metal itself is lustrous and silvery-blue at room temperature, and exists in two allotropic forms (*see Allotrope*), α and β. The α-form has a hexagonal closest-packed structure and exists below 417 °C, while the β-form exhibits a face-centered cubic arrangement. Interconversion between the two forms is slow, and may account, in part, for the variability in reported physical data for the metal. The metal is ferromagnetic (*see Ferromagnetism*) at room temperature and has the highest known Curie temperature (*see Curie Temperature*) of all elements (1121 °C). Addition of small amounts of cobalt to iron can increase the already large saturation magnetization of iron, and the Co/Fe alloy containing 35 wt% Co shows a maximum saturation magnetization of 2.45 T. Cobalt has only one naturally occurring isotope, ^{59}Co, and, consequently, the atomic mass of cobalt is known to high precision (58.933200(2)). A list of the known isotopes of cobalt is given in Table 4. The ^{59}Co isotope is NMR-active, and its high abundance results in a sensitivity of 0.28 relative to the ^1H nucleus. However, the ^{59}Co nucleus is quadrupolar (*see Quadrupolar*) with a spin of 7/2, and broad NMR

peaks are often obtained for all but very high symmetry compounds. Despite this, ^{59}Co NMR is now routinely used for the characterization of cobalt compounds both in solution and in the solid state. As can be seen in Table 5, the chemical shift range for Co(III) complexes in solution is large and the signal linewidths vary over at least three orders of magnitude, correlating well with values of T_1 and T_2. Solid-state spectra can be obtained from single crystals and both static and MAS polycrystalline samples. Extensive collections of chemical shift data are available.[6–8] Solid-state ^{59}Co NMR has afforded substantial insight into the electronic structure of Co-containing molecules. For example, studies of several cobalamins, cobaloximes (*see Cobaloxime*), and cobalt porphyrins (*see Porphyrin*) have shown that cobaloximes ($\delta \sim 3200$–5300 ppm) display similar chemical shifts to the cobalamins ($\delta \sim 4300$–4800 ppm), and are thus better models of these biological compounds than the porphyrins ($\delta \sim 8200$–9200 ppm). The sensitivity of the solid-state technique is attested to by the observation that the four crystallographically nonequivalent Co sites in $[Co(NH_3)_6]Cl_3$ can be distinguished by ^{59}Co NMR. While ^{59}Co is the only naturally occurring isotope, some artificial isotopes of Co have important uses. ^{59}Co can be converted to the longest-lived ($t_{1/2} = 5.3$ years) radioactive isotope ^{60}Co by irradiation with thermal neutrons. The ^{60}Co nucleus emits 1.17- and 1.33-MeV γ-rays, and is widely used as a radiotheraputic agent in nuclear medicine. It is also used as a γ-source for food irradiation and industrial radiography. The ^{57}Co isotope finds use as an indirect source of photons for ^{57}Fe Mössbauer spectroscopy; it decays by electron capture to give an excited-state ^{57}Fe nucleus, which emits a 14.4-keV γ-ray on relaxing to the ground state.

2.5 Chemical Reactivity

Elemental cobalt is relatively unreactive in air at ambient temperature, although the finely divided metal is pyrophoric. Cobalt is oxidized on heating in the presence of oxygen to give

Co_3O_4, which then gives CoO at temperatures above 900 °C. CoO can also be formed directly by treatment of cobalt with steam at red heat. Simple Co(II) salts having the formula $CoX_2 \cdot nH_2O$ may be prepared by treatment of the metal with the appropriate mineral acid, while the anhydrous salts $CoCl_2$, $CoBr_2$, and CoI_2 can be prepared by direct treatment of the metal with Cl_2, Br_2, or I_2 at elevated temperatures. Reaction of the metal with F_2 gives the Co(III) salt CoF_3. The metal is unreactive toward both H_2 (although ternary hydrides such as Mg_2CoH_5 do exist) and N_2, but combines with carbon, sulfur, phosphorus, arsenic, boron, and silicon on heating to form binary compounds (*see Binary Compounds*).

3 GENERAL CHEMISTRY

3.1 Overview and Aqueous Chemistry

Simple cobalt salts most commonly contain the metal in the +2 oxidation state. Higher oxidation state compounds, especially those containing the metal in the +4 and +5 oxidation state, are rare, and are usually stabilized by the presence of fluorine or oxygen atoms. Simple salts of Co(III) include CoF_3 and CoO(OH). The yellow hexafluorocobaltate(IV) anion has been reported in Cs_2CoF_6, obtained by fluorination of Cs_2CoCl_4 or $Cs_2Co(SO_4)_2$ at 300 °C.[10] Co(IV) is also present in red–brown Ba_2CoO_4, while both Na_3CoO_4 and K_3CoO_4 contain Co(V), seemingly the highest known oxidation state of cobalt. These high-valent compounds have attracted surprisingly little attention since the initial reports of their syntheses and they remain to be completely characterized. There are very few simple compounds containing cobalt in oxidation states lower than +2. The black–red mixed-valence Co(II,I) oxide $Rb_5Co_2O_4$ contains Co(I) in discrete linear $[O–Co–O]^{3-}$ units, similar to those found in the Co(I) oxides K_3CoO_2 and $Na_5[CoO_2]CO_3$,[11] while Co(I) is also found in the nitride Ba[CoN].

The range and distribution of oxidation states in cobalt complexes differ substantially from those found in simple binary and ternary cobalt compounds. Cobalt complexes containing the metal ion in all oxidation states from −1 to +5 are known, with Co(III) complexes being the most numerous. The lower oxidation states are dominated by organometallic complexes (*see* ***Coordination Numbers & Geometries***), although the coordination chemistry of Co(I) is being increasingly explored. Commercially available Co(II) species of the formula $CoX_2 \cdot 4H_2O$ or $CoX_2 \cdot 6H_2O$ generally serve as starting materials for the synthesis of most cobalt coordination complexes, while treatment of commercially available $CoCO_3 \cdot xH_2O$ with the appropriate acid allows the synthesis of Co(II) salts of most anions. Dissolution of these Co(II) salts in aqueous solution yields the octahedral hexaaquacobalt(II) ion $[Co(OH_2)_6]^{2+}$, which is pale pink in color ($\lambda_{max} \sim 510$ nm). Such solutions are stable to aerial oxidation, and are feebly acidic owing to the equilibrium shown in equation (1) (*see Acidity Constants*).

$$[Co(H_2O)_6]^{2+} + H_2O \rightleftharpoons [Co(H_2O)_5(OH)]^{+} + H_3O^{+} \qquad (1)$$

Increasing the pH of solutions of $[Co(OH_2)_6]^{2+}$ leads to the precipitation of amphoteric $Co(OH)_2$ at around pH 11. This exists in two forms, pink and blue, and redissolves on addition of further base to give blue solutions containing the tetrahedral species $[Co(OH)_3(OH_2)]^{-}$ and $[Co(OH)_4]^{2-}$.[12] The blue ($\lambda_{max} = 605$ nm, 401 nm) hexaaquacobalt(III) ion $[Co(OH_2)_6]^{3+}$, by contrast, is highly oxidizing and can only be obtained in strongly acidic solution. The cation is usually prepared by electrochemical oxidation of acidic ($HClO_4$, HNO_3, or H_2SO_4, $[H_3O^+] \geq 4$ M) solutions of $[Co(OH_2)_6]^{2+}$ at 0 °C using a Pt electrode. The high reactivity of $[Co(OH_2)_6]^{3+}$ makes the study of its solution chemistry difficult. While $[Co(OH_2)_6]^{3+}$ is undoubtedly more acidic than $[Co(OH_2)_6]^{2+}$, its exact pK_a is uncertain, with estimates ranging from 0.66 to >2.3. Kinetic studies of the oxidation of a number of organic and inorganic substrates by solutions of $[Co(OH_2)_6]^{3+}$ have shown that $[Co(OH_2)_5OH]^{2+}$ is significantly more reactive than the hexaaqua species in such reactions.

Standard reduction potentials ($E°$) for a variety of Co(III) complexes are given in Table 6, and these data clearly show the enormous stabilization of the +3 oxidation state relative to the +2 as the ligands are changed from O- to N-donors. Thus, while $[Co(OH_2)_6]^{3+}$ is strongly oxidizing ($E° = 1.83$ V), $[Co(NH_3)_6]^{3+}$ is stable to reduction in aqueous solution ($E° = 0.11$ V). Co(III) complexes containing am(m)ine ligands (*see* ***Ammonia & N-donor Ligands***) are also unusual amongst the first-row transition metal ions in that they are comparatively inert to ligand exchange and display an enormous range of rates for such reactions, as shown in Table 7 (*see Ligand Substitution*); for example, $[Co(NH_3)_5OClO_3]^{2+}$ has a half-life in 1.0 M $HClO_4$ of ~7 s, while the half-life for hydrolysis of $[Co(NH_3)_6]^{3+}$ in aqueous solution at pH 1 is of the order of 3800 years. Of the first-row transition metals, only complexes of Cr(III) display comparable (although somewhat more rapid) rates of ligand exchange. This combination of favorable thermodynamic and kinetic factors allows for facile synthesis of Co(III) am(m)ine complexes and the number of such complexes is legion. The first synthesis of a Co(III)

Table 6 Standard reduction potentials (vs SHE) for some Co(III) complexes

Couple	E° (V)
$[Co(H_2O)_6]^{3+} + e^- \rightarrow [Co(H_2O)_6]^{2+}$	1.83
$[Co(C_2O_4)_3]^{3-} + e^- \rightarrow [Co(C_2O_4)_3]^{4-}$	0.57
$[Co(edta)]^{-} + e^- \rightarrow [Co(edta)]^{2-}$	0.37

$[Co(NH_3)_5O_2CCH_3]^{2+}$	2.7×10^{-8}
$[Co(NH_3)_6]^{3+}$	5.8×10^{-12}

complex is generally attributed to B.M. Tassaert who, in 1798, observed that aqueous mixtures containing cobalt(II) chloride and ammonia underwent slow oxidation in air to give brown solutions, and this principle is still used today in the synthesis of Co(III) am(m)ine complexes. Synthesis of such complexes is usually achieved by air oxidation of an aqueous solution containing a Co(II) salt and either ammonia or an amine, while other commonly used oxidants include H_2O_2 and PbO_2. The Co(III) species $Co(acac)_3$, $Na_3[Co(NO_2)_6]$, and $Na_3[Co(O_2CO)_3]\cdot 3H_2O$ have also found use in the synthesis of Co(III) complexes; although formally kinetically inert to ligand substitution, all contain ligands that are acid labile (*see Labile*) and treatment with a protonated amine can give the Co(III) amine complex directly. While the synthesis of Co(II) complexes generally involves simple mixing of the ligand and a suitable Co(II) salt, the synthesis of Co(II) am(m)ine complexes must usually be carried out under an inert atmosphere, so as to preclude facile oxidation to Co(III).

Complexes of Co(III) are probably the most studied of any transition metal, and an extensive literature pertaining to their synthesis, structure, reactivity, and reaction kinetics exists.

3.2 Preparative Methods

A selection of articles detailing synthetic methods used for the preparation of cobalt compounds and complexes and a list of useful starting materials for such syntheses are available.[14]

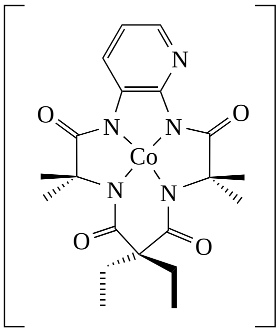
3.3 Structures

The Cambridge Structural Database[15] contains X-ray crystallographic data for all reported compounds and complexes of cobalt that contain carbon (*see X-ray Crystallography*). The November 2002 version of this database lists 10 403 structures containing cobalt, with the earliest, the Co(II) complex of the phthalocyaninate dianion, dating back to 1936.[16] The Inorganic Crystal Structure Database[17] contains structural data for cobalt compounds not containing C–C or C–H bonds, and lists 2569 structures containing cobalt. Notably, several structural determinations of $[Co(NH_3)_6]^{3+}$ salts dating from the 1920s are reported.

3.4 Stereochemistry, Spectra and Magnetism

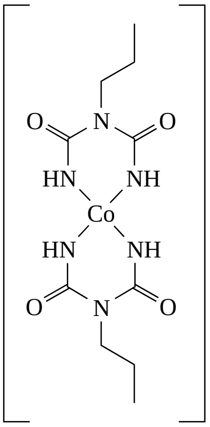
Co(III) complexes usually have a d^6 low-spin electronic configuration, and are almost exclusively six-coordinate, with octahedral (*see Octahedral*) or distorted octahedral geometries. Examples of high-spin six-coordinate Co(III) complexes are rare, and of necessity involve very weak field ligands. Examples include $[CoF_6]^{3-}$ and $[CoF_3(H_2O)_3]$. Although uncommon, square-planar (*see Square Planar*) Co(III) can be stabilized through judicious choice of ligand and complexes such as (**1**) and (**2**), which contain deprotonated amide ligands (*see Amide (Amido) Complexes*) crystallize from solution showing no close axial contacts.[18,19] The four-coordinate Co(III) complex (**3**) shows a significant distortion toward tetrahedral (*see Tetrahedral*) geometry, with a twist angle between the troponiminate rings of 41°.[20]

PPh4



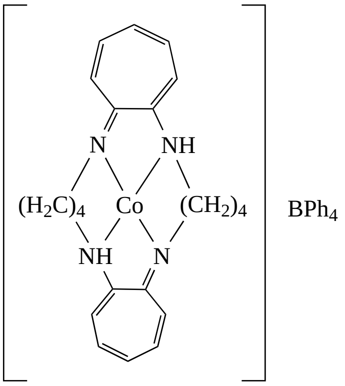
(**1**)

K

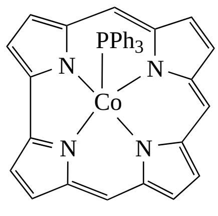


(**2**)

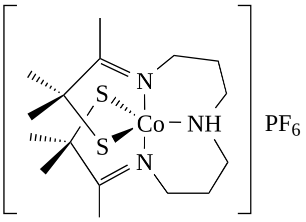
A number of five-coordinate Co(III) complexes have also been crystallographically characterized, with the corrole complex (**4**)[21] and the thiolate complex (**5**)[22] providing



(**3**)



(**4**)



(**5**)

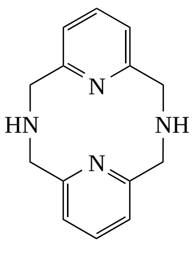
examples of these. Seven-coordinate Co(III) occurs in $[Co(H_2O)(Hedta)]\cdot 2H_2O$,[23] while the small size of the Co^{3+} ion appears to preclude the formation of any higher coordinate complexes. Three-coordinate Co(III) complexes have also been reported.[24]

The low-spin (*see High-spin & Low-spin Compounds*) electronic configuration of typical octahedral Co(III) complexes results in a $t_{2g}{}^6e_g{}^0$ electronic configuration and a corresponding ${}^1A_{1g}$ ground state. Two spin-allowed transitions, ${}^1T_{1g} \leftarrow {}^1A_{1g}$ and ${}^1T_{2g} \leftarrow {}^1A_{1g}$, are usually observed in the visible region of the spectrum. Such transitions are responsible for the wide variety of colors exhibited by Co(III) complexes, which literally span the entire spectrum of visible colors from red $[Co(NH_3)_5NCO]^{2+}$ to violet *cis*-$[Co(en)_2Cl_2]^+$. In fact, Co(III) complexes were originally named according to their colors. Thus, golden yellow $[Co(NH_3)_6]Cl_3$, purple $[Co(NH_3)_5Cl]Cl$, and green *trans*-$[Co(NH_3)_4Cl_2]Cl$ were named luteocobaltic chloride, purpureocobaltic chloride, and praseocobaltic chloride respectively. Lower-symmetry Co(III) complexes exhibit different spectral characteristics. In particular, geometric isomers of the type *cis*- and *trans*-$[CoA_4B_2]^{n+}$ display very different visible spectra, owing to a pronounced splitting of the ${}^1T_{1g}$ state in the trans isomer, which is absent in the cis. The centrosymmetric trans isomer also displays less intense absorption bands, and assignments of cis and trans isomers can thus often be made on the basis of the UV/vis spectrum. The magnetic behavior of low-spin octahedral Co(III) complexes is not noteworthy, as they are formally diamagnetic (*see Diamagnetism*). However, such complexes can display temperature-independent paramagnetism (TIP) (*see Paramagnetism*) through mixing of the excited ${}^1T_{1g}$ state with the ${}^1A_{1g}$ ground state. Four- and five-coordinate Co(III) complexes are paramagnetic, generally displaying magnetic moments ranging from 3.1 to 3.6 BM.[25,26]

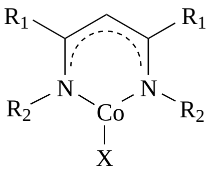
The Co(II) oxidation state is unique in that it is the only commonly occurring example of a d^7 electron configuration. Co(II) complexes are generally six- or four-coordinate, often high spin (*see High-spin & Low-spin Compounds*), and predominantly adopt distorted octahedral or tetrahedral geometries. Low-spin Co(II) complexes are rare, and generally contain strong-field ligands; $[Co(CN)_5]^{3-}$ is a notable example. Spin-crossover behavior has been observed in a number of Co(II) complexes, with $[Co(terpy)_2]X_2$ complexes ($X = ClO_4{}^-$, Cl^-, NCS^-, Br^-) for example, exhibiting anion-dependent magnetic moments ranging from 2.96 BM ($X = Br^-$) to 4.65 BM ($X = ClO_4{}^-$) at room temperature. Some square-planar Co(II) complexes containing phthalocyanine, porphyrin and macrocyclic (*see Macrocycle*) ligands are known, and examples of both square pyramidal (*see Square Pyramidal*) ($[Co(CN)_5]^{3-}$) and trigonal bipyramidal (*see Trigonal Prism*) ($[Co(Me_6tren)Br]^+$) geometries have been found in five-coordinate complexes. Octahedral and tetrahedral Co(II) complexes are often in equilibrium, and the interconversion between octahedral pink $[Co(OH_2)_6]^{2+}$ and tetrahedral blue $[CoCl_4]^{2-}$ (equation 2) is the basis of both the well-known children's 'weather forecasting' toy that turns pink in humid conditions and blue on dry days, and the blue to pink color change in self-indicating silica gel drying agents.

$$[Co(H_2O)_6]^{2+} + 4Cl^- \longrightarrow [CoCl_4]^{2-} + 6H_2O \qquad (2)$$

Seven-coordinate Co(II) complexes are known,[27–29] and eight-coordinate Co(II) is found in both $(Ph_4As)_2[Co(O_2NO)_4]$[30] and the diazapyridinophane complex $[CoL_2]BPh_4\cdot Et_2O$ (L = (**6**)).[31] The three-coordinate β-diketiminate complexes (**7**) and (**8**) are also known.[32,33]



(**6**)



(**7**) R_1 = *t*-Bu, R_2 = 2,6-diisopropylbenzene, X = Cl

(**8**) R_1 = Me, R_2 = 2,6-diisopropylbenzene, X = $N(SiMe_3)_2$

More tetrahedral complexes of Co(II) are known than for any other transition metal ion, because, at least in part, of the fact that the crystal field stabilization energy (*see Crystal Field Stabilization Energy*) difference between the octahedral and tetrahedral geometries is small for a high-spin d^7 electron configuration. The polarizibility (*see Polarizability*) of the ligand also appears to be important in determining the stereochemistry of the complex; complexes of ligands containing soft donor atoms (P, S, As, aromatic N) are often tetrahedral, while O- and amine N-donor ligands usually give octahedral complexes. Octahedral high-spin Co(II) complexes have a ${t_{2g}}^5$ ${e_g}^2$ electronic configuration and a corresponding $^4T_{1g}$ ground state. They are often pink to violet in color and show absorbance maxima around 500 nm, owing to the transition $^4T_{1g}(P) \leftarrow {}^4T_{1g}$ (F). The lower-energy transitions $^4A_{2g}(F) \leftarrow {}^4T_{1g}$ (F) and $^4T_{2g}(F) \leftarrow {}^4T_{1g}$ (F) can also be observed, the former as a shoulder on the main visible band and the latter in the near infrared. Tetrahedral high-spin Co(II) complexes ($e^4t_2^3$) have a $^4A_2$ ground state and their usual intense blue color results from the transition $^4T_1(P) \leftarrow {}^4A_2(F)$. Two lower-energy transitions, $^4T_1(F) \leftarrow {}^4A_2(F)$ and $^4T_2(F) \leftarrow {}^4A_2(F)$, occur in the infrared. The magnetic behavior of Co(II) complexes has been extensively studied. Monomeric high-spin octahedral complexes have orbital contributions to their magnetic moment, owing to the T ground term, with values between 4.8 and 5.2 BM typically observed at room temperature. Tetrahedral complexes have magnetic moments in the range 4.4–4.8 BM, with a TIP component arising from mixing of the $^4T_2(F)$ level into the $^4A_2$ ground state.

3.5 Analysis

Many methods for the qualitative and quantitative analysis of cobalt have been reported. The classic qualitative test for Co(II) salts in solution involves formation of the blue $[Co(SCN)_4]^{2-}$ complex anion by addition of NH_4SCN to the neutral or mildly acidic test solution (the Vogel reaction). Shaking the resulting solution with a small volume of amyl alcohol results in a blue coloration of the organic (top) layer. Interference from Fe(III) can be avoided by prior addition of fluoride to give colorless ${FeF_6}^{3-}$, or reduction to Fe(II) with ascorbic acid. Addition of ammonium sulfide to a neutral or alkaline solution containing Co(II) ions gives a black precipitate of CoS, which is insoluble in dilute HCl and dilute acetic acid. Co(II) salts also give a yellow–brown precipitate with rubeanic acid and a deep red coloration with nitroso-R-salt reagent. Quantitative gravimetric tests for cobalt include precipitation with α-nitroso-β-napthol reagent and subsequent conversion to elemental cobalt, and precipitation of blue $Co[Hg(SCN)_4]$ following addition of $HgCl_2$ and NH_4NCS to a neutral solution containing the Co(II) salt. Potentiometric titrations with edta or cyanide can also be used for analysis of Co(II).

4 SALTS AND OTHER SIMPLE COMPOUNDS

4.1 Oxides, Hydroxides, Oxyanions, Sulfides

Only two pure oxides have been characterized unequivocally. CoO can be prepared from the metal as described in Section 2.5, and also by heating Co(II) salts (hydroxide, carbonate, nitrate) in the absence of air. CoO is antiferromagnetic (*see Antiferromagnetism*), with a Néel Point of ~290 K, and above this temperature exhibits a NaCl-type structure (space group *Fm*3*m*). Synchrotron powder diffraction studies have, however, shown that CoO has a monoclinic structure (space group *C*2/*m*) below the Neel point.[34] The mixed valent oxide Co_3O_4 ($Co^{II}Co_2{}^{III}O_4$) has a spinel-type structure, with the Co(II) ions occupying tetrahedral sites and the Co(III) ions occupying octahedral sites. Both Co_2O_3 and CoO_2 have been reported, but their purity is doubtful. Cobalt(II) hydroxide, $Co(OH)_2$, can be prepared as described in Section 3.1. The hydroxide is usually pink (octahedral) but a blue tetrahedral form can be obtained by slow precipitation at temperatures below 0 °C. $Co(OH)_3$ has been reported, but appears to be poorly characterized. Oxidation of $Co(OH)_2$ gives the dark brown Co(III) oxide hydroxide CoO(OH). Cobalt forms a number of ternary oxo compounds, although those containing Co(IV) and Co(V) remain to be fully characterized. Impure Na_3CoO_4 can be prepared by heating Co_3O_4 with Na_2O at 450 °C under 100 atm pressure of O_2, while K_3CoO_4 has been reported from the reaction of the nonstoichiometric oxides $KO_{1.7}$ and $CoO_{\sim 1.5}$ at 460 to 550° in an O_2 atmosphere (0.5–1 atm.) for 6 to 23 h. Ba_2CoO_4 is prepared from a mixture of $Ba(OH)_2$ and $Co(OH)_2$ at 1150 °C. Other known oxo species include $Na_5[CoO_2]CO_3$, $Rb_2Co_2O_3$, $LaCoO_3$, $LiCoO_2$, K_2CoO_2, and $Na_{10}Co_4O_9$. Of the numerous cobalt sulfides reported, CoS_2 (pyrite structure), Co_3S_4 (spinel structure), cobalt-deficient $Co_{1-x}S$ (NiAs structure), and Co_9S_8 have been well characterized, while laser ablation of cobalt sulfide yields 83 gaseous ions ranging from ${CoS_2}^-$ to ${Co_{38}S_{24}}^-$.[35]

4.2 Halides

The only known halides containing Co(III) and Co(IV) are the fluorides. CoF_4 is formed in low yield in the gas

phase by the reaction of CoF_3 with TbF_4 over the temperature range 620 to 720 K,[36] while brown CoF_3 can be prepared by treatment of $CoCl_2$ with F_2 at 250 °C or from the reaction of elemental cobalt with ClF_3. The crystal structure of CoF_3 (space group $R\bar{3}c$) shows corner-sharing CoF_6 octahedra in which each cobalt ion is equidistant from six fluoride ions.[37] The anhydrous dihalides $CoCl_2$ and $CoBr_2$ can be prepared by reaction of the elements, while CoF_2 is prepared from the reaction of either CoO or $CoCl_2$ with HF, and CoI_2 results from the action of HI on the metal. The dihalides adopt the rutile (CoF_2), $CdCl_2$ ($CoCl_2$), and CdI_2 ($CoBr_2$, CoI_2) structures, in which the metal ions have a coordination number of 6 in all cases. The hydrated versions of the dihalides are well known, and are used extensively as starting materials for the synthesis of cobalt complexes. CoF and CoCl have been identified in the gas phase, and the latter can be stabilized in water clusters for several seconds under ultrahigh vacuum.[38] No authenticated examples of cobalt oxohalides have been reported.

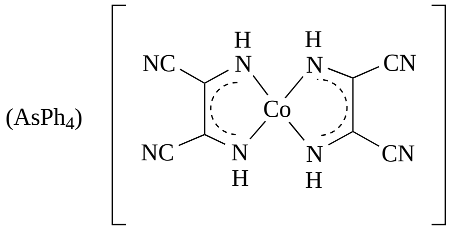
5 COORDINATION COMPLEXES

5.1 Low Oxidation States: Co^{-I}, Co^{0}, Co^{I}

The low oxidation state chemistry of cobalt is dominated by organometallic complexes containing C-donor ligands (*see* ***Coordination Numbers & Geometries***), and ‘classical’ coordination complexes containing cobalt in oxidation states lower than +2 are comparatively rare. Despite this, the Co(I) oxidation state is important in vitamin B_{12} chemistry, where the blue–green vitamin B_{12s} contains five-coordinate Co(I) in a square pyramidal N_5 coordination environment. Extensive studies of this and a wide variety of Schiff-base (*see Schiff Base*), macrocyclic, and porphyrin model compounds have shown that these Co(I) species behave as ‘supernucleophiles’; they undergo facile alkylation by oxidative addition (*see Oxidative Addition*) to give Co(III) alkyl compounds, and can liberate H_2 from water. Details of this chemistry are outlined elsewhere in this volume (*see* ***Cobalt: Organometallic Chemistry***). Co(I) has a d^8 electron configuration and its complexes might be expected to favor a square-planar geometry, as found for complexes of the isoelectronic metal ions Ni^{2+}, Pd^{2+}, and Pt^{2+}. In practice, however, a variety of stereochemistries are found for Co(I) complexes, and five-coordinate geometries appear to be favored, as these lead to a formal 18-electron count (*see Eighteen Electron Compounds*). The Co(I) ion appears to be appreciably softer than its more highly charged congeners, preferring aromatic N-donor ligands over aliphatic, and there is an extensive chemistry of Co(I) with phosphorus donor ligands. Nearly all complexes of Co(I) are unstable with respect to oxidation in air, and must therefore be prepared and handled under an inert atmosphere.

5.1.1 *Aliphatic Amine Ligands*

In contrast to the higher oxidation states, the chemistry of Co(I) with aliphatic amine ligands is virtually nonexistent. Simple homoleptic (*see Homoleptic Compound*) Co(I) complexes of ligands such as ammonia or ethylenediamine are unknown, and Co(I) complexes of saturated N-containing macrocycles appear to be very unstable. A rare example of a Co(I) complex containing only nonaromatic N-donor ligands is found in the square-planar complex $(AsPh_4)[Co(s\text{-}disn)_2]$ (**9**). The unusually short Co–N bonds (1.831(2) Å) in this complex are thought to result from extensive charge delocalization over the entire molecule.[39]



(**9**)

5.1.2 *Aromatic Amine Ligands*

The dark blue Co(I) complex $[Co(bipy)_3](ClO_4)$ can be prepared by reduction of $[Co(bipy)_3](ClO_4)_3\cdot 3H_2O$ by $NaBH_4$ in aqueous ethanol under an inert atmosphere. It is stable in ethanol solution in the absence of oxygen. The analogous dark brown 1,10-phenanthroline complex can be prepared in a similar fashion from $[Co(phen)_3](ClO_4)_2$. The crystal structure of $[Co(bipy)_3]Cl\cdot H_2O$ shows the Co(I) ion in a distorted octahedral environment with an average Co–N distance of 2.115 Å. This compares with values of 2.130 and 1.932 Å in the analogous Co(II) and Co(III) complexes $[Co(bipy)_3]Cl_2\cdot 2H_2O\cdot EtOH$ and $[Co(bipy)_3][Fe(CN)_6]\cdot 8H_2O$ respectively. The $[Co(bipy)_3]^+$ ion is an excellent reducing agent, and can reduce water to H_2, CO_2 to CO, and phenylacetylene to styrene. $E°$ values (*see Redox Potential*) for the $[Co(bipy)_3]^{2+}/[Co(bipy)_3]^+$ couple ranging from −0.95 to −1.37 V versus SCE have been reported. The Co(0) species $[Co(bipy)_3]$ is known, and electrochemical evidence for the formation of $[Co(bipy)_3]^-$ by the two-electron reduction of $[Co(bipy)_3]^+$ in DMF has been obtained, but a solid compound has not been isolated. The $E°$ value for this $[Co(bipy)_3]^+/[Co(bipy)_3]^-$ couple has been estimated as −1.94 V versus SCE. The four-coordinate species $[Co(bipy)_2]$ and $[Co(bipy)_2]^+$ are both known, as is the homoleptic pyridine species $[Co(py)_6]BPh_4$. This latter compound was the first example of a Co(I) compound containing a monodentate N-donor ligand, and was originally synthesized from an organometallic Co(I) complex by dissolution in pyridine. However, a more convenient synthesis involves photoreduction of a pyridine

solution of $[Co(py)_6](BPh_4)_2$.[40] Pyridine-containing tripodal ligands (*see Tripodal Ligand*) can also stabilize the Co(I) oxidation state. Thus, the approximately octahedral complex $[CoL_2]Br\cdot H_2O$ (L = tris(2-pyridyl)methane) can be synthesized using preparative electrochemical reduction of $[CoL_2]Br_2$ in dry ethanol/acetonitrile under argon. X-ray crystallographic analysis shows an average Co–N bond length of 2.111 Å in the Co(I) cation, approximately equal to that found in the $[CoL_2]^{2+}$ cation (2.109 Å) and significantly longer than in the Co(III) cation (1.95 Å).[41]

5.1.3 Macrocyclic, Schiff-base, and Porphyrin Ligands

Macrocyclic square-planar complexes containing Co(I) have been extensively studied as catalysts for the photo- and electrocatalytic reduction of water and carbon dioxide. Studies of the Co(I) complexes of a number of cyclam derivatives have shown that the equilibrium constants for CO_2 binding increase as the Co(II)/(I) redox potential becomes more negative, with binding constants up to $\sim 10^6\ M^{-1}$ measured. Steric factors are also important in determining the magnitude of the binding constant.[42] Co(I) complexes of the acyclic Schiff-base ligand salen and its derivatives also show a propensity to bind CO_2 in the presence of an alkali metal cation. X-ray structural data for the propyl salen derivative show that the CO_2 binds to the metal through the carbon atom, as shown in Figure 1, and the oxygen atoms interact with the alkali metal cation.

Some Co(I) macrocyclic complexes have been implicated in C–H activation reactions. The observation of N–H exchange with solvent CD_3CN in solutions of Co(I) cyclam derivatives has been interpreted as evidence for C–H activation by a mechanism involving oxidative addition of CD_3CN to the Co(I) center.[43] Co(I) Schiff-base complexes have been proposed to be important intermediates in ethene polymerization. Treatment of Co(II) complexes containing 2,6-bis(imino)pyridyl ligands with MAO leads to highly

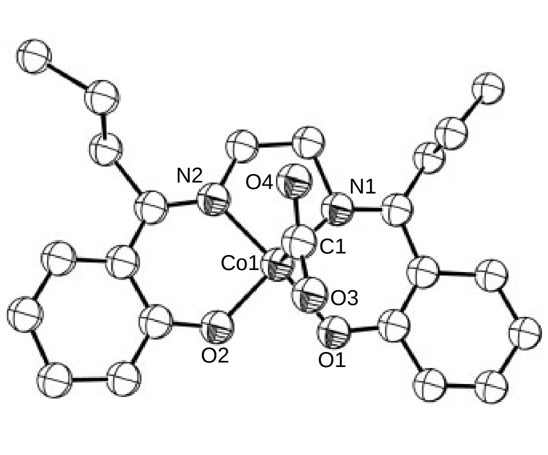


Figure 1 X-ray structure showing the coordination sphere of the Co(I) ion in [Co(n-Pr-salen)(CO_2)K(THF)]n

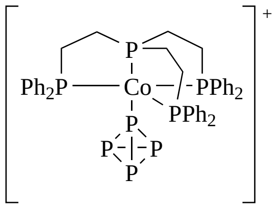
active catalysts for the polymerization of ethene, and square-planar Co(I) complexes are thought to be involved in the polymerization reaction.[44,45] The Schiff-base ligands used are noninnocent, but a detailed study has shown that reduction of the Co(II) bis-ligand complex leads to an authentic Co(I) complex, rather than a ligand radical species.[46] Co(I) complexes of porphyrin and porphyrin-derived ligands are well known, and can be prepared by chemical and electrochemical reduction of the Co(II) or Co(III) porphyrin species. The complexes are low spin and show no evidence of axial ligand coordination in the solid state.

5.1.4 Phosphorus Ligands

The majority of nonorganometallic Co(I) complexes contain P-donor ligands, presumably because of the π-acceptor (*see π-Acid Ligand*) character of such ligands. Reaction of $[(PP_3)CoH]$ with $MeOSO_2CF_3$ in THF under N_2 gives uncharacterized solution species, which then react with added elemental phosphorus (P_4) to give the trigonal bipyramidal $[(PP_3)M(\eta^1\text{-}P_4)]^+$ cation (**10**), in which the tetrahedral P_4 molecule is bound end-on to the metal ion. This complex decomposes above −40 °C.[47]



(**10**)

Several complexes containing the *cyclo*-P_3 unit as a ligand are also known. The diamagnetic, air-stable parent complex $[Co(triphos)P_3]$ can be prepared by reaction of $Co(BF_4)_2\cdot 6H_2O$ with an equimolar amount of the triphos ligand and excess white phosphorus at 50 °C under an inert atmosphere. The *cyclo*-P_3 unit in this complex is appreciably nucleophilic and may be protonated and alkylated. It can also coordinate to other metal ions in a variety of ways; the symmetrical dimer $[\{Co(triphos)\}_2\mu(\eta^3\text{-}P_3)](BPh_4)_2$ and analogous mixed Co/Fe, Co/Ni, and Co/Rh dimers contain a bridging $\eta^3 P_3$ unit (*see Hapticity*), while both η^2 and η^1 bridging modes are also known. $[Co(triphos)P_2S]$ and $[Co(triphos)P_2Se]$ can be prepared using the above synthetic method with P_4S_3 or P_4Se_3 in place of white phosphorus, and the P_2S unit can also bridge in an η^2 fashion to other metal ions.

A number of simple four-coordinate Co(I) species containing monodentate phosphine ligands are known. Complexes such as $[Co(PPh_3)_3X]$ (X = Cl, Br, I) were first prepared by reduction (electrochemical, $NaBH_4$, or powdered Zn) of

an ethanol solution containing a Co(II) salt and a monodentate arylphosphine ligand.[48] Subsequent work extended the series of complexes to include alkylphosphine ligands.[49] The complexes are paramagnetic, implying an unusual tetrahedral, rather than square-planar, geometry about the d^8 metal ion, and this has been confirmed by X-ray structural analysis of compounds such as $[Co(PMe_3)_4](BF_4)$, $[Co(PMe_3)_3Cl]$, $[Co(PMe_3)_3I]$, $[Co(PPh_3)_3OSiMe_3]$, $[Co(PPh_3)_3OPh]$, and $[Co(PPh_3)_3Cl]$. The 17-electron Co(0) species $[Co(PPh_3)_4]$ and $[Co(PMe_3)_4]$ can be prepared by reduction of anhydrous $CoCl_2$ with sodium amalgam or magnesium in the presence of the appropriate phosphine. These complexes have a distorted tetrahedral structure and are excellent nucleophiles, undergoing a variety of oxidative addition and dimerization reactions. The dark brown $[Co(PMe_3)_4]$ has found use in polypeptide synthesis, as an initiator for polymerization of α−amino acid−N-carboxyanhydrides[50] and can also mediate aldol-type reactions.[51] Low-temperature reduction of $[Co(PMe_3)_4]$ by alkali metals leads to the powerfully reducing Co(−I) species $[Co(PMe_3)_4]^-$; its reduction potential of ≥ -2.5 V makes this one of the strongest reducing agents known. Dinitrogen complexes (*see Dinitrogen & Dinitrogen Complexes*) of Co(−I) containing monodentate phosphine ligands can also be prepared. $K[Co(PMe_3)_3N_2]$ is formed spontaneously from a THF or Et_2O solution of $K[Co(PMe_3)_3L]$ (L = propene, cyclopentene) under 1 bar pressure of N_2, and this propensity to bind nitrogen often necessitates the use of Ar as an inert atmosphere for the study of low-valent Co-phosphine complexes. The X-ray crystal structure of $K[Co(PMe_3)_3N_2]$ shows a tetrahedral ligand geometry around the d^{10} metal ion.

The behavior of the monodentate phosphine complexes is mirrored in those containing multidentate phosphine ligands, and Co(I), Co(0) and Co(−I) species containing such ligands are all known. Thus, $[Co(dppe)_2]BF_4$ can be prepared by Zn reduction of the Co(II) species $[Co(dppe)_2CH_3CN](BF_4)_2$, while the hydride complex $[Co(dppe)_2H]$ is obtained if $NaBH_4$ is used as the reductant.[52] In contrast to the homoleptic monodentate phosphine compounds however, $[Co(dppe)_2]X$ complexes ($X = ClO_4$, BF_4) are diamagnetic, and hence square planar, both in solution and in the solid state. The paramagnetic Co(0) complex $[Co(dppe)_2]$ can be prepared by Na reduction of $[Co(dppe)_2Br_2]$ and the deep red Co(−I) complex $[K(18\text{-crown-}6)(THF)_2][K(18\text{-crown-}6)][Co(dppe)_2]_2$ has been isolated from the reaction of $[Co(\eta^4\text{-anthracene})_2]^-$ with dppe in THF. X-ray structural analysis shows a slightly distorted tetrahedral geometry around the metal ion, with average Co–P bond lengths of 2.109 Å (Figure 2).

Five-coordinate complexes of Co(I) are relatively common, and this can be rationalized on the basis of the 18-electron rule, which is satisfied by this coordination number for the d^8 metal center. Hence, tetrahedral Co(I) phosphine complexes tend to react readily with an additional ligand to give five-coordinate species, with addition of

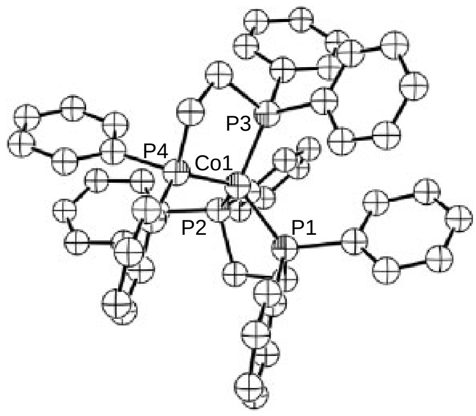


Figure 2 Diagram of the anion of $[K(18\text{-crown-}6)(THF)_2][K(18\text{-crown-}6)][Co(dppe)_2]_2$

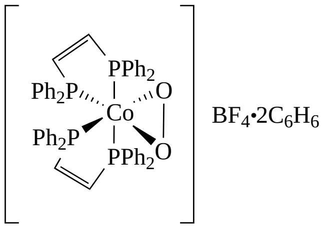
hydride and carbon monoxide ligands being particularly common. Mention must also be made of the planar Co(I) phosphine complex $[Co(2{=}phos)_2]BF_4$, which reacts irreversibly with dioxygen to give the mononuclear pseudo trigonal bipyramidal peroxo complex (*see Peroxo Complexes*) $[Co(O_2)(2{=}phos)_2]BF_4{\cdot}2C_6H_6$ (**11**).[53]



(**11**)

Five-coordinate metal centers are commonly found in complexes containing tripodal phosphine ligands. Thus, the ligand PP_3 enforces a trigonal bipyramidal geometry in the dark green halide complexes $[Co(PP_3)Cl]$, $[Co(PP_3)Br]$, and $[Co(PP_3)I]$, and red $[Co(PP_3)NCS]$. These are low spin and are prepared by $NaBH_4$ reduction of a $CH_2Cl_2/EtOH$ solution of the appropriate Co(II) salt and the ligand at room temperature. The halides can be displaced by other P-donor ligands and complexes such as $[Co(PP_3)\{P(OMe)_3\}]BF_4$, $[Co(PP_3)PEt_3]AsF_6$, and $[Co(PP_3)PPhMe_2]AsF_6$ can be prepared by this method. The five-coordinate hydride complex $[Co(PP_3)H]{\cdot}0.5(CH_3)_2CO$ can be prepared by reduction of a mixture of $Co(BF_4)_2{\cdot}6H_2O$ and PP_3 with excess $NaBH_4$ in EtOH/acetone, and a crystal structure shows a regular trigonal bipyramidal geometry about the Co(I) ion. The hydride ligand can be protonated with CF_3SO_3H in THF solution to yield the dihydrogen complex $[Co(PP_3)(H_2)]PF_6$, which is stable for days in the solid state, and also in solution under argon. This complex can also be prepared directly by treatment of $[Co(PP_3)H]$ with CF_3SO_3Me to generate the 16-electron

fragment $[Co(PP_3)]^+$, which then reacts with $H_2(g)$. This fragment can also react with $N_2(g)$ to give the dinitrogen complex $[Co(PP_3)N_2]PF_6$. The mixed-donor tripodal ligand NP_3 also forms a diamagnetic trigonal bipyramidal hydride complex $[Co(NP_3)H]$. However, the $[Co(NP_3)X]$ complexes ($X = Cl$, Br, I, NCS) are paramagnetic, with magnetic moments corresponding to two unpaired electrons, and the crystal structure of $[Co(NP_3)Br]$ confirms hypodentate coordination of the tripodal ligand, with the tertiary nitrogen atom not coordinated to the cobalt ion (Figure 3). Co(I) thus adopts a tetrahedral geometry in these compounds, with the rearrangement to the five-coordinate species being symmetry-forbidden.

Phosphite ligands are also common in low-valent cobalt chemistry. Co(I), Co(0), and Co(−I) complexes containing these ligands are known, and this is nicely illustrated by the series of compounds $[Co\{P(OMe)_3\}_4]^+$, $[Co\{P(OMe)_3\}_4]$, and $[Co\{P(OMe)_3\}_4]^-$. The blue complex $[Co\{P(OMe)_3\}_4]PF_6$ is obtained from the propylene complex $[Co\{P(OMe)_3\}_4(C_3H_6)]PF_6$ in vacuum at room temperature. It is highly reactive, and forms $[Co\{P(OMe)_3\}_5]^+$ quantitatively on treatment with $P(OMe)_3$. Neutral $[Co\{P(OMe)_3\}_4]$ can be isolated from decomposition of a low-valent cobalt phosphite salt and exhibits an EPR spectrum (*see Electron Paramagnetic Resonance*) consistent with C_{3v} symmetry. The 'superreduced' complex $K[Co\{P(OMe)_3\}_4]$ was originally obtained as an insoluble material from the reaction of the hydride complex $[CoH\{P(OMe)_3\}_4]$ with KH. Treatment of the potassium salt with cryptand 222 (*see Cryptands & Cryptates*) gives the soluble species $[K\text{-}(222)][Co\{P(OMe)_3\}_4]$, the X-ray structural characterization of which shows a near-perfect tetrahedral geometry about the Co(−I) ion. The strongly reducing nature of this complex is evidenced by the reduction potential for the $[Co\{P(OMe)_3\}_4]/[Co\{P(OMe)_3\}_4]^-$ couple of −1.77 V versus Fc^+/Fc.[54] The influence of phosphite ligands in stabilizing the Co(I) oxidation state is illustrated by the fact that addition of trimethylphosphite to a solution of the Co(II) complex of the macrocyclic ligand (**12**) makes the Co(II)/(I) reduction potential less negative by 0.24 V. The

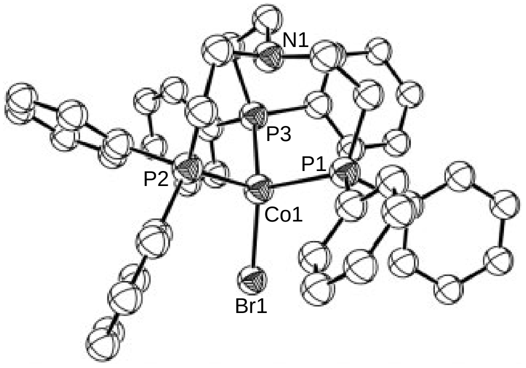


Figure 3 Structural diagram of $[Co(NP_3)Br]$ showing the noncoordinated tertiary N atom

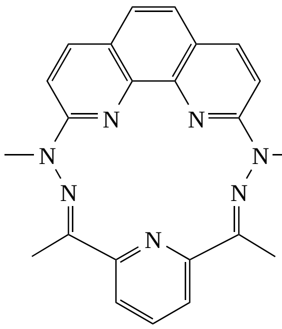

(**12**)

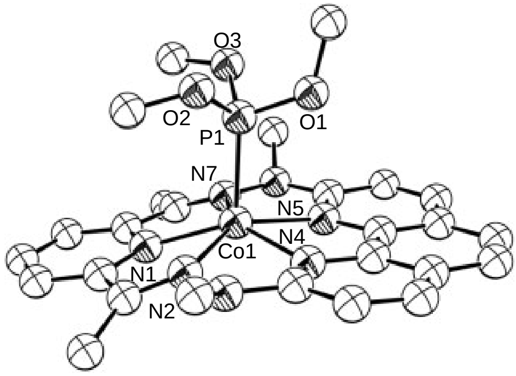

Figure 4 Structural diagram of $[Co(\mathbf{12})\{P(OMe)_3\}]$

dark green high-spin $[Co(\mathbf{12})\{P(OMe)_3\}]$ complex (Figure 4) was isolated following controlled potential electrolysis, and X-ray structural analysis confirmed an unusual pentagonal pyramidal structure.[55]

5.2 Co(II) Complexes

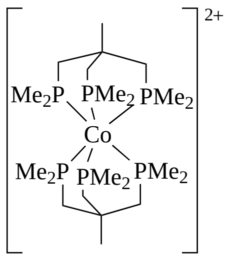
Complexes of Co(II) can be easily prepared by mixing solutions of a commercially available Co(II) salt with the appropriate ligand in a noncoordinating solvent. The complexes may be isolated by concentrating the mixture to effect crystallization, or, in the case of cationic and anionic complexes, addition of a suitable counterion to precipitate the product, and subsequent crystallization. Reactions can often be carried out in air without the need for an inert atmosphere, although such precautions are generally warranted in the syntheses of Co(II) amine complexes, which can often undergo facile air oxidation. Reactions of the Co(II) precursors with added ligand are generally rapid, owing to the lability of Co(II) complexes. Such lability is demonstrated by the rate of water exchange (*see Water Exchange*) in the $[Co(H_2O)_6]^{2+}$ ion, with rate constants for this process of the order of $3 \times 10^6\ s^{-1}$ having been measured using ultrasound absorption and ^{17}O NMR spectroscopy. Likewise, rate constants for the reaction of $[Co(OH_2)_6]^{2+}$ with various anionic and neutral ligands range from 10^4 to $10^8\ M^{-1}\,s^{-1}$, with those for the

Table 8 Rate data for the complexation reaction of $[Co(H_2O)_6]^{2+}$ with various ligands[12]

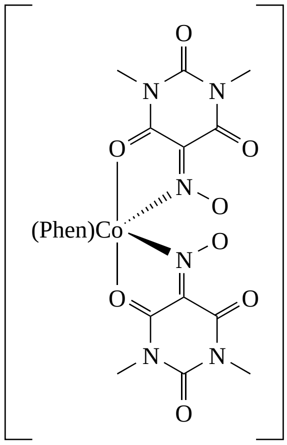
Ligand	k ($M^{-1} s^{-1}$)
$HP_2O_7^{3-}$	9.3×10^7
ATP^{4-}	9.2×10^7
$Hedta^{3-}$	4.0×10^6
H_2O	3.2×10^6
NH_3	9.5×10^5
Phen	1.2×10^5
Bipy	6.3×10^4

anionic ligands being larger (Table 8). A $\Delta V^{\ddagger}$ value (*see Activation Volume*) of $(+6.1 \pm 0.2)\ cm^3\ mol^{-1}$ obtained for the water exchange reaction is consistent with a dissociative mechanism for this process, and similar positive values have been obtained for other solvent exchange reactions in $[CoL_6]^{2+}$ complexes (L = MeOH, MeCN, DMF), as well as for the reaction of $[Co(OH_2)_6]^{2+}$ with a number of ligands, pointing to a common dissociative mechanism for substitution reactions at a Co(II) center. Octahedral (high-spin) and tetrahedral geometries predominate for Co(II) complexes, and in the case of such compounds as $[Co(Me_2SO)_6](CoCl_4)$ and $[Co(EtOH)_6](CoBr_4)$, both the geometries are found in a single species. Homoleptic octahedral high-spin Co(II) complexes often display tetragonal distortions, owing to the Jahn–Teller effect (*see Jahn–Teller Effect*), but these effects are usually nowhere near as pronounced as those found in Cu(II) complexes. For example, the axial and equatorial Co–O bond lengths in $[Co(OH_2)_6](p\text{-}CH_3C_6H_4SO_3)_2$ differ by only 0.024 to 0.028 Å, with an axial compression observed in this case.[56] A similar axial compression is seen in the $[Co(EtOH)_6]^{2+}$ cation of $CoCl_2 \cdot 2.5EtOH$ (actually $[Co(EtOH)_6][Cl_3CoClCo(EtOH)_4ClCoCl_3]$), with the axial Co–O bond lengths being 0.013 Å shorter than the equatorial.[57] However, the Jahn–Teller effect is not manifested in all high-spin octahedral Co(II) complexes. For example, all Co–O bond lengths in the homoleptic species $[Co(THF)_6](Co(THF)I_3)_2 \cdot THF$ and $[Co(Me_2SO)_6](I_4)$ are identical.[58,59] The effect should theoretically be more pronounced in low-spin octahedral Co(II) complexes, but well-characterized examples of these are few. The phosphine complex $[Co(mmtp)_2]^{2+}$ (**13**)[60,61] displays rapid Co^{3+}/Co^{2+} electron self-exchange kinetics, consistent with a low-spin formulation for the Co(II) complex, while *trans*-$[Co(diphos)_2Cl_2]$[62] exhibits a magnetic moment of 1.97 BM. Neither complex has been structurally characterized.

A series of low-spin tris chelate complexes containing bidentate 2-(arylazo)pyridine derivatives has been prepared,[63] while X-ray structural characterization of the complex $[Co(dmvi)_2(phen)] \cdot 2CHCl_3$ (**14**) showed a pronounced elongation of the Co–O bonds relative to the low-spin Fe(II) complex (2.17 vs 1.98 Å, respectively), consistent with an axial Jahn–Teller distortion.[64]



(**13**)



(**14**)

Surprisingly, the best-characterized examples of low-spin octahedral Co(II) are found in complexes containing thioether ligands. Purple $[Co(9S3)_2](BF_4)_2$ (Figure 5) has a magnetic moment of 1.71 BM, which is temperature independent down to 77 K, and its crystal structure shows two Co–S bonds to be substantially (0.12Å) shorter than the remaining four.[65] The opposite situation is seen in $[Co(9S3)_2](I_3)_2$, where an axial elongation results in two long (2.4088 Å) and four short (2.2742 and 2.2959 Å) bonds.[66] Macrocyclic $[Co(18S6)](picrate)_2$ (Figure 6) and acylic $[Co(ttn)_2](BF_4)_2$ (Figure 7) also show elongation of the axial bonds, magnetic moments of 1.81 and 1.78 BM respectively, and EPR behavior consistent with a d_{z^2} ground state. Significantly, these complexes are stable to air oxidation. They do, however, undergo reversible electrochemical oxidation, consistent with no change of spin state during the redox process.[67]

Tetrahedral complexes of Co(II) often contain ligands having soft donor atoms, while square-planar geometries are usually only found in complexes containing rigid multidentate ligands such as porphyrins and Schiff-base species, which contain a square-planar arrangement of donor atoms. Such complexes are often low spin. Polymeric Co(II) complexes are quite common in the solid state, especially complexes containing chloride and bromide ligands, through which bridging can occur. Thus, the complex $[Co(py)_2Cl_2]$ exists as a blue tetrahedral monomer, and as a violet octahedral polymer, with bridging chloride ligands (*see Bridging Ligand*).

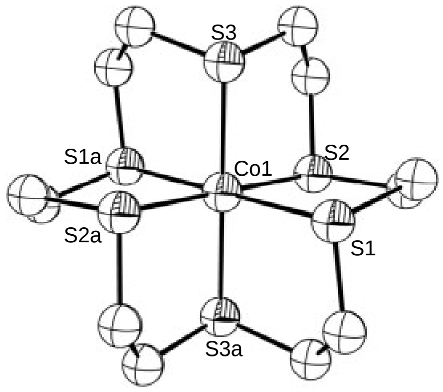

Figure 6 Structural diagram of the cation of $[Co(18S6)](picrate)_2$

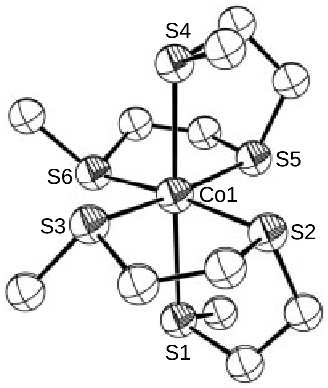

Figure 7 Structural diagram of the cation of $[Co(ttn)_2](BF_4)_2$

5.2.1 *Carboxylate Ligands*

Given the propensity of carboxylate ligands to form polynuclear complexes, it is somewhat surprising that commercially available $Co(O_2CCH_3)_2{\cdot}4H_2O$ is monomeric. The structure consists of a six-coordinate, approximately

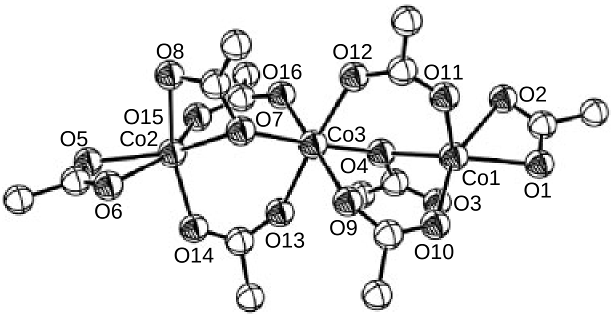

Figure 8 Structural diagram of the anion of $(NEt_4)_2[Co_3(O_2CCH_3)_8]$

octahedral, Co(II) ion coordinated to two trans monodentate acetate ligands and four equatorial waters, with extensive intramolecular and intermolecular hydrogen bonding (*see Hydrogen Bonding*).[68,69] Similar monomeric structures have been observed for a variety of $Co(O_2CR)_2{\cdot}4H_2O$ compounds. Slow crystallization of $Co(O_2CCH_3)_2{\cdot}4H_2O$ from acetic acid gives polymeric $Co(O_2CCH_3)_2{\cdot}2H_2O$, which contains two different types of bridging acetate ligands as well as a bridging water ligand, with a distorted octahedral geometry about the Co ions.[70] The unusual anion $[Co_3(O_2CCH_3)_8]^{3-}$, which contains a linear arrangement of three six-coordinate Co(II) ions and three different types of acetate coordination ($\mu_1\mu_2$, $\mu_1\eta_1$, and chelating) has also been structurally characterized in the salt $(NEt_4)_2[Co_3(O_2CCH_3)_8]$ (Figure 8).[71]

$Co(O_2CH)_2{\cdot}2H_2O$ is polymeric, with octahedral Co ions and monodentate bridging formate ions,[72] while polymeric anhydrous $Co(O_2CC_6H_5)_2$ contains both bridging and chelating benzoate ligands coordinated to octahedral Co(II) centers.[73] Discrete high-nuclearity complexes containing carboxylate ligands can be readily prepared, and complexes containing up to 13 Co(II) centers have been characterized.[74] $Co(O_2CCH_3){\cdot}4H_2O$ is used extensively as a catalyst in a number of industrial oxidations, most notably the synthesis of terephthalic acid from *p*-xylene in the presence of $Mn(O_2CCH_3){\cdot}4H_2O$ and HBr. Co(II) complexes such as cobalt oleate, cobalt ethylhexanoate, and cobalt linoleate, containing higher-molecular-weight carboxylate ligands, are used to accelerate drying in oil-based paints, varnishes, and inks.

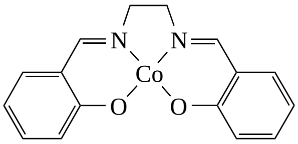
5.2.2 *Heterocyclic Ligands*

Co(II) complexes containing polypyridyl ligands have attracted attention due to their unusual spin properties. Magnetic susceptibility measurements of a number of black and brown $[Co(terpy)_2]X_2$ complexes ($X = Cl^-$, Br^-, I^-, $NO_3{}^-$) over the temperature range 4.2 to 293 K show a decrease in magnetic moment from ~3 to ~1.9 BM as the temperature is lowered, consistent with a transition from a 70:30 mixture of low-spin/high-spin forms at room temperature to pure

low spin at the lowest temperatures studied. The transition is gradual, in contrast to the abrupt changes seen in Fe(III)/(II) spin-crossover species. The red perchlorate salt behaves differently, exhibiting magnetic moments of 4.2 BM at room temperature and 3.5 BM at 4.2 K, and is thus predominantly high spin over the entire temperature range.[75] Room-temperature crystal structures of $[Co(terpy)_2](ClO_4)_2\cdot 1/2H_2O$ and $[Co(terpy)_2]Br_2\cdot 3H_2O$ ($\mu_{eff} = 2.94$ BM) show a shorter average Co–N bond length in the bromide salt, consistent with a greater proportion of low-spin molecules in this salt, although the exact extent of the structural difference between the high- and low-spin forms could not be determined because of both forms being disordered in the structure.[76] A higher proportion of the low-spin form is seen when the terpy complex (nitrate salt) is prepared in Zeolite Y,[77] and $[Co(bpy)_3]^{2+}$ also displays a thermal high-spin/low-spin interconversion when encapsulated in Zeolite Y, even though the free ion shows no evidence of a spin equilibrium at any temperature or with any counterion.[78] This behavior is thought to stem from the near-octahedral geometry imposed on the complex by the zeolite, in contrast to the trigonal prismatic distorted geometry adopted by the free complex.[79] The interconversion between the high- and low-spin forms of $[Co(terpy)_2]^{2+}$ is extremely rapid, as might be expected from a spin state change involving only one electron, with a relaxation time of less than 2 to 15 ns suggested by Raman laser T-jump and ultrasonic absorption experiments.[80,81]

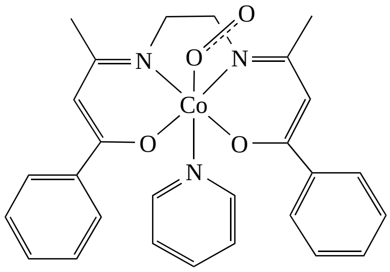
5.2.3 Oxygen Carrier Complexes

In 1933, Pfeiffer and Tsumaki reported that a solid sample of the red square-planar Co(II) complex [Co(salen)] (**15**) slowly turned black on exposure to air for several days. Tsumaki later showed that the color change was due to coordination of dioxygen and that this process could be reversed by heating the solid compound in a stream of CO_2.



(**15**)

Since this time, a variety of Co(II) complexes have been found to reversibly bind dioxygen, and complexes containing salen and other Schiff-base ligands have been extensively studied. Such complexes have been found to act as catalysts in the oxygenation of a variety of organic substrates by oxygen and hydroperoxides. These complexes bind oxygen reversibly both in solution and in the solid state in ratios of 1 or 0.5 mol of O_2 per mole of complex to give mononuclear species with a terminal O_2-derived ligand or binuclear species with a bridging O_2-derived ligand respectively, depending on the nature of the Schiff-base ligand. The oxygenation reactions are generally rapid, with rate constants for O_2 binding between 10^6 and 10^8 M^{-1} s^{-1} having been measured. The complexes slowly lose O_2-binding capacity, and this is thought to be due to ligand oxidation reactions. The first structurally characterized examples of oxygenated Schiff-base species, $\{[Co(salen)]_2(O_2)(dmf)_2\}$[82] and $\{[Co(3\text{-fluorosalen})]_2(O_2)(H_2O)\}_2$,[83] contained bridging O_2-derived ligands, with O–O distances of 1.339 (6) and 1.308 (28) Å respectively, consistent with a superoxo (*see Superoxide*) formulation for the O_2 bridge. Structural analysis of the monomeric species $[Co(bzacen)(py)(O_2)]$ (**16**) showed a six-coordinate Co ion and an O_2-derived ligand bound in a bent (Co–O–O = 126(2)°) monodentate fashion, with an O–O distance of 1.26(4) Å, again consistent with a superoxide formulation.[84] The ν(O–O) frequency of 1128 cm^{-1} also supports this assignment.



(**16**)

The exact nature of the metal–ligand interaction in these complexes has been the subject of intense debate, but it now appears generally accepted that significant electron transfer from Co to O_2 occurs on binding of the ligand and that the unpaired electron is located primarily on the ligand in both mononuclear and dinuclear species. Several non-Schiff-base complexes have also been found to bind dioxygen, most notably the amino acid complex $[Co(his)_2]$, which binds dioxygen reversibly in aqueous solution. The tris(3-*tert*-butyl-5-methylpyrazolyl)borate complex $Tp'Co(O_2)$ (Figure 9), which is formulated as a Co(II)-superoxo complex, contains a pseudotetrahedral Co ion coordinated to a side-on bound superoxide ligand. The O–O distance of 1.262(8)Å and the ν(O–O) frequency of 961 cm^{-1} is consistent with this formulation, while the magnetic moment of 3.88 BM at 298 K requires strong antiferromagnetic coupling between the metal and the superoxide ligand to give an $S = 1$ ground state with a large orbital component.[85] An unusual bis(μ-superoxo) complex containing a Tp′ ligand has also been characterized (Figure 10),[86] as has the mixed-valence Co(II)-Co(III) bis(μ-superoxo) complex (**17**) containing Me_3TACN.[87]

The dicobalt complex of the cryptand ligand O-BISTREN (**18**) displays reversible oxygenation in aqueous solution, with the maximum concentration of the oxygenated species being observed over the pH range 7.8 to 8.8. Purging

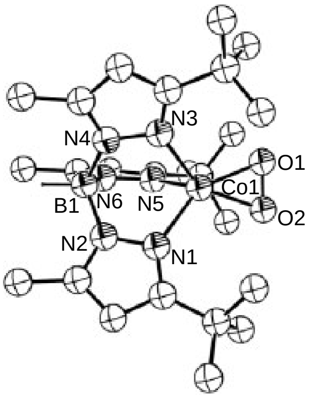


Figure 9 Structural diagram of [(HB(3-*t*-Bu-5-Mepz)$_3$)Co(O$_2$)]

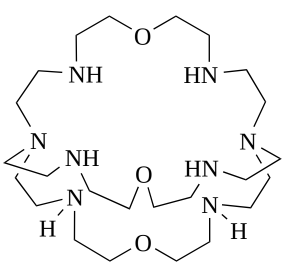
(**17**)

a solution of the oxygenated complex with N$_2$ regenerates the UV/vis spectrum of the starting material, which then reoxygenates on exposure to air. Heating the solution of the oxygenated complex to 75 °C also results in deoxygenation, and the oxygenated complex is regenerated on cooling. Irreversible degradation of the complex to what is thought to be a dicobalt(III) complex is observed above 90 °C.

5.3 Co(III) Complexes

Complexes of Co(III) are arguably the best studied of all transition metal complexes. They are easily prepared,



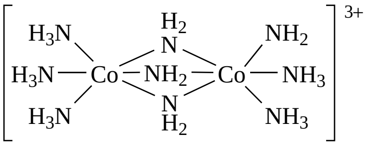
(**18**)

generally from Co(II) precursors, they exhibit a huge variety of colors, they are usually air- and light-stable, and their relative inertness to ligand exchange allows purification by column chromatography and facilitates studies of these complexes in solution. The $t_{2g}{}^6e_g{}^0$ electron configuration means that these complexes are diamagnetic and allow NMR to be used as a tool for structural characterization, while their well-defined d-d bands in the UV/vis region provide a convenient spectroscopic handle for studies of their reactions in solution. Their slow rates of ligand exchange allow rate data for these reactions to be collected by conventional means using a variety of techniques, and also allow studies of the reactivity of coordinated ligands to be made. Co(III) is a prototypical 'hard' metal ion and generally binds aliphatic N- and O-donor ligands particularly well. However, there are many examples of stable complexes containing S-, As-, P- and even C-donor ligands. Despite its high oxidation state, Co(III) can bind quite strongly, reducing ligands such as thiolates, $H_2PO_2{}^-$, $H_2PO_3{}^-$, $NO_2{}^-$, $SO_3{}^{2-}$, and $S_2O_3{}^{2-}$ without undergoing internal redox reactions. Similarly, complexes containing strongly oxidizing ligands such as $MnO_4{}^-$ and $CrO_4{}^{2-}$ are stable.

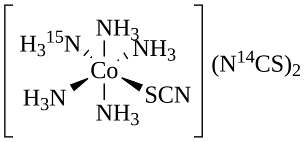
5.3.1 *Ammine and Amine Complexes*

The golden yellow $[Co(NH_3)_6]^{3+}$ cation can be prepared by air oxidation of an ammoniacal solution of Co(II) in the presence of charcoal. $[Co(NH_3)_6]Cl_3$ crystallizes in the monoclinic space group $C2/m$, and the X-ray structure shows four independent $[Co(NH_3)_6]^{3+}$ units, none of which display perfectly octahedral symmetry. Co–N bond lengths lie in the range 1.955 to 1.983 Å.[88] $[Co(NH_3)_6]^{3+}$ undergoes proton exchange even in mildly acidic solution via a mechanism involving deprotonation of the coordinated ammonia ligands, attesting to the enhanced acidity of these ligands on coordination to the 3+ metal center. This is further evidenced by the fact that treatment of $[Co(NH_3)_6](ClO_4)_3$ with KNH_2 in liquid ammonia at 100 °C gives the triply amido-bridged dimer $[(NH_3)_3Co(NH_2)_3Co(NH_3)_3](ClO_4)_3$ (**19**), which is stable in aqueous solution.

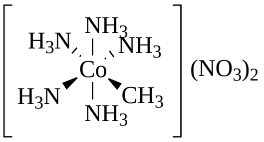
Literally hundreds of Co(III) complexes having the formula $[Co(NH_3)_5X]^{n+}$ have been reported, and there are few commonly available ligands that have not been coordinated to the $[Co(NH_3)_5]^{3+}$ moiety. The complexes span a vast range of reactivities in aqueous solution, from



(**19**)



(**20**)



(**21**)

$[Co(NH_3)_5OClO_3]^{2+}$, which has a $t_{1/2}$ of 7 s for hydrolysis, to $[Co(NH_3)_6]^{3+}$, which has a half-life of thousands of years. $[Co(NH_3)_5X]^{n+}$ complexes can be synthesized from Co(II) starting materials, but are often more conveniently prepared from formally substitutionally inert $[Co(NH_3)_5X]^{n+}$ species containing X ligands that can be chemically labilized. Thus, treatment of $[Co(NH_3)_5Cl]^{2+}$ with either Ag^+ or Hg^{2+} in a noncoordinating solvent in the presence of the entering ligand has been used to prepare a large number of $[Co(NH_3)_5X]^{n+}$ complexes. Similarly, treatment of $[Co(NH_3)_5OCO_2]^+$ with acid or treatment of $[Co(NH_3)_5(N_3)]^{2+}$ with NO^+ in noncoordinating solvents generates very labile leaving groups, which can be easily replaced by a wide variety of entering ligands. Complexes such as $[Co(NH_3)_5OSO_2CF_3]^{2+}$ and $[Co(NH_3)_5OSMe_2]^{3+}$, which contain labile ligands, are also useful in synthesis. The mechanism of ligand substitution in $[Co(NH_3)_5X]^{n+}$, and numerous other Co(III) complexes, has been the topic of an enormous number of studies. The rates of hydrolysis of these complexes show significant dependence on the nature of the leaving group, while the rates of the reverse (anation) reactions are relatively insensitive to the identity of the entering ligand. These and other observations are consistent with a mechanism having dissociative character in which bond breaking to the leaving group is rate determining, although the question of whether a true five-coordinate intermediate is produced has yet to be conclusively answered. The rates of base hydrolysis of these and other similar Co(III) complexes show a first-order dependence on $[OH^-]$, which is consistent with am(m)ine deprotonation prior to loss of the leaving group. This has been termed the S_N1CB mechanism, and a review of the historical development of this chemistry is available.[89] Despite their apparent simplicity, much elegant chemistry has been carried out on $[Co(NH_3)_5X]^{n+}$ systems, and a selection of these studies are outlined below. The CN^- ligand binds to metal ions almost exclusively through the carbon atom, but the unusual N-bound isocyano complex $[Co(NH_3)_5NC]^{2+}$ can be formed through selenium extrusion from $[Co(NH_3)_5NCSe]^{2+}$ by treatment with CN^- in aqueous solution,[90] equation (3).

$$[(NH_3)_5CoNCSe]^{2+} + CN^- \longrightarrow [(NH_3)_5CoNC]^{2+} + SeCN^- \quad (3)$$

The thermal isomerization of the purple S-bound *trans*-$[Co(NH_3)_4(^{15}NH_3)SCN](N^{14}CS)_2$ complex (**20**) to the thermodynamically stable red N-bound isomer has been studied in the solid state (*see Ambidentate Ligand*), and the results are consistent with backside attack by ionic lattice thiocyanate as well as an intramolecular process. These results mirror those found in solution.[91]

The remarkable complex $[Co(NH_3)_5CH_3](NO_3)_2$ (**21**), which could reasonably be called an organometallic Werner complex, can be prepared by air oxidation of an ammoniacal solution of Co(II) nitrate in the presence of methylhydrazine. The complex is stable in dilute aqueous ammonia solution for several months at 4 °C in the solid state.[92] The Co–C bond length is 1.980(2) Å, while the four cis Co–N bond lengths lie between 1.97 and 1.98 Å. The trans Co–N bond length of 2.1048(14) Å, shows the significant trans effect (*see Trans Effect*) exerted by the methyl ligand, and this is also manifested in the reactivity of $[Co(NH_3)_5CH_3]^{2+}$, which undergoes substitution of the normally inert ammonia ligands with remarkable ease.

The chelated phosphoramidate (**22**) is formed as an intermediate in the reaction of $[Co(NH_3)_5(DNPP)]^+$ in alkaline solution, through intramolecular nucleophilic attack of a deprotonated *cis*-ammine (Scheme 1).[93] Similar reactivity is observed in the monodentate pyruvate complex $[Co(NH_3)_5OC(O)C(O)CH_3]^{2+}$, where the imino carboxylate chelate (**23**) is formed at pH > 12.[94]

While a huge number of Co(III) ammine complexes have been prepared, there are markedly fewer Co(III) alkylamine complexes known, presumably due to the steric demands imposed by these larger ligands. Both $[Co(MeNH_2)_6]^{3+}$ and $[Co(NH_2OH)_6]^{3+}$ are known, and a small number of $[Co(RNH_2)_5X]^{n+}$ (R = Me, Et, Pr, Bu, *iso*-Bu) complexes have been prepared. The ethylenediamine (en) ligand (1,2-diaminoethane) occupies an important position in the development of coordination chemistry and a vast number of Co(III) complexes containing this ligand are known. In the majority of cases, the ethylenediamine ligand coordinates as a bidentate chelate, but complexes such as *cis*-$[Co(en)_2(enH)Cl](Cl)(ZnCl_4)$[95] (**24**) and $[Co(NH_3)_5(enH)]Cl_4$[96] (**25**) contain rare examples of monodentate ethylenediamine (*see Chelate Effect*).

The golden yellow $[Co(en)_3]^{3+}$ can exist as Δ and Λ enantiomers, and each chelate ring can adopt a δ- or λ-conformation. The enantiomers can be separated by crystallization using a chiral anion such as d-tartrate.

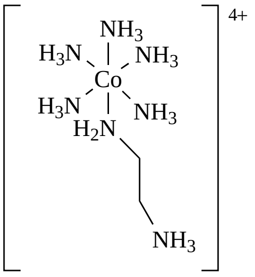
(24)



(25)

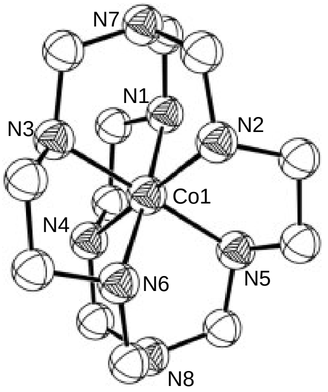


Figure 11 Structural diagram of the $[Co(sep)]^{3+}$ cation

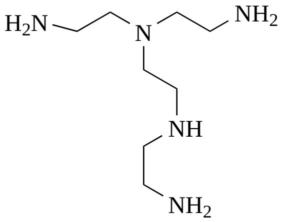
Δ- and Λ-$[Co(en)_3]^{3+}$ undergo enantioselective binding with nucleotides, and the Δ isomer has been found to bind more strongly than the Λ to the major groove of the dodecanucleotide d(CAATCCGGATTG)$_2$. Co(III) complexes of a large number of bidentate diamine ligands such as 1,2-diaminopropane, 2,3-diaminobutane, 1,3-diaminopropane, and 1,2-diaminocyclohexane have been prepared and studied and a comprehensive review of their chemistry is available.[97] It is worth noting that $[Co(\pm\text{-1,2-diaminopropane})_3]^{3+}$, an apparently simple tris chelate complex, has a staggering 48 possible isomeric forms, comprising enantiomeric pairs, ring conformational isomers, and configurational isomers resulting from the relative positions of the methyl groups. The $[Co(en)_3]^{3+}$ ion has been used as a template for the synthesis of a large number of cage compounds. The first of these was prepared by treatment of Λ-$[Co(en)_3]^{3+}$ with HCHO and NH_3 at room temperature to give the sepulchrate $[Co(sep)]Cl_3{\cdot}H_2O$ in >95% yield (Figure 11).[98] The reaction is stereospecific, and gives only one out of a possible 16 isomers. The mechanism of formation is complex, and involves initial deprotonation of a coordinated ethylenediamine $-NH_2$ group and subsequent condensation with HCHO to give the imine, which then reacts with NH_3. This process is repeated until deprotonation of all six nitrogen atoms has occurred and the cage is formed. Reduction of the complex with zinc dust in mildly acidic conditions gives the Co(II) complex, which, remarkably, retains its absolute configuration and shows no exchange with added $^{60}Co^{2+}$ over one day.

Replacement of NH_3 with CH_3NO_2 in the reaction mixture leads to the production of the nitro-substituted C-capped 'sarcophagine' cage $[Co(diNOsar)]Cl_3{\cdot}H_2O$, which was originally prepared on a 156-g scale! The parent complex $[Co(sar)]Cl_3$ can be obtained following reduction to the diamine, nitrosation in the presence of Cl^-, and reductive dehalogenation. A large number of cages having a variety of capping substituents have been prepared, and the carbon bridgehead atoms can be replaced by N, P, P(O), and As. The Co(II) sarcophagine complexes are again kinetically inert, and resolved $[Co(sar)]^{2+}$ does not racemize in solution over 2 h. The metal ion can, however, be removed under forcing conditions, either in concentrated HCl at 130 °C in a sealed

tube or by treatment with NaCN at 65 °C for 6 h in aqueous solution.

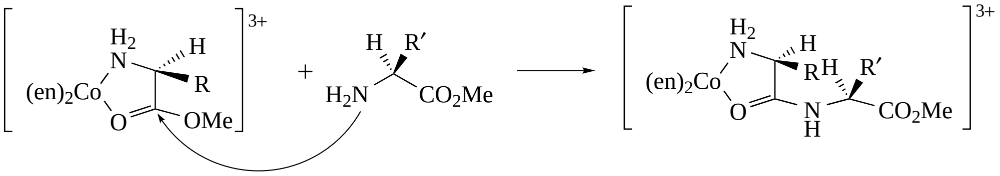
$[Co(en)_2X_2]^{n+}$ can exist as geometric isomers in cis and trans forms, with the violet *cis*-$[Co(en)_2Cl_2]^+$ and green *trans*-$[Co(en)_2Cl_2]^+$ cations being the textbook examples. The cis forms of $[Co(en)_2X_2]^{n+}$ complexes can also exist as enantiomers. The $[Co(en)_2]^{3+}$ moiety has been used as a combined protecting and activating group in peptide synthesis reactions, where reaction of $[Co(en)_2AAOMe]^{2+}$ complexes with an amino acid ester rapidly gives the coordinated peptide (Scheme 2). These reactions proceed with high retention of stereochemistry, and the coordinated peptide can be removed from the metal center by chemical or electrochemical reduction of the complex.[99]

The chemistry of Co(III) complexes of polyamine ligands has been extensively studied. Linear polyamines containing three or more N atoms give rise to numerous isomers on coordination to Co(III), due to the many possible ways of folding the ligand about the metal ion, and the differing possible orientations of protons on the secondary N atoms. For example, there are 9 possible isomers of the $[Co(trien)Cl_2]^+$ cation and 15 possible isomers of $[Co(tetraen)X]^{n+}$ systems. A significant body of meticulous work concerning the separation and characterization of such isomers exists and has contributed much to our ideas of inorganic stereochemistry. Crucial to much of this work has been the use of ion-exchange chromatography (*see Ion Exchange*) to effect separation of isomers, and this technique is now an indispensable part of Co(III) chemistry. Tripodal tetraamine ligands (*see Tetradentate Ligand*) such as tris(2-aminoethyl)amine (tren) and tris(3-aminopropyl)amine (trpn) have fewer isomeric possibilities on coordination to Co(III) than their linear tetraamine counterparts, although geometric isomers occur through the inequivalence of the remaining two coordination sites, and this property has been used in studies of $[Co(tren)XY]^{n+}$ complexes in particular to elucidate the amount of stereochemical change in anation and hydrolysis reactions. Co(III) complexes of the type $[Co(N)_4(OH/H)(OH/H)]^{+/2+/3+}$, where $(N)_4$ is a tripodal or macrocyclic tetraamine ligand, have been found to be efficient agents for the hydrolysis of phosphate esters, nitriles, polyphosphates, organic esters, and amides, with maximum rates found at around neutral pH values. The pentadentate ligand (*see Pentadentate Ligand*) trenen (**26**) is difficult to prepare by conventional routes, but the intramolecular condensation reaction of $[Co(tren)Cl(NH_2CH_2CHO)]^{2+}$ (**27**) under alkaline conditions and subsequent BH_4^- reduction of the resulting imine gives $[Co(trenen)Cl]^{2+}$ (**28**) in excellent yield (Scheme 3).

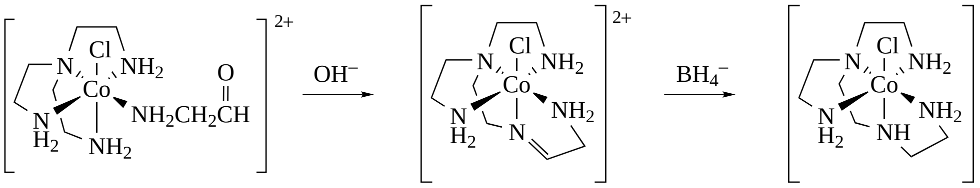


(**26**)

Co(III) complexes of macrocyclic amine ligands are well known, and such complexes display some interesting chemistry. The secondary N–H protons in $[Co(cyclen)XY]^{n+}$ complexes are remarkably acidic due at least in part to the high formal charge on the metal ion, and as a result, proton exchange occurs with great ease. This has significant effects on the reactivity of such complexes. For example, the carbonato chelate $[Co(cyclen)O_2CO]^+$ (**29**)



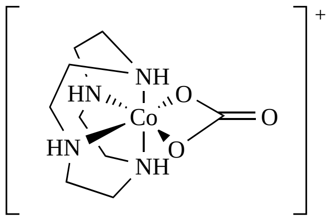
Scheme 2 Co(III)-promoted peptide synthesis



(**27**) (**28**)

Scheme 3 Intramolecular synthesis of the trenen ligand

undergoes base-catalyzed ring opening in 1.0 M OH^- at least 1000 times more rapidly than either $[Co(tren)O_2CO]^+$ or $[Co(en)_2O_2CO]^+$, and this has been attributed to the higher concentration of N–H deprotonated species in the cyclen complex. Spectrophotometric evidence for the participation of singly deprotonated complexes in the ring-opening reaction has been obtained, while kinetic data are also consistent with the involvement of doubly N–H deprotonated species in the hydrolysis of the resulting monodentate carbonate complex.



(**29**)

The highly acidic nature of Co(III) cyclen complexes is confirmed by the measured pK_a values for $[Co(cyclen)en]^{3+}$ and $[Co(cyclen)tn]^{3+}$ of 12.92 and 12.21 respectively, with deprotonation giving a color change from orange to red.[100] Co(III) cyclen complexes also offer isomeric possibilities with respect to the syn or anti configuration of the equatorial N–H protons relative to the remaining two coordination sites in the complex. These isomers can be fully characterized in solution using nOe and COSY ^{1}H NMR spectroscopy, and the substitution-inert nature of the Co(III) center has allowed them to be separated by ion-exchange chromatography, crystallized, and characterized by X-ray crystallography.[101] Co(III) complexes containing predominantly monodentate aromatic amine ligands are much less numerous than their ammine counterparts. $[Co(py)_6]^{3+}$ is unknown, although the $[Co(imH)]^{3+}$ ion has been reported, and there are no reported $[Co(py)_5X]^{n+}$ complexes. Green *trans*-$[Co(py)_4Cl_2]Cl\cdot 6H_2O$ can be prepared by liquid chlorine oxidation of a methanolic solution containing pyridine and anhydrous $CoCl_2$,[102] and has proved to be a useful starting material for the synthesis of a variety of Co(III) complexes.[103] The $[Co(py)_4O_2CO]^+$ ion shows extraordinary stability in acidic solution, with its UV/vis spectrum remaining essentially unchanged over 2 h in 1 M HCl at room temperature. Use of more concentrated acids leads to an eventual decarboxylation, but this is immediately followed by rapid reduction to Co(II) species. Similar behavior has been observed in acidic solutions containing the $[Co(tepa)O_2CO]^+$ ion, and the unusual chelated bicarbonate complex $[Co(tepa)O_2COH](ClO_4)_2\cdot 3H_2O$ (Figure 12) can be crystallized from 2.7 M $HClO_4$ solution. The reasons for the stability of these complexes in acidic solution and for the reduction of the hydrolysis product are not immediately apparent, but the presence of pyridyl ligands is a requirement for such behavior.

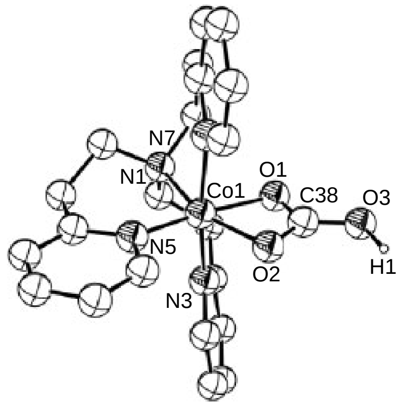


Figure 12 Structural diagram of the $[Co(tepa)O_2COH]^{2+}$ cation

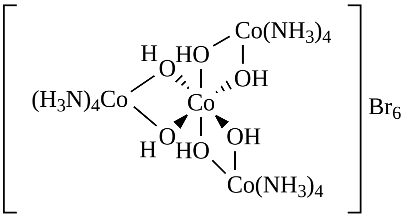
5.3.2 O-donor Ligands

There are few examples of Co(III) complexes that contain solely O-donor ligands, and these almost invariably have limited stability in aqueous solution. Ironically, their very instability makes them ideal candidates as starting materials for the synthesis of other Co(III) complexes, and $Na_3[Co(O_2CO)_3]\cdot 3H_2O$, $K_3[Co(ox)_3]$, $Co(acac)_3$, and $Na_3[Co(NO_2)_6]$ have all proven useful in this respect. One of the earliest characterized examples of a Co(III) ion with complete O-ligation was the tetrameric complex $[Co\{Co(OH)_2(NH_3)_4\}_3]Br_6$ (**30**), first prepared by Jørgensen. This was resolved into its enantiomers by Werner, and in so doing, he showed conclusively that optical activity was not a phenomenon associated solely with carbon.



(**30**)

Co(III) carboxylate complexes can be prepared by oxidation of a Co(II) carboxylate with oxygen, ozone, and peracids, and these have been widely used as homogeneous catalysts for the oxidation of a wide variety of organic substrates. Despite this, the exact structures of these complexes remain unknown. The dark green solution obtained on oxidation of cobalt(II) acetate in acetic acid is thought to primarily contain the trinuclear μ_3-oxo (*see μ-Oxo Bridge*) complex $[Co_3O(OAc)_6(HOAc)_3]^+$, although this has yet to be confirmed by X-ray structural analysis of the solid obtained on removal of the solvent. Evidence for the presence of a trinuclear mixed-valence $Co(III)_2Co(II)$

species and a hydroxo-bridged dimer $[Co_2(OAc)_4(OH)_2]$ has also been obtained. However, the dark red–brown complex $[Co_3O(OAc)_6(py)_3](ClO_4)\cdot H_2O$ has been shown by X-ray crystallography to adopt a triangular structure (Figure 13).[104]

Tetranuclear Co(III) carboxylate complexes having the formula $[Co_4O_4(O_2CR)_2(bpy)_4](ClO_4)_2$ have been prepared and characterized. These are built around a central cubane-type $[Co_4O_4]^{4+}$ core (Figure 14) and, most interestingly, exhibit a reversible one-electron oxidation to give what are formally $Co(III)_3Co(IV)$ species.[105]

A large number of high-nuclearity Co(III) and mixed-valence Co(III)Co(II) carboxylate-based species containing up to 13 cobalt ions are known, and a review of these is available.[74] The unusual polynuclear chemistry of Co(III) carboxylates is not mirrored in Co(III) complexes of other oxoanions (*see Oxoanion*); these are generally mononuclear, and with the homoleptic exceptions described at the beginning of this section, usually contain N-based ancillary ligands. Complexes such as $[Co(en)_2O_2CO]^+$ and $[Co(en)_2O_2PO_2]$ containing chelated oxoanions are well known, despite the

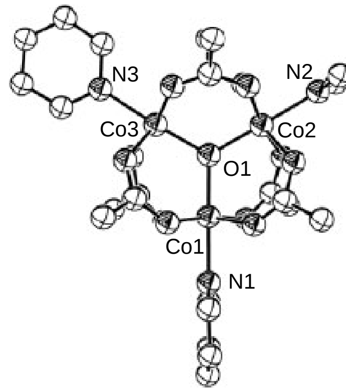


Figure 13 Structural diagram of the cation of $[Co_3O(OAc)_6(py)_3](ClO_4)\cdot H_2O$

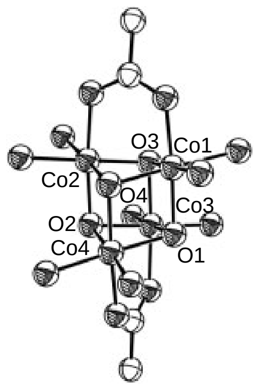

Figure 14 Structural diagram showing the coordination environment of the Co ions in the cation of $[Co_4O_4(O_2CC_6H_4NO_2)_2(bpy)_4](ClO_4)_3$

distortion from octahedral geometry caused by the presence of the four-membered chelate ring (O–Co–O angles of 68.39° and 75.74° respectively).[106,107] The acid hydrolysis of chelated carbonate in a variety of $[Co(L)_nO_2CO]^+$ complexes is a well-studied reaction. A detailed spectrophotometric study of the acid hydrolysis of the $[Co(en)_2O_2CO]^+$ ion showed biphasic kinetics corresponding to consecutive first-order processes involving chelate ring opening and subsequent hydrolysis of the monodentate bicarbonate ion. Protonation of the chelated carbonate is significant, with K_a for the bicarbonate chelate being ~1 M.[108] A subsequent study of a variety of $[Co(L)_nO_2CO]^+$ complexes rationalized the large variation in acid hydrolysis rates with changing L (approximately seven orders of magnitude) in terms of the differing ability of the complexes to transfer the proton on the exo-oxygen to an endo (coordinated) oxygen atom, thus effecting ring opening, as the rates for hydrolysis of the monodentate bicarbonate were fairly constant over the range of complexes studied.[109] Somewhat surprisingly, $[Co(en)_2O_2SO_2]^+$ is unknown, with attempted syntheses of this giving the bis-monodentate sulfato bridged dimer $[(en)_2Co(OS(O)_2O)_2Co(en)_2]^{2+}$,[110] and the first crystallographically characterized example of a chelated Co(III) sulfato complex, $[Co(trpn)O_2SO_2]ClO_4\cdot H_2O$, has been reported only relatively recently.[111] Chelated nitrate is found in the unusual tris chelate $[Co(O_2NO)_3]$[112] and doubly chelated phosphate acts as a bridging ligand in $[(trpn)CoO_2PO_2Co(trpn)](ClO_4)_3\cdot 3H_2O$.[113] There are a vast number of Co(III) complexes containing monodentate oxoanion ligands as diverse as NO^-, NO_2^-, SO_3^{2-}, $S_2O_3^{2-}$, ReO_4^-, ClO_4^-, and $CF_3SO_3^-$. The isomeric nitrite complexes $[Co(NH_3)_5ONO]^{2+}$ (pink) and $[Co(NH_3)_5NO_2]^{2+}$ (yellow) provided the first examples of linkage isomers (*see Linkage Isomerism*) in coordination chemistry, and the spontaneous isomerization of the O-bound nitrito to the N-bound nitro complex has been well studied both in solution and in the solid state, with an intramolecular mechanism being proposed in both cases. The reverse reaction can be photochemically induced, and again occurs via an intramolecular mechanism. Similar linkage isomerism has been seen in complexes containing $S_2O_3^{2-}$ (O-bound to S-bound), sulfinate (S-bound to O-bound), sulfamate (N-bound to O-bound) and SO_3^{2-} (O-bound to S-bound) ligands. Coordination of water to a Co(III) center increases its acidity significantly and such aqua complexes typically have pK_a values ranging from 5 to 8. The resulting hydroxo complexes are potent nucleophiles toward a variety of organic and inorganic substrates. Of particular interest in this respect are complexes containing two cis-disposed aquo ligands; monodeprotonation of these gives cis-aqua/hydroxy complexes, which have been found to be efficient agents for the remarkably rapid stoichiometric hydrolysis of phosphate esters, polyphosphates, organic esters, nitriles, and amides around neutral pH values. Such reactions proceed at least in part via an intramolecular mechanism involving initial coordination of the substrate to the Co(III) center followed by intramolecular nucleophilic

attack of the coordinated hydroxide. Given the normally slow rates of ligand exchange in Co(III) complexes, such rapid reactions might be considered anomalous. However, ^{17}O NMR studies of water exchange rates in a number of $[Co(N)_4(OH/H)(OH/H)]^{+/2+/3+}$ complexes ($(N)_4$ = tren, cyclen, N-Mecyclen) have shown that, whereas the diaqua and dihydroxo complexes undergo relatively slow exchange with solvent water ($k_{ex} \sim 10^{-7}$–$10^{-4}\,s^{-1}$), the aquahydroxy complexes react approximately five orders of magnitude more rapidly ($k_{ex} \sim 10^{-2}$–$10^{1}\,s^{-1}$), thus allowing rapid anation of these species. This remarkable reactivity difference has been ascribed to the ability of the complex to partially transfer a proton to the departing hydroxide ligand in the transition state for Co–OH bond cleavage, and the cyclen complexes are particularly efficient in this respect.[114] Neutral O-donor ligands such as alcohols, ketones, esters, and ethers are generally poor ligands toward Co(III) and such ligands are usually rapidly replaced by water in aqueous solution.

5.4 Co(IV) and Co(V) Complexes

Although both the alkyl complex $[Co(nor)_4]$ (Figure 15)[115] and the hydride complex $[Co(C_5Me_5)(Si(H)Ph_2)_2(H)_2]$ (Figure 16)[116] offer well-characterized examples of organometallic Co(IV) and Co(V) complexes, the situation with 'classical' coordination complexes is much less clear.

The majority of reported Co complexes in oxidation states higher than 3+ contain noninnocent ligands, and this hence renders the assignment of metal oxidation state difficult. This problem has existed since Werner's time; indeed, he initially formulated the superoxo-bridged dimers $[(NH_3)_4Co(O_2)(NH_2)Co(NH_3)_4]^{4+}$ and $[(en)_2Co(O_2)(NH_2)Co(en)_2]^{4+}$ as mixed-valence peroxo-bridged Co(III)/(IV) complexes. One-electron oxidation of the unusual square-planar Co(III) complex (**31**) using Ce(IV) gives a deep blue low-spin species. This is soluble and stable in benzene, and exhibits a reversible one-electron reduction at 1.26 V versus NHE. EPR data indicate that the unpaired electron is located primarily on the metal center, although Co(II) resonance contributors are also possible, owing to the presence of the noninnocent diaminobenzene fragment.[117]

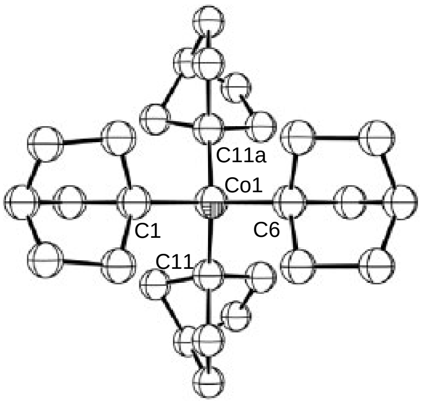

Figure 15 Structural diagram of the organometallic Co(IV) complex $[Co(nor)_4]$

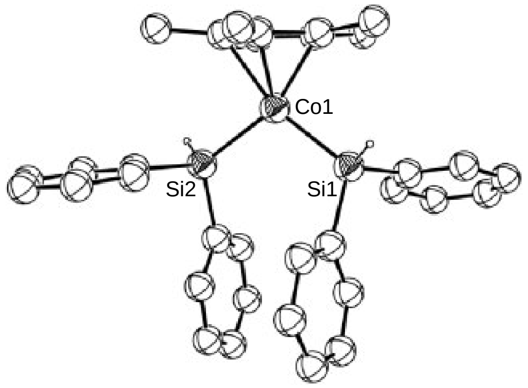

Figure 16 Structural diagram of the organometallic Co(V) complex $[Co(C_5Me_5)(Si(H)Ph_2)_2(H)_2]$. Hydride ligands bound to the Co are not shown

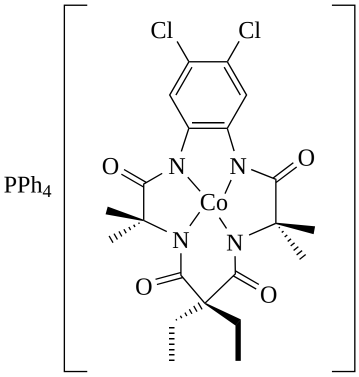


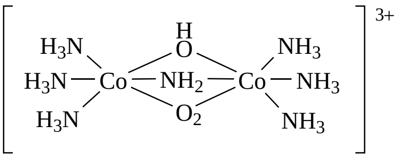
(**31**)

The corrole complex $[Co(OEC)(C_6H_5)]$, which was originally formulated as a Co(IV) complex,[118] has since been shown to have significant spin density on both the metal ion and the corrole ligand,[119] while EPR data collected on electrochemically generated $[Co(S_2CNR_2)_3]^+$ complexes (R = Et, cyclohexyl) are consistent with a Co(IV) formulation.[120] Obviously, the stabilization of highly oxidizing Co(IV) and Co(V) complexes remains a challenge for synthetic chemists.

6 CONCLUDING REMARKS

'... we desire to state our conviction that the subject is by no means exhausted, but that on the contrary there is scarcely a single point which will not amply repay a more extended

study'.[1] The words of Gibbs and Genth are as true today as they were in the mid-nineteenth century. Similarly, Werner's influence extends even into the twenty-first century, with a paper published in 2001 (coauthored by Werner!) reporting the crystallographic characterization of $[(NH_3)_3Co(\mu\text{-}OH)(\mu\text{-}O_2)(\mu\text{-}NH_2)Co(NH_3)_3](NO_3)_3 \cdot 1.25H_2O$ (**32**), using crystals prepared in Werner's laboratory around 1909.[121] This represents the first crystallographically characterized example of a triply bridged transition metal complex containing O_2^{-}, NH_2, and OH bridges.



(**32**)

Cobalt chemistry, nowadays, might be regarded by some as unfashionable but its importance, both historical and current, is undeniable, as demonstrated by the work outlined in this chapter. Cobalt will always retain its capacity to surprise, as evidenced by the recent serendipitous isolation of both $[Co(tmen)(OH_2)(H)](NO_3)(ClO_4) \cdot C_2H_5OH$ (**33**), a hydride complex that can be recrystallized from 5 M aqueous $HClO_4$[122] and (**34**), a carbanionic perchlorato complex isolated from aqueous solution.[123] We await further developments in cobalt chemistry with interest.

1 INTRODUCTION

From the time of Alfred Werner, the coordination chemistry of cobalt has been dominated by the synthesis and reactions of octahedral Co^{III} complexes (*see* ***Coordination Chemistry: History***). In contrast, the organometallic chemistry of cobalt displays a great diversity of structures and oxidation states. In addition, the transition from organometallic to pure coordination chemistry, that is, the change from a set of π-acceptor (*see π-Acid Ligand*) to σ-donor ligands (*see σ-Donor*), is smoother for cobalt than for its neighboring elements of the same period. For example, organometallic complexes in higher oxidation states, in particular Co^{III}, are more common than the rare examples found with manganese, iron, and nickel, and are encountered not only with strong σ-donors such as alkyl (*see Alkyl Complexes*) and hydride (*see Hydrides*), but also with the harder halide ligands. This trend is also valid for Co^{II} organometallic complexes (*see Organometallic Complexes*).

Owing to the odd number of valence electrons in the element (nine), the formal oxidation state +I is prominent in the organometallic chemistry of cobalt, as documented by the vast diversity of complexes of the type $CpCoL_2$ (Section 5). A particular feature of cobalt organometallic chemistry is the relative abundance of low oxidation state (i.e. −I) complexes, not only with carbonyl but also with phosphine (Section 5.1.3) and alkene ligands (*see Alkene Complexes*) (Section 5.1.2). Co^{II} is confined to sandwich complexes (*see Sandwich Compound*), mostly of the bis(cyclopentadienyl) type, and to a few mono- and dinuclear $CpCo^{II}$ half-sandwich complexes. More abundant are $CpCo^{III}$ half-sandwich complexes. This class of compound is closest to analogous rhodium complexes, although the coordination chemistry of cobalt and rhodium is more similar than is the organometallic chemistry of these metals.

A general introduction and overview of the organometallic chemistry of cobalt is intended in this article. In each section, a description of a few basic types of complexes is presented. These compounds have played a major role in developing the scope of the known organometallic chemistry of cobalt. Proceeding from these basic complexes as a starting point, more specialized compounds (which are treated and understood as derivatives) will be described. Special emphasis is placed on complexes and reactions that have opened or may open new synthetic transformations of organic molecules. Early reviews of the organometallic chemistry of cobalt can be found in the treatise by White[1] and in the articles in *Comprehensive Organometallic Chemistry*;[2] the latter have been updated.[3]

2 COBALT CARBONYLS

2.1 $Co_2(CO)_8$

Together with $Ni(CO)_4$ and $Fe(CO)_5$, dicobaltoctacarbonyl, $Co_2(CO)_8$ (**1**), was among the earliest metal carbonyls (*see Metal Carbonyls*) to be detected and characterized by Mond and coworkers.[4,5] It was prepared from finely divided metal (or by hydrogen reduction of the oxide, CoO) in a Cu-lined autoclave made from Ni steel at 150 °C and a CO pressure of 30–40 bar. Other preparations employ reductive carbonylation of cobalt salts, mainly $Co(OAc)_2$, or the carbonylation of an alkaline cobalt cyanide solution.[6] The acetate salt is also the common precursor for $Co_2(CO)_8$ or $Co(CO)_4H$ in the Co-catalyzed hydroformylation (*see Hydroformylation*) process (Section '$HCo(CO)_4$ in Hydroformylation Reactions').

Among the earliest known reactions of $Co_2(CO)_8$ was oxidation to Co^{II} salts by halogens with liberation of CO (a

method used as an analytical tool to determine its molecular composition), slow air oxidation of the solid to give a violet basic carbonate and, noticeably, controlled thermal decomposition. Though molecular weight measurements in benzene indicated the formula $Co_2(CO)_8$, the orange compound was formulated as the radical $Co(CO)_4$. As with other metal carbonyls, the discoverers of $Co_2(CO)_8$ were puzzled by its properties and composition, which did not fit into the accepted concepts of chemical bonding at the time. An X-ray structure determination of crystals of (**1**) and its subsequent IR investigation in solution have disclosed three different structures: a C_{2v} isomer (**1a**) with two bridging CO groups in the solid state, a D_{3d} isomer (**1b**), and another isomer (**1c**) of unknown structure (possibly of D_{2d} point symmetry) in solution (Figure 1).

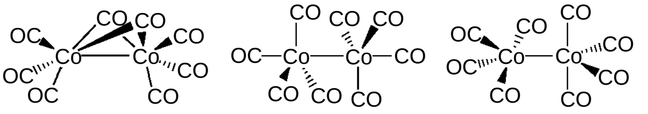
The structure of $Co_2(CO)_8$ has been investigated with computational techniques. In one study, 19 homoleptic binary carbonyls were probed using Density functional theory (DFT) methods; theoretical structures of C_{2v}, D_{3d}, and D_{2d} symmetries were found as energetic minima in agreement with experimental data.[7]

2.1.1 *Substitution at $Co_2(CO)_8$*

Despite the relatively low bond energy of the Co–CO bond in $Co_2(CO)_8$ ($92\,kJ\,mol^{-1}$, the same strength as in $Ni(CO)_4$, cf. $Fe(CO)_5$ at $156\,kJ\,mol^{-1}$), CO substitution in $Co_2(CO)_8$ is complicated by the interference of valence disproportionation (*see Disproportionation*). CO substitution to give a monosubstituted complex has been observed with a few donor ligands such as PPh_3 and $AsPh_3$ in nonpolar solvents. The kinetics of the reaction between $Co_2(CO)_8$ and $AsPh_3$ are zero order in ligand and first order in metal carbonyl. From other characteristics of the reaction, such as noninterference of O_2 and a rate very close to the one found for ^{13}CO exchange under the same conditions, a dissociative mechanism with rate-determining CO dissociation (*see Dissociation*) followed by fast recombination with the ligand (equations 1 and 2) was concluded.[8]

$$Co_2(CO)_8 \rightleftharpoons Co_2(CO)_7 + CO \quad (1)$$

$$Co_2(CO)_7 + L \rightleftharpoons Co_2(CO)_7L \quad (2)$$



2071, 2044, 2042, 1866, 1857 cm^{-1} 2069, 2032, 2055 cm^{-1}

(**1a**) C_{2v} (**1b**) D_{3d} (**1c**) D_{2d}

Figure 1 Possible structures of $Co_2(CO)_8$

The addition of strongly basic phosphines in polar solvents give the ionic products $[Co^I(CO)_3(PR_3)_2][Co(CO)_4]$ (see below). Valence disproportionation in the presence of these ligands generates Co^I and Co^{-I} instead of Co^{II} and Co^{-I}, as is the case with only σ-donor ligands. Cations $[Co(CO)_{5-n}L_n]^+$ ($n = 1, 2, \ldots$) of coordination number five and trigonal bipyramidal structure (*see Trigonal Bipyramidal*) are known with many different substituents, and can be isolated from the above reactions by metathesis with suitable anions, such as BPh_4^-. Heating of the ion pair $[Co(CO)_3(PR_3)_2][Co(CO)_4]$ effects symmetrization with loss of CO to give the covalent disubstitution products $Co_2(CO)_6(PR_3)_2$ (equation 3). The PR_3 ligands in these hexacarbonyls occupy axial positions in what is probably a D_{3d} structure. Depending on the size of the ligands, non-bridged and bridged forms are in equilibrium in solution as judged from IR spectral bands; however, non-bridged forms predominate. One substituted dicobalt carbonyl complex synthesized in this manner is $Co_2(CO)_6(TPPTS)_2$ (TPPTS = $P\{m\text{-}C_6H_4SO_3Na\}_3$).[9]

$$[Co_2(CO)_3L_2][Co(CO)_4] \xrightarrow{\text{heat}} Co_2(CO)_6L_2 + CO \quad (3)$$

The mechanism for the formation of the ion pair $[Co(CO)_3L_2][Co(CO)_4]$ has been investigated in detail with L = $P(n\text{-}Bu)_3$ and was found to be extremely complicated. Mixed reaction orders, between 1 and 1.5 in $Co_2(CO)_8$ and 0.3 to 0.6 in L, which depend not only on the ligand chosen but also on concentrations and temperature, show that a number of parallel reaction routes are followed where one or the other pathway has preponderance. The principal scheme, however, given by equations (4–10), is initiated by cleavage of a dinuclear species (equation 5) to start a radical chain (*see Radicals*).

$$Co_2(CO)_8 + L \longrightarrow Co_2(CO)_8L \quad (4)$$

$$Co_2(CO)_8L \longrightarrow Co(CO)_3L + Co(CO)_4 + CO \quad (5)$$

$$Co(CO)_3L + Co_2(CO)_8 \longrightarrow [Co(CO)_3L]^+[Co(CO)_4]^- + Co(CO)_4 \quad (6)$$

$$Co(CO)_3L^+ + L \longrightarrow Co(CO)_3L_2^+ \quad (7)$$

$$Co(CO)_3L_2^+ + Co(CO)_4^- \longrightarrow [Co(CO)_3L_2]^+[Co(CO)_4]^- \quad (8)$$

$$Co(CO)_4 \longrightarrow Co(CO)_3 + CO \quad (9)$$

$$Co(CO)_3 + L \longrightarrow Co(CO)_3L \quad (10)$$

Since the overall reaction proceeds under conditions where no $Co(CO)_4$ radicals from $Co_2(CO)_8$ cleavage can be detected, splitting of the dinuclear species $Co_2(CO)_8L$, which is formed in a rapid preequilibrium (equation 4), is responsible for radical formation during the induction period. The important step for the formation of the observed products is then outer-sphere electron transfer (*see Outer-sphere Reaction*) as depicted in equation (6). This requires the $Co(CO)_3L$ radical to act as a reducing agent towards $Co_2(CO)_8$. Since, from electrochemistry and pulse radiolysis of $Co_2(CO)_8$, it can

be inferred that the cleavage of the Co–Co bond in the dimeric carbonyl requires transfer of just a single electron, and dissociation of the radical monoanion ($Co_2(CO)_{8-n}L_n^-$) is very fast, the electron transfer could even be driven slightly uphill by the follow-up reaction. This mechanistic scheme requires further that reaction of $Co(CO)_3L^+$ with L to form $Co(CO)_3L_2^+$ is faster than reaction with $Co(CO)_4^-$.[10]

This trend is reasonable in view of the coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*) nature of $Co(CO)_3L^+$ (16-electron count) and the much higher concentration of L in solution as compared to that of $Co(CO)_4^-$. Recombination reactions, for example between $Co(CO)_3L$ and $Co(CO)_4$, or of $Co(CO)_3L$ with itself, that would lead to $Co_2(CO)_7L$ and symmetric $Co_2(CO)_6L_2$, respectively, are kinetically fast ($k_{dim} \sim 10^7 - 10^8\ M^{-1}\,s^{-1}$). However, they are less important owing to the low steady-state concentration of the radicals. Simulation of this mechanistic scheme with insertion of reasonable second-order rate constants results in a rate constant k_{12} for dissociation of $Co(CO)_4$, the step that drives the radical chain after the induction period, of about $10^6\,s^{-1}$ (or greater) and a rate for electron transfer, k_9, of about $10^8\,s^{-1}$ (*see Kinetic Methods*).

Higher substitution products of $Co_2(CO)_8$ are available through CO dissociation followed by ligand association, as described in equations (1) and (2). However, in cases where valence disproportionation (*see Disproportionation*) has occurred, valence conproportionation can also result in more substituted complexes (equations 11 and 12). Reduction of a cation solution of $Co(CO)_3L_2^+$ results in a two-electron reduction from the cation to the monoanion, which combines with excess cation in solution with loss of CO to form the product. An example that has been obtained by this procedure is $Co_2(CO)_4(PMe_3)_4$.[11] The preparation of these highly substituted species proves that the Co–Co bond is retained upon phosphine substitution.

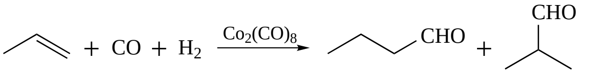
$$Co(CO)_3L_2^+ \longrightarrow Co(CO)_2L_2^- + CO \quad (11)$$

$$Co(CO)_3L_2^+ + Co(CO)_2L_2^- \longrightarrow Co_2(CO)_4L_4 + CO \quad (12)$$

2.1.2 *Reaction of $Co_2(CO)_8$*

$Co_2(CO)_8$ has been used in numerous reactions in addition to the plethora of substitution reactions that it undergoes with phosphines, nitrosyls, alkynes, and so forth. Many of these substituted carbonyl complexes and their reactions have been discussed elsewhere in this report. One area in which $Co_2(CO)_8$ has received much attention is catalysis; two classes of catalytic reactions of which $Co_2(CO)_8$ plays a major role are hydroformylation (*see Hydroformylation*) and Pauson–Khand cycloaddition (*see Pauson–Khand Reaction*).

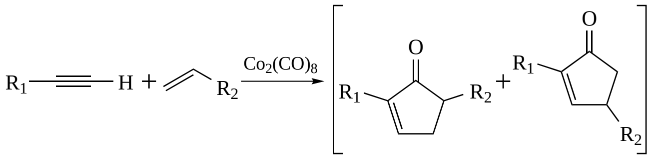
Hydroformylation. $Co_2(CO)_8$ is used as a catalytic precursor to convert alkenes to aldehydes in hydroformylation reactions (equation 13). Aldehydes can be further reduced to produce alcohols. The addition of CO to an alkene is called an 'oxo' process (*see Oxo Process*). Hydroformylation products and subsequent derivatives provide chemical components for many industries including polymer manufacture. More than four million tons of aldehydes are made annually, making hydroformylation one of the largest scale applications of homogeneous catalysis (*see Catalysis*). When substituted silanes are used instead of H_2, silyl enol ethers are obtained. The active catalytic species in hydroformylation is $HCo(CO)_4$ (Section 'General and Acid Properties'), and the mechanism is discussed in section '$HCo(CO)_4$ in Hydroformylation Reactions'.



(13)

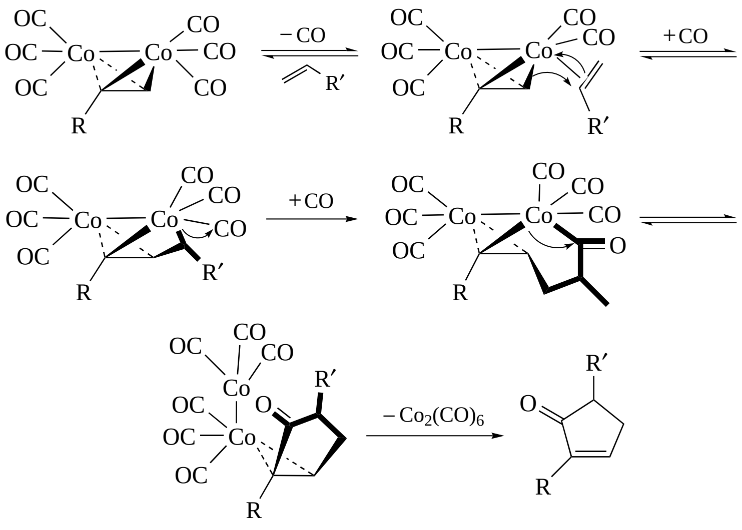
Substituted cobalt carbonyls of the type $Co_2(CO)_6L_2$ have also been compared to binary cobalt carbonyls as hydroformylation catalysts for linear aldehydes. One study compared four $Co_2(CO)_6L_2$ complexes (L = tertiary phosphines with functionalized alkyl groups) to the well-known complexes $Co_2(CO)_6(P\{n\text{-Bu}\}_3)_2$ and $Co_2(CO)_8$.[12] The bulky phosphine substituent $P(CH_2CH_2CH_2OCH_2CH_2)_3$ showed lower activity than the others, but analogous selectivity.

Pauson–Khand Cycloaddition. Pauson–Khand cycloaddition (*see Pauson–Khand Reaction*) is a cobalt-mediated method to prepare cyclopentenone from the cyclization of an alkyne with an alkene and CO (equation 14). This method is widely used to produce cyclic ketones. Originally, stoichiometric amounts of $Co_2(CO)_8$ were used in these reactions with the cobalt carbonyl being the CO source. However, it was shown that a strict temperature profile and high-purity reagents allowed the use of catalytic amounts of $Co_2(CO)_8$ for reactions with 1 atm of CO.[13] Currently, there is intense interest in developing catalytic cobalt starting materials for use in Pauson–Khand reactions.



(14)

The mechanism is believed to begin with dissociation of CO, leaving $Co_2(CO)_6$ as the active catalyst. This carbonyl species adds an alkyne, forming a tetrahedrane complex (Section 2.4.1). Insertion of the alkene, upon CO loss, followed by CO insertion and reductive elimination from one of the Co units results in a cyclopentenone. Dissociation of the cyclopentenone from the other Co unit regenerates $Co_2(CO)_6$ (Scheme 1).

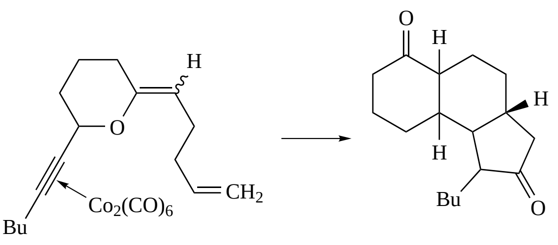


Scheme 1

Steric differences have been shown to affect the regiochemistry of cyclization, as the CO inserts in the α-position of the larger alkynyl substituent. However, theoretical studies on dicobalt hexacarbonyl alkyne complexes have suggested that electronic differences in alkyne substituents may also exert control over the regiochemistry of cyclization.[14,15] Calculations have also provided information on geometries and configurational stabilities of these complexes.

Reactions as described in Scheme 1 are intermolecular (*see Intermolecular*) reactions. An unusual example is the synthesis of 2-phenylcyclopentenone from phenylacetylene and ethane.[16] In this reaction, the substrate ethylene was also the solvent because the reaction was run in supercritical ethylene.

In addition to intermolecular cyclization products, Pauson–Khand reactions can also occur intramolecularly (*see Intramolecular*) to give cyclopentenones. One example of this is the conversion of a cyclic ketone into a functionalized polycyclic system (equation 15).[17]



(15)

Many variations on this reaction have been studied over the last several years including use of $Co_2(CO)_8$ on a solid support to accelerate reaction rates,[18] the use of microwave radiation,[19] and the use of ionic liquids as solvents.[20] Asymmetric synthesis has also been given close attention.[21]

2.2 Mononuclear Cobalt Carbonyl Derivatives

2.2.1 $Co(CO)_4$

Depending on the wavelength of radiation used, irradiation of $Co_2(CO)_8$ produces either CO dissociation (at 250 nm) or cleavage into $Co(CO)_4$ radicals (at 360 nm). The radical $Co(CO)_4$ (**2**) itself has been detected by its Raman, infrared, UV–vis, and EPR (*see Electron Paramagnetic Resonance*) spectra.[22] It can be found by EPR when (**1**) is heated and sublimed on a 77 K cold finger in the EPR cavity, or it can be generated in a matrix at low temperature either by photolysis of (**1**) or by the metal vapor technique (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***).

These methods have produced the full range of fragments from CoCO to $Co(CO)_4$, which could be identified through their IR absorptions. Addition products have been generated, not only with the usual spin traps, but also with dioxygen. In the latter case, a matrix-stabilized trigonal bipyramidal (*see Trigonal Bipyramidal*) adduct $O_2Co(CO)_4$ has been detected. Most significantly, the formation of radical (**2**) is detected with EPR in hexane solution above 120 °C under pressure, thereby indicating the start of thermal dissociation of (**1**) under these conditions. Solutions of (**1**) at ambient temperature are EPR silent and no direct proof for any detectable concentration of (**2**) has been given. Furthermore, reactions like the one between $Co_2(CO)_8$ and CCl_4 giving $Co(CO)_4Cl$ and $Co(CO)_4CCl_3$ are characteristic of radical intermediates. However, it has been shown that dimeric metal carbonyls, including the cyclopentadienyl derivatives $[CpM(CO)_3]_2$ (M = Cr, Mo, W) and $[CpM(CO)_2]_2$ (M = Fe, Ru), undergo fairly rapid redistribution reactions in benzene solution to form equilibrium mixtures of the homo- and heteronuclear dimers (equations 16 and 17).[23] This reaction is most easily explained

through the presence of monomeric radicals, albeit in very low concentration.

$$Co_2(CO)_8 + Mn_2(CO)_{10} \rightleftharpoons 2(CO)_4Co\text{–}Mn(CO)_5 \quad (16)$$

$$Co_2(CO)_8 + [CpFe(CO)_2]_2 \rightleftharpoons 2(CO)_4Co\text{–}Fe(CO)_2Cp \quad (17)$$

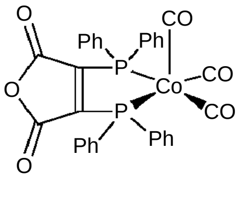
CO substitution in heteronuclear cobalt carbonyl complexes has also been studied. Several phosphines were used in exchange reactions with CO in the complex $CpMo(CO)_3$–$Co(CO)_4$. Both a CO dissociative pathway, leading to substitution, and a radical chain pathway, initiated by associative attack of the phosphine and subsequent disproportionation (*see Disproportionation*), were found depending on reaction conditions (thermal or photochemical treatment) and the basicity and sterics of the phosphine ligands. As seen in substitution reactions with $Co_2(CO)_8$, strongly basic phosphines add to the complex via disproportionation, while less basic phosphines add via substitution. However, the metal centers help determine where the phosphine adds because the rates of substitution on each metal center differ depending on which pathway, dissociative or radical chain, is operative.[23,24]

A unique air-stable 19-electron derivative (*see Nineteen Electron Configuration*) of (**2**) was obtained with the ligand bis(diphenylphosphino)maleic anhydride. DFT calculations on this system predict that the spin density should reside on the ring. Experimental data support this prediction, as a large hyperfine coupling to P and a small hyperfine coupling to cobalt indicate that the odd electron delocalizes over the dppm unit (Figure 2) (*see* ***Paramagnetic Organometallic Complexes***).[25]

Electrochemical experiments on bidentate phosphorus ligands indicate that ligands with reduction potentials more positive than −1 V (versus SCE) form long-lived 19-electron species with cobalt carbonyls, whereas ligands with more negative potentials form reactive species. For example, with a reduction potential of −0.7 V, bis(diphenylphosphino)maleic anhydride was expected to form a stable species with cobalt carbonyls, a prediction confirmed by its synthesis.[26]

2.2.2 HCo(CO)$_4$

General and Acid Properties. The carbonyl hydride $HCo(CO)_4$ (**3**) is formed in situ from $Co_2(CO)_8$ and H_2 in hydroformylation mixtures or by acidification of the anion



$g_{iso} = 2.0041$
$A_P = 11.11$ G, $A_{Co} = 1.4$ G
$\mu_{eff} = 2.04$ BM
$\nu_{CO} = 2015$–$2075\ cm^{-1}$

Figure 2 Structure of (dppm)$Co(CO)_3$

$Co(CO)_4^-$ with a strong acid. The $Co(CO)_4^-$ anion is easily made by reduction of $Co_2(CO)_8$. Interestingly, if $Co_2(CO)_8$ is dissolved in strong acids under a CO atmosphere, the positively charged $[Co(CO)_4]^+$ cation is formed instead.[27]

$HCo(CO)_4$ is a volatile, very toxic liquid with an extremely unpleasant odor. It is rather unstable as a pure material, decomposing into $Co_2(CO)_8$ and H_2 below room temperature. The equilibria between $Co_2(CO)_8$ and $HCo(CO)_4$ under different H_2 pressures have been studied. Dilute solutions are more stable, from which observation of a second-order decomposition pathway has been concluded. However, very pure, colorless samples of (**3**) are much more stable, and $Co_2(CO)_8$ acts as a catalyst for the decomposition of (**3**). Since this decomposition follows a rate law of half-order in $Co_2(CO)_8$, the radical $Co(CO)_4$ is invoked as the active species in the decomposition process according to equations (18–21). From electron diffraction measurements, the geometry of (**3**) is trigonal bipyramidal (*see Trigonal Bipyramidal*), with hydrogen occupying an axial position.

$$HCo(CO)_4 + Co(CO)_3 \longrightarrow HCo_2(CO)_7 \quad (18)$$

$$HCo_2(CO)_7 + HCo(CO)_4 \longrightarrow H_2Co_2(CO)_7 + Co(CO)_4\cdot \quad (19)$$

$$H_2Co_2(CO)_7 \longrightarrow H_2 + Co_2(CO)_7 \quad (20)$$

$$Co_2(CO)_7 + Co(CO)_4 \longrightarrow Co(CO)_3 + Co_2(CO)_8 \quad (21)$$

$HCo(CO)_4$ is soluble in water to the extent of 5.6×10^{-2} M. It titrates as a strong mineral acid in water and deprotonation in methanol suggests a pK_a value around −4. The reason for the very high acidity of (**3**) may stem from the extra stabilization of the anion (**2**$^-$) owing to its d^{10} configuration.

High pressure NMR experiments performed over a temperature range of 80–200 °C in supercritical CO_2 showed that a hydride ligand transfer reaction between $HCo(CO)_4$ and $Co_2(CO)_8$ results in cobalt–metal exchange between $HCo(CO)_4$ and $Co_2(CO)_8$ (equation 22). A hydride transfer reaction between $HCo(CO)_4$ and $HMn(CO)_5$ is also evident; however, manganese exchange does not occur between $HMn(CO)_5$ and $Mn_2(CO)_{10}$ or $MnCo(CO)_9$. The lack of manganese exchange does not support an oxidative addition (*see Oxidative Addition*) reaction mechanism for the heterometallic hydride transfer, so the mechanism is regarded as a hydrogen atom transfer between $Co(CO)_4$ and $Mn(CO)_5$ radicals (equation 23).[28]

$$H^*Co(CO)_4 + Co_2(CO)_8 \rightleftharpoons HCo(CO)_4 + Co^*Co(CO)_8 \quad (22)$$

$$^*HMn(CO)_5 + HCo(CO)_4 \rightleftharpoons HMn(CO)_5 + {}^*HCo(CO)_4 \quad (23)$$

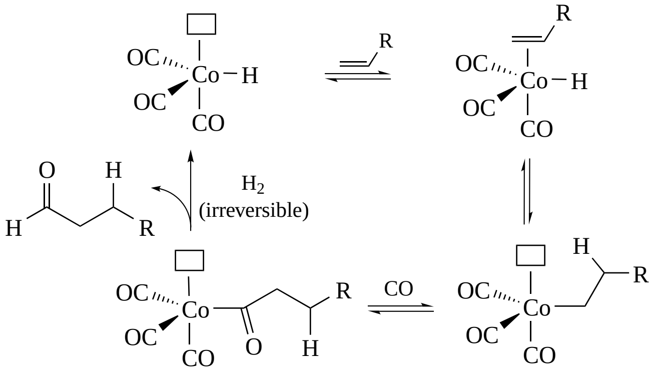
The majority of homoleptic carbonyls and many other derivatives can be formed with PF_3 ligands instead of CO.[29] In many instances, CO is exchanged by PF_3 under pressure. In contrast to the elusive nature of (**3**), its PF_3 analog $HCo(PF_3)_4$ is of very high thermal stability and does not decompose below 250 °C. Its acid–base properties seem to resemble those of the carbonyl hydride, however.

$HCo(CO)_4$ in Hydroformylation Reactions. As previously mentioned, $HCo(CO)_4$ is a key intermediate in the homogeneous hydroformylation of alkenes with CO/H_2 to aldehydes. Using $HCo(CO)_4$ as the CO component, hydroformylation can be made stoichiometric when run under N_2 as an inert atmosphere.

The coordinatively unsaturated species that adds to the alkene is believed to be the product of CO dissociation from $HCo(CO)_4$ (**3**), since the overall reaction is retarded by high CO pressure, and dissociation of CO from (**3**) or a phosphine substitution product (equation 24) is probably the rate-determining step. After alkene addition to $HCo(CO)_3$, CO adds to the metal center only to form a corresponding acyl via migratory insertion (*see Migratory Insertion*). Addition of H_2, followed by heterolytic cleavage, results in the product aldehyde and regeneration of the catalyst (Scheme 2).[30]

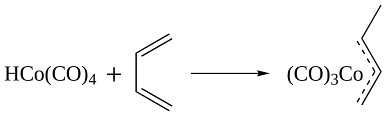
$$HCo(CO)_3P \rightleftharpoons HCo(CO)_2P + CO \qquad (24)$$

It was found in hydroformylation studies that sterically more demanding substituents such as phosphines (e.g. $P(n\text{-}Bu)_3$) influence the *n*/*iso* ratio of the final aldehyde in favor of the straight chain *n*-aldehydes, which are more valuable products from an industrial point of view. The reason seems to be the different migratory ability of terminal



Scheme 2

versus internal intermediate alkyl complexes (Scheme 3).[31] This finding has stimulated extensive synthetic activity in the area of the substituted carbonyls $Co_2(CO)_{8-n}(PR_3)_n$ and $HCo(CO)_{4-n}(PR_3)_n$ as well as the model intermediates $RCo(CO)_{4-n}(PR_3)_n$. Owing to its acidic properties, (**3**) adds to dienes yielding allyl complexes (equation 25), which are also intermediates in the hydrogenation of alkenes catalyzed by (**3**).

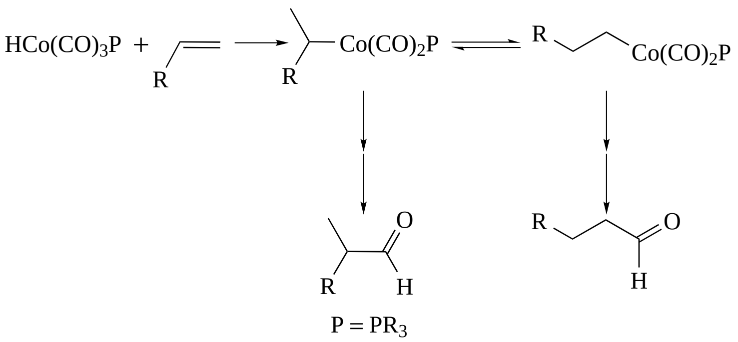


(25)

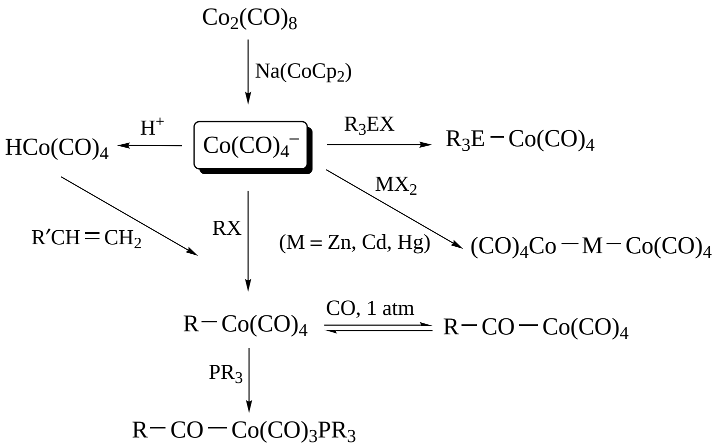
2.2.3 $Co(CO)_4^-$

General Characteristics. In accordance with the high tendency for formation of $Co(CO)_4^-$ (**2**$^-$) and the acidity of (**3**), the former compound behaves in many respects as a pseudohalide (*see Pseudohalide*). Relative rates of electrophilic substitution with MeI and MeOTs classify (**2**$^-$) as a hard and relatively weak nucleophile (*see* ***Hard & Soft Acids and Bases***). Compounds of the type $RCo(CO)_4$ are prepared by two different methods: reaction of an electrophilic halide, sulfate, or tosylate (RX) with (**2**$^-$), or reaction of $HCo(CO)_4$ with alkenes. Simple alkyl derivatives have low stability; nevertheless, many studies have been conducted in which species have been identified as $RCo(CO)_4$ intermediates. Apart from alkyl and aryl derivatives, for example $MeCo(CO)_4$ and $PhCo(CO)_4$, (**2**$^-$) forms derivatives with main group residues R_3E^{IV} and R_2E^{V} and with the main group metals Zn, Cd, and Hg as well as with transition metals, as shown by examples in Scheme 4. Co–E bonding in these compounds appears to be predominantly covalent. The bond distances can be long, and consequently, the coordination number of Co can be high.

Among the numerous substitution products of the complexes $HCo(CO)_4$, $RCo(CO)_4$, and $XCo(CO)_4$, those with phosphines are particularly abundant. Accessible by either gradual photochemical or thermal substitution of CO for phosphine, these compounds can also be obtained in a



Scheme 3



Scheme 4

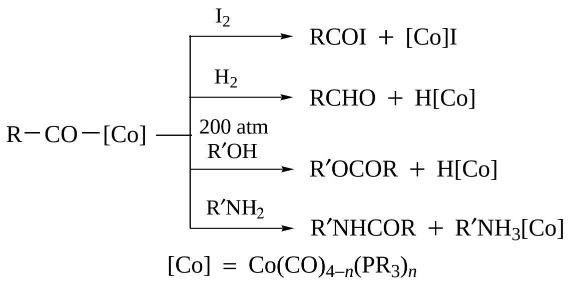
reverse fashion by reaction of $CoCl_2$ with the appropriate phosphine to give cobalt chlorophosphine complexes that can be carbonylated with CO. Dissociative CO loss is probably the crucial step by which decomposition is initiated.

Molecular orbital (MO) calculations on $MeCo(CO)_4$ place a negative charge on the methyl carbon atom with polarization of the Co–Me bond. Substitution of CO ligands withdraws electron density from the alkyl carbon atom and delivers electron density to the metal, thus stabilizing the Co–C bond.

Insertion of CO into $RCo(CO)_4$ to give acyl complexes is facile (*see* ***Mechanisms of Reaction of Organometallic Complexes***). This reaction proceeds at 1 atm of CO at ambient temperature. The alkyl–acyl equilibrium lies far towards the acyl complex. The activation energy for the process has been calculated by MO methods to be about 85 kJ mol^{-1} (*see* ***Molecular Orbital Theory***). Thus, $RCo(CO)_4$ complexes can only be obtained under conditions of low CO pressure, which in turn opens the way for CO dissociative decomposition. Cobalt acyl complexes can be derivatized in several ways to form various products (Scheme 5).

Many industrially important catalytic processes use alkyl and acyl cobalt carbonyl complexes, which can be synthesized from (**2**$^-$). Acyl complexes produced after formation of the cobalt–carbon bond can be transformed in different ways to produce hydrocarbons, carbonyl compounds, or carboxylic acid derivatives. Interconversion of alkyl and acyl moieties results from carbonylation/decarbonylation reactions in which strong electron-withdrawing groups stabilize an alkyl product. The use of perfluorinated groups also gives enhanced stability to the complexes. One such stabilized species is the pentafluorophenylcobalt tricarbonyl triphenylphosphine complex, $C_6F_5Co(CO)_3P(C_6H_5)_3$ (Figure 3).[32]

Use of $Co(CO)_4^-$ in Organic Syntheses. The synthetic potential provided by the various methods for formation, modification, and cleavage of the Co–C bond with the aid of $Co(CO)_4^-$ has been exploited, in a way similar to that done with the Fe congener $Fe(CO)_4^{2-}$ (or $FeH(CO)_4^-$), in versatile stoichiometric and catalytic reactions (*see* ***Iron: Organometallic Chemistry***).



Scheme 5

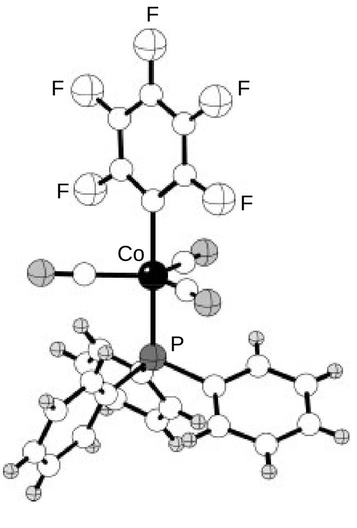


Figure 3 Structure of $C_6F_5Co(CO)_3P(C_6H_5)_3$

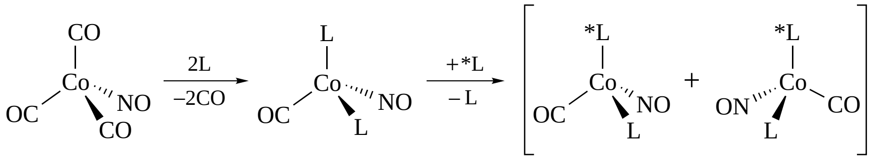

Scheme 6

The tetracarbonylate (2^-) is the driving nucleophile (*see Nucleophile*) in many applications. A procedure by which it can be transferred into a nonpolar organic phase with the aid of a phase transfer agent such as $BnNEt_3Cl$ created the possibility of conducting these reactions at or slightly above room temperature (equations 26–28).

 (26)

$$PhCH_2Cl + Co_2(CO)_8/OH^- \xrightarrow[C_6H_6(\text{solvent})]{BnNEt_3Cl} PhCH_2CO_2H \quad (27)$$

$$Co(CO)_4^- + MeI + Co \xrightarrow[C_6H_6(\text{solvent})]{BnNEt_3Cl} MeCO\text{–}Co(CO)_4 \quad (28)$$

2.2.4 *Nitrosyl–Carbonyl Complexes*

As a metal containing an odd number of valence electrons, cobalt is prone to form mononuclear NO complexes (*see Nitrosyl Complexes*) derived from carbonyls or substituted carbonyls by ligand substitution. The simplest of these compounds, $Co(CO)_3NO$ (**4**), is a dark red liquid at ambient temperature that slowly decomposes in air. Electron diffraction has confirmed its C_{3v} structure with a linear NO group. Compared to the different structural isomers of $Co_2(CO)_8$, the CO stretching vibrations are at higher frequency, indicating less back bonding (*see Back Bonding*) from cobalt into CO. The NO stretch is found in the range where such bonds for linear NO groups usually appear (1650–1900 cm^{-1}). Substitution of the CO ligands of (**4**) leads to the derivatives $Co(CO)_{3-n}L_nNO$ ($n = 1, 2, 3$), with L being primarily phosphines.

Compound (**4**) reacts with halides, preferably their alkylammonium salts, in acetone or DME with exchange of one CO for a halide, giving anionic complexes of the type $Co(CO)_2(NO)X^-$ (X = Cl, Br, I, CN) (equation 29). Owing to the high charge density at the metal, these anions can act as sources for the hyponitrous ion, NO^-, which is transferred in nucleophilic substitutions at activated (benzyl) halides, giving aldoximes (e.g. PhCH=NOH from $PhCH_2Y$) (equation 30).[33]

$$Co(CO)_3NO + NR_4X \xrightarrow{DMF} Co(CO)_2(NO)X^- + CO$$
$$X = Cl, Br, I, CN \quad (29)$$

$$Co(CO)_2(NO)X^- + PhCH_2Y \longrightarrow \frac{1}{2}Co^{2+} + X^- + Y^- + \frac{1}{2}[Co(CO)_4] + PhCH{=}NOH \quad (30)$$

Optically active organometallic complexes have been used to study stereochemical reactions. Substituted cobalt nitrosyl complexes are interesting chiral (*see Chiral*) complexes because they exhibit tetrahedral structures, whereas most optically active organometallic complexes are half-sandwich structures with octahedral geometries. Diastereomeric cobalt complexes of the type Co(CO)(NO)(L)(*L) (L = phosphite or phosphane; *L = optically active phosphane or isocyanide) have been synthesized from (**4**) via substitution (Scheme 6).[34]

2.3 Higher Nuclearity Clusters and Cluster Anions

As noted in early reports, (**1**) undergoes thermal loss of CO at 60 °C (Scheme 7) to give the black, very air-sensitive 'tricarbonyl $Co(CO)_3$', subsequently recognized as the tetranuclear carbonyl $Co_4(CO)_{12}$ (**5**) with one $Co(CO)_3$ group on top of a Co_3 triangle built from three $Co(CO)_2$ groups with three edge-bridging carbonyls. Thermodynamic decomposition parameters have been calculated for this pathway under vacuum.[35]

Further heating leads to complete decomposition, since the third binary carbonyl of Co, $Co_6(CO)_{16}$ (**6**), decomposes at about the same temperature as (**5**) (110–120 °C). The hexacobalt cluster is obtained along with some (**5**) by $FeCl_3$ oxidation of the anions $Co_6(CO)_{15}{}^{2-}$ or $Co_6(CO)_{14}{}^{4-}$. No higher binary carbonyls of cobalt are known, but many heteroclusters and homometallic cluster anions of higher nuclearity have been prepared; $[Co_{10}N_2(CO)_9(\mu\text{-}CO)_{10}]^{4-}$ (Figure 4), a metal cage constructed from three condensed trigonal prisms, is an example of a homometallic cobalt cluster tetraanion.[36]

Reduction of (**5**) with alkali metal forms the green cluster anion $Co_6(CO)_{15}{}^{2-}$, which can be further reduced to the red dianion $Co_6(CO)_{14}{}^{4-}$, and isolated as a potassium salt. The latter cluster anion is an early example of the expanding family of highly reduced transition metal carbonyls, for example $Na_3Co(CO)_3$,[37] where up to two CO groups are replaced by two electrons each. $Co_6(CO)_{15}{}^{2-}$ is also the main product from valence disproportionation of $Co_2(CO)_8$ in ethanol. Oxidation (or acidification) of the cluster anions gives $Co_6(CO)_{16}$.

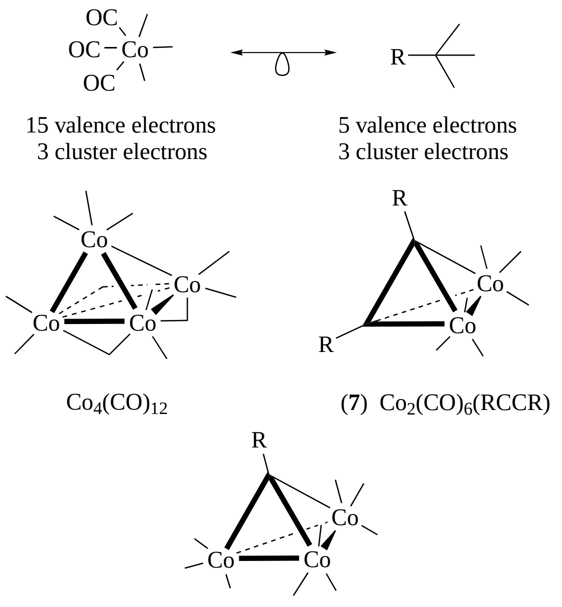
2.4 Complexes with a Tetrahedrane Skeleton

Two classes of complexes are derived from $Co_4(CO)_{12}$ by replacement of one or two $Co(CO)_3$ groups by the isolobal (*see Isolobal Analogy*) RC unit, leading to cluster types $(RC{\equiv}CR)Co_2(CO)_6$ (**7**) and $RCCo_3(CO)_9$ (**8**). Both classes of compounds have an abundant variety of derivatives with widely differing R groups and hetero functions, and they exhibit a rich and extended chemistry (Scheme 8).



$Co_4(CO)_{12}$

(**7**) $Co_2(CO)_6(RCCR)$

(**8**) $Co_3(CO)_9CR$

Scheme 8

2.4.1 *$Co_2(CO)_6(\mu_2\text{-}RC{\equiv}CR)$*

Two-carbon, two-cobalt tetrahedranes $(RC{\equiv}CR)Co_2(CO)_6$ (**7**) are formed with great ease from $Co_2(CO)_8$ and the

respective acetylenes. R groups on the alkyne comprise the usual alkyl, aryl, CF_3 and CO_2Me substituents, but they can also be functionalized organics such as NEt_2 or organometallics like ferrocene (*see Ferrocene*). The structure of these dinuclear compounds resembles a doubly bridged form of $Co_2(CO)_8$, in which the two bridging CO groups are replaced by the alkyne, which is arranged perpendicular to the Co–Co axis (Figure 5). A lowering of the C≡C stretching frequency from values of 2140–2300 cm^{-1} in the free alkyne to 1400–1630 cm^{-1} in the coordinated alkyne is observed. Carbon–carbon distances in the coordinated alkyne are in the range 1.32–1.37 Å, in accordance with a formal C=C double bond. The Co–Co bond, ranging from 2.45 to 2.49 Å, is shortened in comparison to that in $Co_2(CO)_8$ (2.52 Å).

According to an early computational study, bonding in μ-alkyne complexes is mainly through stabilization of the acetylene π*-orbitals by interaction with the dimetal fragment. An electron flow of one electron from an alkyne π-orbital to each cobalt, and back-bonding (*see Back Bonding*) of one d orbital per cobalt into an alkyne π*-orbital accounts for the C–C bond lengthening for the bending of the substituents from the C–C vector, typically by 140°.

Complexes containing terminal alkynes undergo rearrangement to the corresponding tricobalt clusters (**8**) (Section 2.4.2) when refluxed with mineral acid in methanol. This variety of

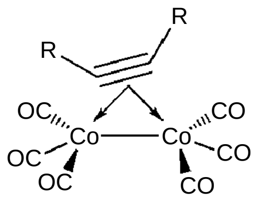


Figure 5 Schematic structure of $(RC{\equiv}CR)Co_2(CO)_6$

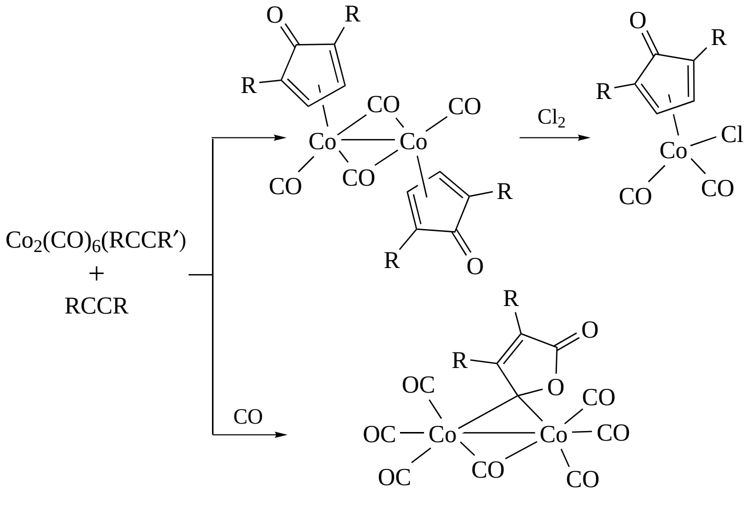
complex is also formed directly under these conditions from $Co_2(CO)_8$ and excess alkyne. (equation 31).

$$Co_2(CO)_8 + RCCR\ (excess) \longrightarrow CO_3(CO)_9CR\ (\mathbf{8}) \qquad (31)$$

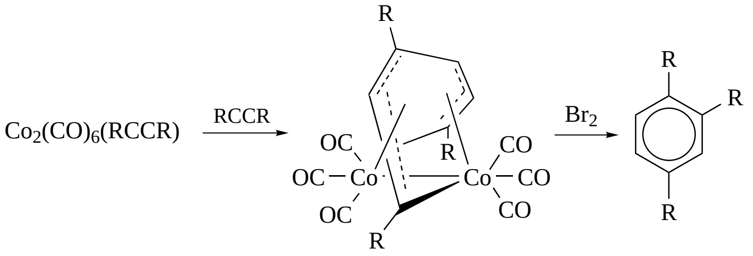
When compounds (**7**) were heated with alkyne in excess, two types of complexes, both involving alkyne coupling, are formed. A compound with the stoichiometry $Co_2(CO)_4(C_4R_2CO)_2$, formed mainly from terminal alkynes having one bulky substituent R, represents derivatives of $Co_2(CO)_8$ where two CO groups at either metal are replaced by a cyclopentadienone ligand. This compound type represents one of the many instances where alkynes combine with CO in the presence of a transition metal fragment to yield mostly cyclopentadienones, often complexed to the metal; this cycloaddition reaction is similar to the Pauson–Khand scheme except for the use of an alkyne in place on an alkene (see also Section 5.1.4 and Scheme 26). The reaction eventually proceeds further to liberate an arene. Thus, from the use of t-BuC≡CH, the alkyne trimerization product 1,2,4-tri-t-Bu-benzene was isolated.

Under more forcing conditions, that is, enhanced CO pressure, the complexed alkyne can combine with excess CO, giving lactones that are bound to the $Co_2(CO)_6$ moiety via a bridging methylidene group (Scheme 9).

At higher temperatures (100–160 °C), alkynes, in particular, those featuring electron-withdrawing R groups, form a different type of complex (Scheme 10). These consist of two metal–metal bonded $Co(CO)_3$ units that are also linked through a chain made up of three alkyne units. Under these more severe conditions, this complex type is also formed from $Co_2(CO)_8$ and the alkyne; at lower temperature, the reaction of $Co_4(CO)_{12}$ and the alkyne suffices. The cobalt moieties are bound to either part of this six-carbon chain in an allylic fashion and, in addition, to the terminal carbon



Scheme 9



Scheme 10

atoms by a σ-bond. The carbon chain becomes a double four-electron ligand where two planar allyl parts are joined by a carbon–carbon single bond. These so-called 'flyover' complexes are represented by $Co_2(CO)_3(PPh_3)\{\mu$-$C(SiMe_3){=}CH{-}CH{=}C(SiMe_3){-}CH{=}C(SiMe_3)\}$ (Figure 6);[38] similar 'flyover' complexes are known with a variety of bimetal units.

Interestingly, these flyover complexes can be degraded and release substituted benzenes by thermal decomposition or oxidation of the metal fragment with halogens. The position of the R groups in the flyover complex, in the cases where they have been located, corresponds to their position in the benzene formed, thus proving ring closure between terminal carbon atoms. Even the product derived from t-BuC≡CH with three t-Bu groups at carbons 1, 3, and 6 in the complex is degraded to give the sterically constrained 1,2,4-tri-t-Bu-benzene. Consequently, the flyover complex is an important model intermediate in dicobalt-catalyzed alkyne trimerization (*see Cyclodimerization & -trimerization Reactions*), which has been shown to proceed at many different organometallic cobalt residues (Section 5.1.4). Note that substituted benzenes along with cyclopentadienones have also been formed in the thermal decomposition of (**7**).

Biologically Significant Reactions of $Co_2(CO)_6$ (μ_2-RC≡CR). Many dicobalt carbonyls with complexed alkynes have been used in natural product synthesis. In one study, $Co_2(CO)_6(\mu_2$-RC≡CR) complexes were shown to play an important role as stable intermediates for the construction of the antitumor enediyne agents dynemicin, calicheamiin, esperamicin, and neocarzinostatin.[39] The same type of cobalt complex was also involved in the syntheses of ingenol[40] and ciguatoxin.[41]

The $Co_2(CO)_6(\mu_2$-RC≡CR) complexes themselves can be biologically active; some exhibit antitumor activity exceeding that of cis-platin.[42] The first organometallic derivative of 11b-ethynylestradiol has also been synthesized; it incorporates the $Co_2(CO)_6(\mu_2$-RC≡CR) moiety and is a potential high-affinity estrogen receptor marker.[43]

2.4.2 Formation and Properties of $(CO)_9Co_3CR(= [Co_3C]R, 8)$

Geometrical parameters (from an X-ray structure determination) of a common derivative, the methyl compound $[Co_3C]CH_3$, are given in Figure 7. This class of complex can formally be generated by removing the apical $Co(CO)_3$ group from $Co_4(CO)_{12}$ and substituting for it a carbyne moiety RC (Scheme 8).[44] Electrochemistry of the tricobalt cluster has revealed a reversible one-electron reduction at about -0.4 V (vs. Ag/AgCl) to form stable radical anions.[45]

Although derivatives of (**8**) are formed in many different reactions, rational syntheses usually begin with trihalocarbons and $Co_2(CO)_8$ as reagents.[46] Bromoform gives the hydrocarbon $[Co_3C]H$, whereas CCl_4 yields $[Co_3C]Cl$.[47]

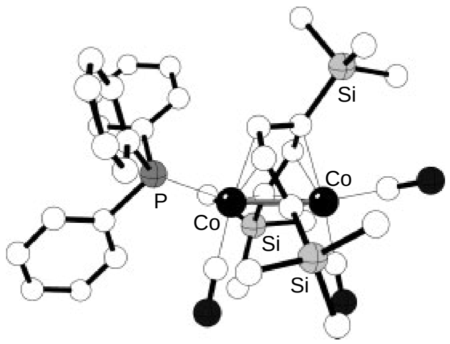


Figure 6 Structure of $Co_2(CO)_3(PPh_3)\{\mu$-$C(SiMe_3){=}CH{-}CH{=}C(SiMe_3){-}CH{=}C(SiMe_3)\}$

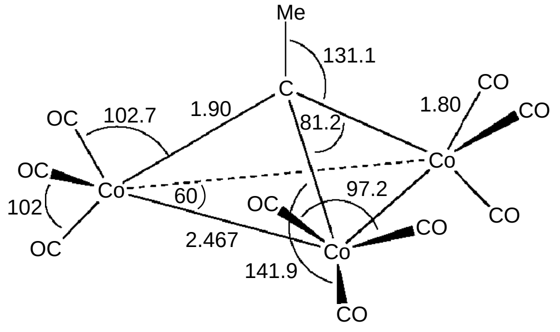

Figure 7 Structural parameters in $Co_3(CO)_9CMe$

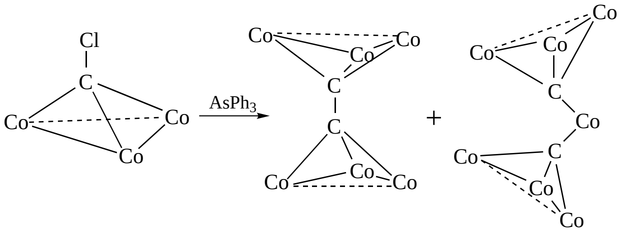
The chloro derivative $[Co_3C]Cl$ can be used for Friedel–Crafts electrophilic aromatic substitution,[48] showing the electrophilic nature (*see Electrophile*) of the cation $[Co_3C]^+$. Apart from hydrogen and halogen, many other functionalities (R) are tolerated on the halocarbon X_3CR in the synthesis of organic derivatives $[Co_3C]R$. Dehalogenation of $[Co_3C]Cl$ with $AsPh_3$ at 100 °C gives a dimer (equation 32).



(32)

The steric properties of the $(CO)_9Co_3$ core are such that the apical carbon group is highly shielded by six of the nine CO groups pointing towards the apex. Substitutions at the carbon atom of $[Co_3C]$ are therefore subject to severe steric hindrance. With respect to its electronic properties, $[Co_3C]$ seems to be a strongly electron-releasing group. This effect is indicated by the facile formation of the black, isolable acylium cation formed from an acid or ester, for example, with HPF_6 in propionic anhydride (equation 33).

$$[Co_3C]CO_2R + HPF_6 \longrightarrow [Co_3C]CO^+PF_6^- + ROH$$
$$[Co_3C] = Co_3(CO)_9C \qquad (33)$$

Ketones of the type $[Co_3C]COR$ show very low carbonyl stretching frequencies in the IR (*see Infrared Reflection Adsorption Spectroscopy*) (1560–1654 cm^{-1}), indicating a high degree of polarization of the C≡O bond, and are thus very reactive as carbonyl compounds. They are susceptible to acidic hydrogenation with CF_3CO_2H/Et_3SiH and produce hydrocarbon derivatives in up to 90% yield (equation 34).

$$[Co_3C]COR + CF_3CO_2H + 2Et_3SiH \longrightarrow [Co_3C]CH_2R + CF_3CO_2SiEt_3 + Et_3SiOH \qquad (34)$$

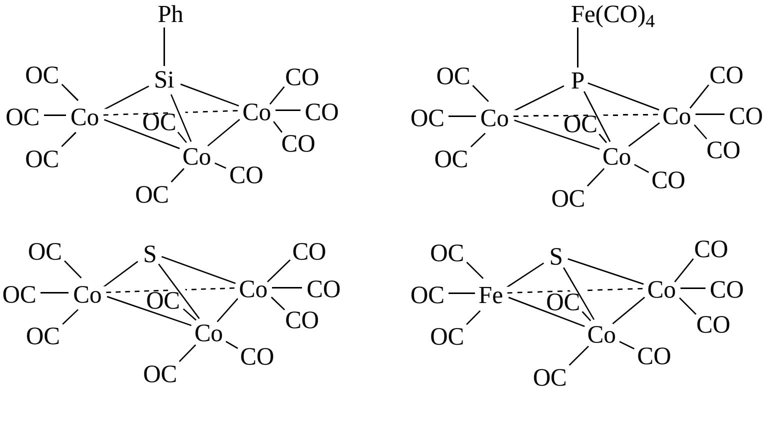
The carbonyl activation by $[Co_3C]$ allows ketones $[Co_3C]COR$ to be hydrosilylated (*see Hydrosilation*), without catalyst under mild conditions, to silyl ethers $[Co_3C]CH(OSiEt_3)R$, whose acid hydrolysis gives the corresponding alcohols $[Co_3C]CH(OH)R$. These alcohols in turn are the sources for $[Co_3C]$ stabilized carbocations $[Co_3C]CRH^+$ (equation 35).

$$[Co_3C]CHROH + HPF_6 \xrightarrow{-H_2O} [Co_3C]CHR^+PF_6^- \qquad (35)$$

Aryl groups bound to $[Co_3C]$ as $[Co_3C]$-aryl are activated in the *para* position for electrophilic substitution (*see Electrophilic Reaction*). From the ν_{CO} of 1685 cm^{-1} for *p*-$[Co_3C]$-C_6H_4COMe, a Hammett σ-constant of −0.35 was estimated for $[Co_3C]$, which is nearly equivalent to that for an OH group. The ^{13}C chemical shift of the apical carbon appears at δ300 ppm (in $[Co_3C]CH(OH)C_9H_{19}$) and shifts to 255–275 ppm in the carbonium ions. This region is outside the range for carbon in organic compounds and is found typically in carbyne complexes (*see Carbyne Complexes*) $(X(CO)_4M{\equiv}CR)$. This similarity leads one to consider the $[Co_3C]$ core as a triply bridging carbyne.

2.4.3 *Heteroatom Derivatives of $Co_3(CO)_9CR$*

The apical carbon fragment of $[Co_3C]R$ complexes can be replaced by heteroatoms or heterofunctional groups. Clusters containing RSi, RGe, and RSn in place of RC have all been studied. Group 15 analogs (Scheme 11) can be prepared in which from one to three $Co(CO)_3$ groups in $Co_4(CO)_{12}$ are replaced by P, As, or Sb, and nearly the complete series has been synthesized. Surprisingly, derivatives $Co_3(CO)_9E$ with one 'heterovertex' appear to be the least stable. Thus $Co_3(CO)_9P$ has only been detected in solution by its IR



Scheme 11

absorbances (in comparison to the better studied As congener) and is further stabilized by coordination to a $Fe(CO)_4$ group. In contrast, derivatives $Co_2(CO)_6E_2$, formally containing the coordination stabilized E=E molecules, are all known, as are the tetrahedranes $Co(CO)_3E_3$, which are stable compounds that can be sublimed and recrystallized without decomposition.

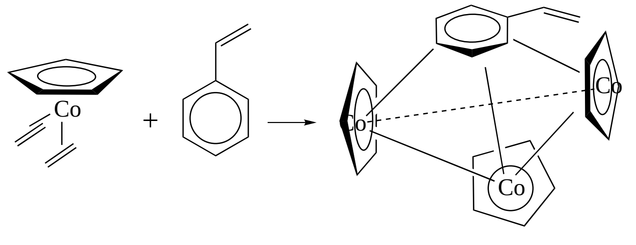
Since an unsubstituted group 16 atom contributes four electrons (one more than RC) the resulting $(CO)_9Co_3E$ (E = S, Se, Te) complexes are paramagnetic. The odd electron resides in an a_2 orbital in the M–M–M plane and is metal–metal antibonding (*see Antibonding*). The effect has been substantiated by X-ray structures of $(CO)_9Co_3S$ and $(CO)_9Co_2FeS$,[49] the latter being diamagnetic and isoelectronic with $(CO)_9Co_3S^+$. In the paramagnetic cluster, a Co–Co distance elongated by some 0.1 Å relative to Co–Co distances in diamagnetic clusters is observed.

2.4.4 Cp and Arene Derivatives

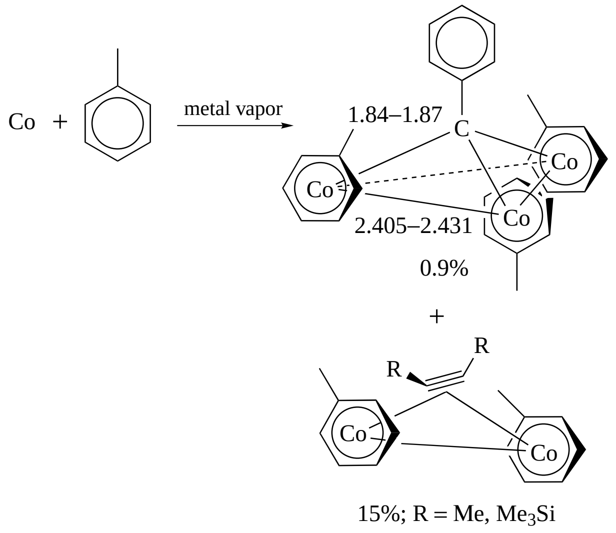
Pseudotetrahedral cyclopentadienyl derivatives that retain the metal-core bonding scheme commonly feature the Co_3Cp_3 moiety. Since each CpCo unit contributes one electron fewer than does $(CO)_3Co$, stability requires that the apical group should be a six-electron ligand. Complexes that meet this requirement are of composition Cp_3Co_3(arene), and are prepared thermally from $CpCo(C_2H_4)_2$ (Section 5.1.2). The synthesis is only successful if the arene bears a vinyl group.[50]

The vinyl substituent is needed to anchor the first $CpCo(C_2H_4)$ group, which then can form Co–Co bonds with two other CpCo fragments to yield the final complex. The arene ligand is oriented so that the C–C bonds eclipse the cobalt atoms. Crystallographic studies show a Kekulé-type (threefold) distortion in the arene ring; the bonding asymmetry is emphasized by a hindered rotation of the arene ring around the Co–Co–Co triangle that is observed with NMR spectroscopy (Scheme 12).

Additional tetrahedrane clusters are formed when vertices in $Co_4(CO)_{12}$ are substituted with isolobal (*see Isolobal Analogy*) (or nonisolobal) metal fragments. In this category are the mixed Co–Rh and Co–Ir carbonyl complexes, which can be formed from the reaction of $M_4(CO)_{12}$ (M = Rh, Ir) and $Co_2(CO)_8$. For example, $Co_3Rh(CO)_{12}$, which has been used as a hydroformylation catalyst precursor, is prepared in this way.[51] Furthermore, since the $Co(CO)_3$ group is isolobal



Scheme 12



Scheme 13

to a Co(arene) fragment, a series of substitutionally related polynuclear cobalt complexes is conceivable (Scheme 13), some of which have been identified from the metal vapor reaction of cobalt atoms with a toluene matrix in the presence of an alkyne.[52]

2.5 Triangular Co_3 Clusters

The homoleptic carbonyl (*see Homoleptic Compound*) $Co_3(CO)_9$ is not known, but a few substituted derivatives have appeared in the literature. The best characterized cluster seems to be $Co_3(CO)_9H$, which is found in 10% yield as a decarbonylation product of $Co_3(CO)_{10}H$ ($[Co_3C]OH$). The X-ray structure has disclosed a regular triangle with three bridging and six terminal CO groups. The hydrogen atom was not located in the diffraction study.

Similar compounds of formula $[Co(CO)_2P(n\text{-}Bu)_3]_3$ have been isolated from stoichiometric hydroformylation of α-alkenes with $HCo(CO)_3P(n\text{-}Bu)_3$, where only hydrogen but no CO is present. Susceptibility measurements (*see Magnetic Susceptibility*) showed Curie–Weiss behavior with magnetic moments between 2.86 and 3.10 BM, appropriate for two unpaired electrons. Chemically or spectroscopically, hydrogen could not be located, but one additional hydrogen atom is needed to explain the observed magnetism and suggested structure (*see* ***Paramagnetic Organometallic Complexes***).

3 ALKYL COMPLEXES

3.1 $RCoL_4$

Only one example is known of a binary homoleptic (*see Homoleptic Compound*) cobalt alkyl compound, $Co(nb)_4$

(nb = norbornyl, bicyclo[2.2.1]heptyl) (Section 3.4). Otherwise, Co−alkyl σ-bonds are found combined with various alkenic and cycloalkenic ligands, in cobaltacarbocycles, and in $CpCo^{III}$ complexes, and will be treated in the respective sections. In addition to $Co(nb)_4$, two groups of alkyl compounds will be presented in this section: complexes of the type $RCo(PR'_3)_n$, and the monoalkyl derivatives of the so-called 'cobalamines' and 'cobaloximes', Schiff base (*see Schiff Base*) and glyoxime-derived coordination compounds of Co, respectively. Cobalt−cyano complexes are described elsewhere (*see* ***Cyanide Complexes of the Transition Metals***) and will not be covered here.

As noted above, σ-carbon complexes derived from $HCo(CO)_4$ are of low thermal stability and most of the isolated examples contain phosphine and phosphite ligands. Thus $Co(PMe_3)_4{}^-$ is readily alkylated by MeI to $MeCo(PMe_3)_4$. With excess MeI, oxidative addition with loss of one phosphine to $Me_2CoI(PMe_3)_3$ is found. Higher alkyls are subject to β-elimination (*see β-Elimination*).

The composition $MeCo(PR_3)_4$ is realized, apart from PMe_3, with various phosphines. The PPh_3 complex, however, has a lower coordination number, that is, $MeCo(PPh_3)_3$ is found in the solid, but it partially dissociates in solution into $MeCo(PPh_3)_2$, reminiscent of the behavior of $RhCl(PPh_3)_3$ (*see Wilkinson's Catalyst*). In protic solvents, this compound decomposes by proton abstraction, releasing methane, and this observation may explain its ability to effect aldol condensation of certain ketones (acetone and methyl ethyl ketone) in an aprotic solvent (equation 36).

$$MeCo(PPh_3)_{2,3} + RCH_2COR \longrightarrow CH_4 + Co(PPh_3)_3{}^+ + RCHCOR^- \quad (36)$$

3.2 Co^{II} and Co^{III} Alkyl Complexes

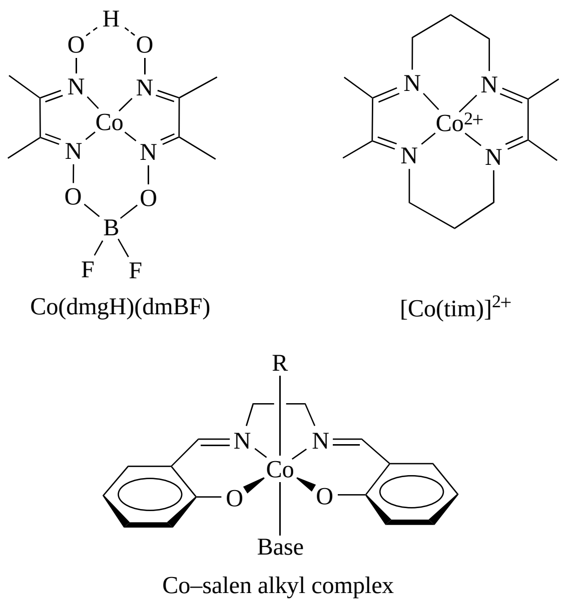
Co^{II} alkyl complexes are represented by some $Co(Ar)_2(PR_3)_2$ and anionic acetylides $Co(C{\equiv}CR)_4{}^{2-}$ and $Co(C{\equiv}CR)_6{}^{4-}$; the latter complexes are closely related to Co^{II} cyano complexes (*see* ***Cyanide Complexes of the Transition Metals***). Chelating ligands have also been used in the synthesis of cobalt alkyl complexes. Cobalt(II) halides react with $LiN(SiMe_2CH_2PPh_2)_2$ to form the high-spin (d^7) tetrahedral complex $Co(X)N(SiMe_2CH_2PPh_2)_2$ (X = Cl, Br, I). These blue coordination complexes can be alkylated via salt metathesis, producing orange organometallic complexes (e.g. $Co(Me)N(SiMe_2CH_2PPh_2)_2$). The color change is indicative of both a geometry change (tetrahedral to square planar) and a spin state change from high-spin ($3.89\mu_B$, three unpaired electrons) to low-spin ($1.9-2.2\mu_B$, one unpaired electron).[53]

A considerable number of organo Co^{III} complexes of general formula $CoR_2L_2L'_2$, have been prepared, where L and L′ are acac, PR'_3, or bipy, and R is mostly Me but is Et in a few cases. The synthetic approach involves the reaction of $Co(acac)_3$ and R_2AlOR for acac derivatives, or the reaction of $CoCl_2$ with the ligand bipy and/or phosphine, the halocarbon, and $NaBH_4$. In these complexes, the R groups are either mutually trans, or trans to a hard σ-ligand (halide, ammine, acac), but not *trans* to a phosphine, owing to the strong labilizing effect of an alkyl group on a π-acceptor ligand trans to it (*see Trans Effect*).

3.3 Alkylcobaloximes and Cobalamins

A class of organocobalt complexes built from cobalt complexed in a square-planar geometry (*see Square Planar*) with a tetradentate ligand (*see Tetradentate Ligand*) is depicted in Scheme 14. Several tetradentate ligands have been studied including salen, a modified bis(dimethylglyoximate), in which the O–H–O bridge is replaced by F_2BO_2 or $–(CH_2)_3–$, and a variety of tetraaza macrocycles including porphyrin. An additional axial base such as a phosphine, pyridine, or most significantly, water is complexed to the cobalt (III) center resulting in complexes of the type $Co^{III}L_4(B)^+$. These complexes have been shown to accommodate an alkyl or other σ-carbon ligand trans to the axial base as the sixth ligand of an octahedral Co^{III} complex.

Cobalamins consist of a cobalt central atom, a substituted corrin ring that binds in a tetradentate fashion, a benzimidazole base that is linked to a pyrrole moiety of the corrin ring, and an axial ligand. The identity of the axial ligand can vary, but it can be a carbon-bound ligand. Vitamin B_{12} (*see* ***Cobalt: B_{12} Enzymes & Coenzymes***) is a cyanocobalamin, and an adenosyl group as the axial ligand makes the complex coenzyme B_{12}. Cobalamins are examples of naturally occurring organometallic compounds, and coenzyme B_{12} was the first recognized example of a biological organometallic



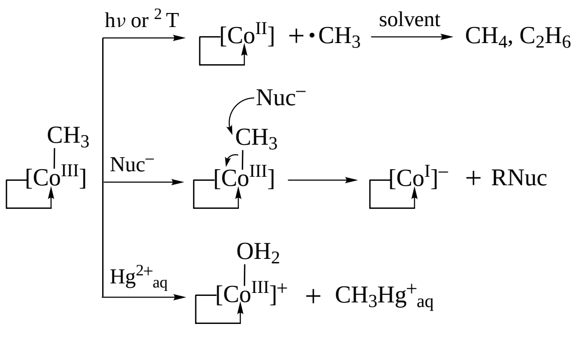
Scheme 14

compound. Methylcobalamins also play a role in biology, where they are found in microorganisms and can release methane at temperatures above 180 °C or methylate mercury in the environment.

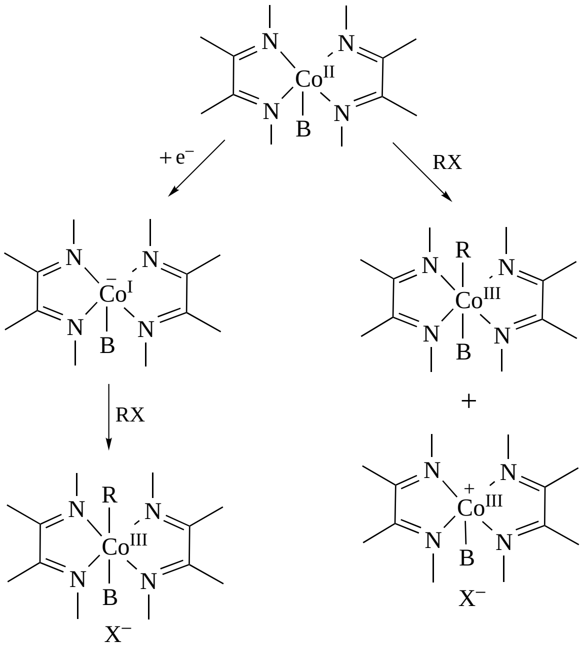
Three methods of Co–C bond cleavage have been proposed to occur in cobalamins (Scheme 15). Heat or photochemical irradiation can induce homolysis of the Co–C bond with a consequent one-electron reduction of cobalt. Nucleophilic attack on the methyl group can occur, resulting in reduction of Co^{III} to Co^{I}. Electrophilic attack (e.g. mercury methylation) can also occur, where the methyl group is transferred as a carbanion.[54]

Cobaloximes have been studied as model systems for cobalamins. In the square pyramidal cobaloximes, CoL_4(Base), cobalt is known in three oxidation states (Co^{III}, Co^{II}, and Co^{I}), where the latter are monoanions in cases when the L_4 system is a dianion (as in bisglyoximates). Redox potentials interrelating the oxidation states as a function of the ligand and the axial base have been extensively investigated. Redox potentials become increasingly negative in the sequence H_2O > phosphine > pyridine. The Co^{II} complexes are square pyramidal (*see Square Pyramidal*) low-spin d^7 species, and the Co^{I} complexes (d^8) have the same geometry with two electrons in a nonbonding or weakly antibonding d_z^2 orbital, a fact that makes them strong nucleophiles (*see Nucleophile*). Co^{III} cobaloximes react with hydrogen in alkaline solution to give hydrides. Some of the compounds reversibly bind O_2.

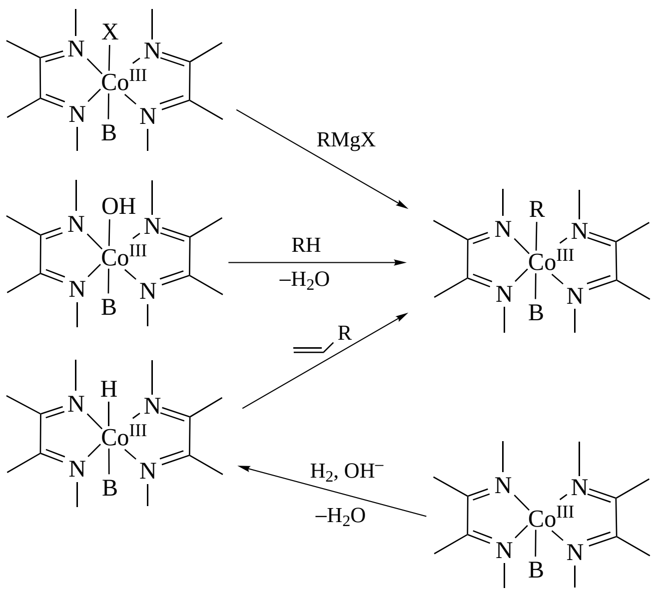
Alkylcobaloximes, $RCo^{III}L_4(B)$, are of interest as B_{12} cofactor model compounds and have been generated in many different ways from Co^{III}, Co^{II}, or Co^{I} precursors (Schemes 16 and 17). Co^{III} complexes featuring axial halide ligands are susceptible to alkylation by nucleophiles, for example, Grignard reagents (*see Grignard Reagents*) and other organometals. Alkenes and alkyls insert into the corresponding hydrides, and hydroxo complexes react with even weakly acidic CH functionalities by water elimination and formation of a Co–carbon bond. Co^{II} complexes react with activated halides in a two-step oxidative addition (*see Oxidative Addition*) through an intermediate radical (cf. Section 7.1).



Scheme 15



Scheme 16

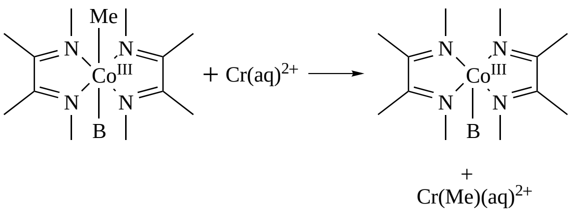


Scheme 17

A general route for synthesizing a great variety of cobaloximes is by reaction of Co^{I} complexes with electrophiles. Co^{I} precursors are generated by reduction of Co^{II} or Co^{III} electrochemically, by Na/Hg, or with borohydride. The reaction has been extensively investigated and rates have been compared with those found for various organic nucleophiles. It was found that Co^{I} cobaloximes are among the

strongest nucleophiles known, and have been termed 'supernucleophiles' for that reason. These Co^{I} cobaloximes can undergo oxidative addition of alkyl halides to form Co^{III}–alkyl bonds. An organometallic compound with the longest known n-alkyl chain has been synthesized and characterized using a cobaloxime reagent.[55]

A significant observation for cobaloximes as B_{12} models was the reduction of $MeCo^{III}L_4(B)$ by $Cr(aq)^{2+}$, which gave $Co^{II}L_4(B)$ and $Cr(Me)(aq)^{2+}$ (equation 37). These products are indicative of an inner-sphere (*see Inner-sphere Reaction*) electron transfer with Me as the bridging ligand. This result has promoted further studies, notably methyl transfer between cobaloximes and nickel tetraazacycle complexes, which provides a possible model for the methylcobalamin alkylation of CO hydrogenase.[56]



(37)

3.4 CoR_4

$Co(nb)_4$ is a unique compound formed from $CoCl_2$ and Li(nb) in THF. The somewhat surprising formal oxidation state of Co^{IV} is believed to stem from the intermediate hydrolysis of $Co(nb)_3^-$ to the hydride $HCo(nb)_3$, which on repeating the same sequence of reactions would give $H_2Co(nb)_4$; subsequent evolution of H_2 gives the stable alkyl complex. An X-ray structure (Figure 8) of a single crystal obtained by slow oxidation of the anion $Co(nb)_4^-$ shows, apart from some disorder of the Norbornyl (nb) ligands around the threefold axis, the expected D_{2d} geometry with two larger (114°) and two smaller (108°) C–Co–C angles and rather short Co–C bond lengths of 1.92 Å (mean).[57] The susceptibility of the compound was measured between 1.7 and 299 K and gave Curie–Weiss behavior with $\mu_{eff} = 1.89$ BM, that is, one unpaired electron that indicates a low-spin tetrahedral d^5 complex. $Co(nb)_4$ is the only known example of a low-spin tetrahedral complex.

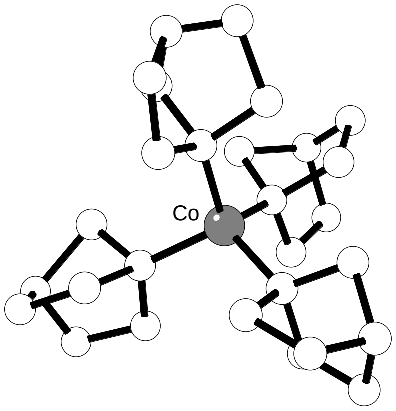


Figure 8 Structure of $Co(nb)_4$

4 ALKENE AND ALLYL COMPLEXES

Alkene complexes of cobalt generally have to be stabilized by CO, phosphine, or phosphite supporting ligands or contain a CpCo moiety. Homoleptic alkene ligands cannot match the electronic requirements of a single d^9 metal atom, but this is not the case for allyl ligands. The orbital energies of the cobalt 3d and 4s/4p atomic orbitals lie considerably above the filled π and somewhat below the π^* level of an unconjugated alkene, so that an alkene would act primarily as an electron acceptor to cobalt.

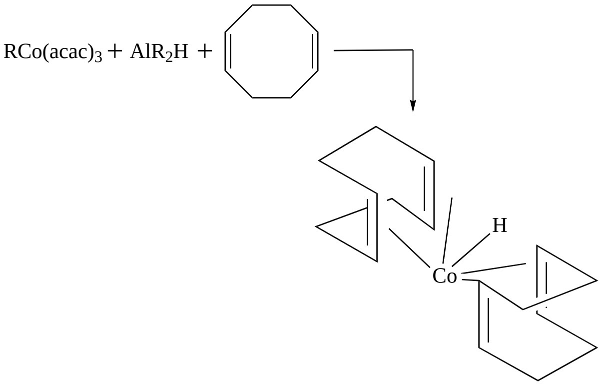
4.1 Matrix and Metal Vapor Reactions

Study of the interaction of metal atoms with ethylene in a noble gas matrix has led to the identification of a number of species, mostly by absorption spectra. They have been assigned formulas such as $Co(C_2H_4)$, $Co_2(C_2H_4)$, and $Co_2(C_2H_4)_2$. These species decompose at about 35 K.

Condensation of cobalt atoms into an ethylene matrix at 77 K yields $Co(C_2H_4)_3$, which decomposes at about 210 K. Reaction of this complex with phosphine ligands gives the more stable, neutral, paramagnetic complexes $Co(PR_3)_3(C_2H_4)$. Even more resistant to thermal decomposition is the green paramagnetic tris(norbornene) complex $Co(C_7H_{10})_3$, which decomposes at 258 K. This complex can be stabilized, and is similar to the green paramagnetic compound $Co(C_7H_{10})(PR_3)_3$. $Co(cod)_2$, obtained by the metal vapor technique in the same way, is not a stable compound and has been characterized by a variety of in situ reactions, such as reaction with cyclopentadiene to give CoCp(cod). Thus, these alkene complexes, though not isolated and characterized as pure compounds, can nevertheless, serve as starting materials for a variety of transformations (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***).

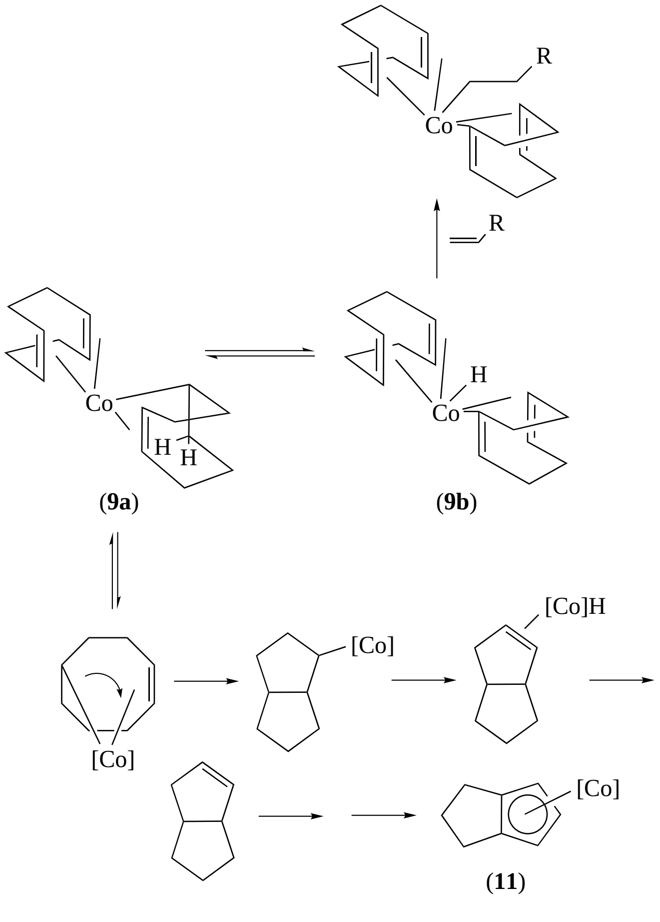
4.2 Cyclooctadiene Complexes

The hydride $Co(cod)_2H$ was prepared by Wilke from AlR_2H and $Co(acac)_3$ (equation 38). It forms black, air-sensitive crystals of unknown structure that ignite spontaneously in air. An equilibrium between a cyclooctadiene/cyclooctenyl form (**9a**) and a bisalkene hydride (**9b**) in solution is inferred from chemical reactions of the compound (Scheme 18).

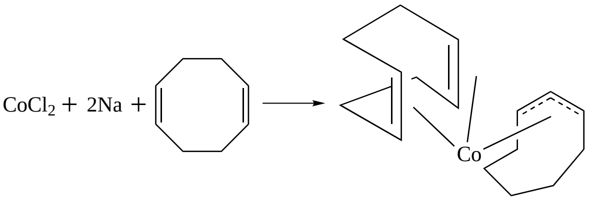


(38)

A different synthetic approach, namely, Na reduction of $CoCl_2$ in the presence of cyclooctadiene (cod) in a THF/pyridine mixture (equation 39),[58] gives a 16-electron complex (**10**) of identical composition, which is the conjugate analog of (**9a**), containing a π-cyclooctenyl ligand. Compound (**10**) is considerably more stable towards heat and air than is (**9**). It has also been observed as a by-product when excess $AlHR_2$ was employed in the synthesis of (**9**).



Scheme 18



(39)

(**10**)

Reaction of (**9**) with $AlH(i\text{-Bu})_2$ liberates cyclooctene, but at 40 °C it slowly isomerizes thermally in solution to the stable CpCo derivative (**11**) (Scheme 18). In the presence of excess cod, this latter complex is converted catalytically to tetrahydropentalene. Ring contraction to the pentalenyl system can be understood as an intraligand reductive elimination (*see Reductive Elimination*), the driving force of which may be coordination of cobalt to the double bond of free cod in solution. In the catalytic cycle some (**10**) is formed.

Many organometallic complexes use cod as a ligand because it can be easily substituted. For that reason, many cobalt cyclooctadiene complexes are important in catalytic reactions, particularly when used with cyclopentadienyl in complexes (Section 5.1.2).[59,60]

4.3 (Allyl)cobalt Complexes

4.3.1 Synthesis and Properties

The homoleptic complex $Co(\eta^3\text{-}C_3H_5)_3$ (**12**) obeys the 18-electron rule (*see Eighteen Electron Compounds*) and could be expected to be stable by analogy to the abundant allyl chemistry of Ni. The compound has been prepared from $Co(acac)_3$ and C_3H_5MgCl (equation 40) or, alternatively, from $CoCl_2$ and C_3H_5MgCl/C_3H_5Cl (equation 41) in about 50% yield.[61] The latter method has also furnished a number of substituted allyl derivatives. Despite its favored electron count, complex (**12**) decomposes in solution around −60 °C, and the pure crystalline solid decomposes spontaneously in an inert atmosphere at −20 °C. The solid ignites spontaneously in air (cf. $Co(allyl)_2(ethylene)Li$, Section 5.1.2).

$$Co(acac)_3 + 3(allyl)MgX \longrightarrow Co(allyl)_3 + 3MgX(acac) \quad (40)$$

$$2CoX_2 + 5(allyl)MgX + allylX \longrightarrow 2Co(allyl)_3 + 5MgX_2 \quad (41)$$

Mass spectra of (**12**) show loss of allyl and of hydrogen as main fragmentation patterns. The ^1H NMR spectrum consists of three independent allyl (AA′MM′X) patterns for three chemically inequivalent allyl groups. A structure compatible with this symmetry (C_s) is depicted in Figure 9. It is based on a trigonal prism with allyl groups along the three parallel edges (an attempted X-ray structure determination was thwarted by extensive disorder).

The main reaction modes of (**12**) are reductive elimination (*see Reductive Elimination*) with C–C coupling to diallyl (1,5-hexadiene) (equation 42), or nucleophilic displacement

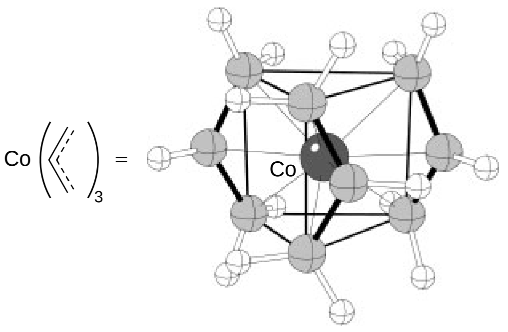


Figure 9 Geometrical arrangement of allyl groups in Co(allyl)$_3$

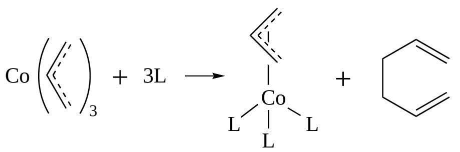
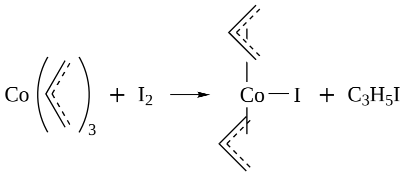
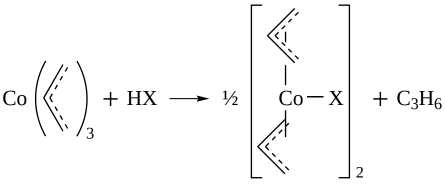
of one allyl group. Thus, with two-electron ligands, the displacement of two basal allyl groups and addition of three ligands gives Co(allyl)L$_3$. For substituted allyl ligands, it can be shown that the reaction proceeds with retention of the *syn/anti* conformation at the remaining allyl group, which can be used to determine the *syn/anti* distribution in the original tris(allyl) complex. Electrophiles selectively attack the edge-bound allyl, which is displaced in the form of C_3H_5X (equation 43) or C_3H_6 (equation 44) to give a thermally labile bis(allyl) halide complex, Co(allyl)$_2$X. Because of their low solubility, these cobalt complexes are presumed to be dimeric.



(42)



(43)



(44)

Recently, the synthesis and characterization of the only known homoleptic bis(allyl)cobalt complex has been reported.[62] The bulky bis(1,3-trimethylsilyl)allyl ligand has been shown to increase the thermal stability of allyl compounds, and examples of first-row transition metal complexes, for which no unsubstituted analogs exist, have been prepared with this ligand.[63] The formally 15-electron species [1,3-$(SiMe_3)_2C_3H_3$]$_2$Co is an air- and moisture-sensitive solid. The η^3-allyl ligands are in a staggered arrangement about the metal center, and the trimethylsilyl moieties are in a *syn-anti* arrangement on each allyl ligand (Figure 10). The range of Co–C bond distances in this complex (1.996–2.096 Å) suggests that the steric encumbrance (*see Steric Effect*) of the ligands leads to bond lengthening (cf. 1.918–1.948 Å in (η^3-C_3H_5)(η^5-Me_5C_5)Co).

4.3.2 *Reactions of (Allyl)Co Complexes*

A versatile application of Co(allyl)$_3$ has been found in its reaction with butadiene, which effects catalytic dimerization under very mild conditions. Individual reaction steps are reproduced in Scheme 19. These reactions lead to the isolated and structurally characterized complex (**13**) as the true catalyst. Scheme 19 is in fact a collection of all the classical steps involved in homogeneous transition metal C–C bond-forming reactions. The first step consists of replacement of two allyl groups by butadiene, which is reductively eliminated as diallyl, similar to what has been found with cod and with other two- or four-electron ligands.

Co(allyl)(butadiene) (**14**) has been identified by NMR at −40 °C. A crucial step is insertion of butadiene into a Co–allyl bond forming (**15**), which occurs if the temperature is raised to −15 °C. Transfer of one hydrogen from the coordinated heptadienyl to a coordinated butadiene gives (**16**). A second insertion of another molecule of butadiene into the new Co–allyl bond generates a 3-methylheptadienyl complex (**17**), and a final molecule of butadiene liberates heptatriene from the metal to give (**13**).

The 3-methylheptadienyl complex (**13**) is the active catalytic species in butadiene dimerization. The two dimers formed are 2-methylheptatriene and octatriene in a 9:1 ratio, depending on conditions. Attack of the incoming butadiene on C-1 or C-3 of the methylallyl complex (**17**) determines product formation.

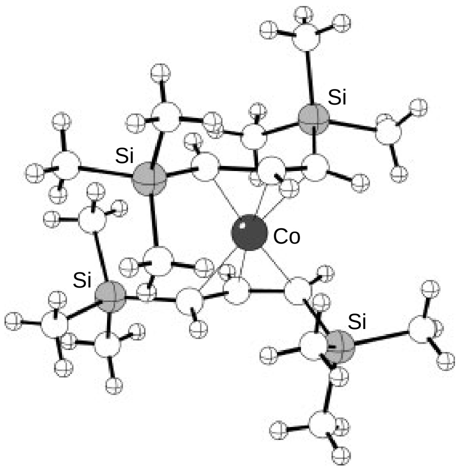


Figure 10 Structure of [1,3-$(SiMe_3)_2C_3H_3$]$_2$Co

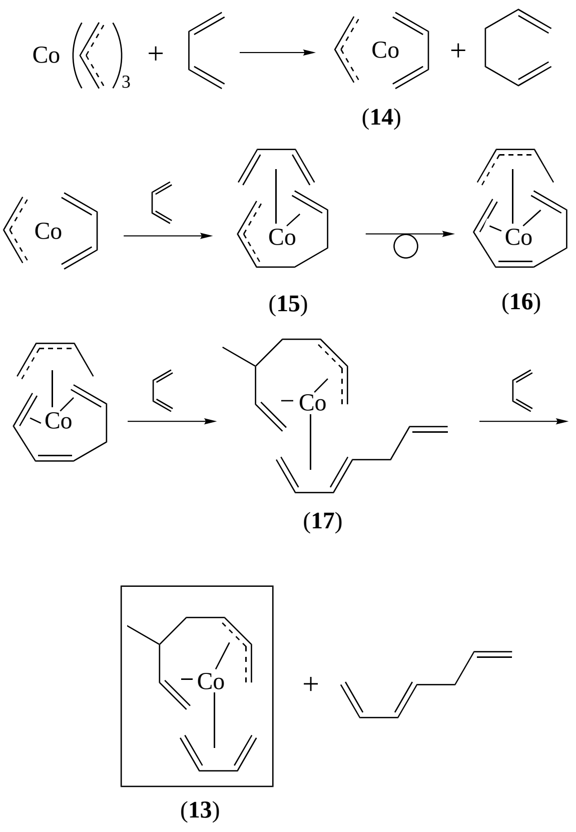


Scheme 19

5 CYCLOPENTADIENYL COMPLEXES

Cyclopentadienyl complexes of cobalt exist mainly in three oxidation states – Co^{I}, Co^{II}, and Co^{III}. Co^{I} is represented by complexes of the type $CpCoL_2$, where L is CO, alkene, alkyne, or phosphine. Apart from derivatives of cobaltocene, half-sandwich complexes (*see Half-sandwich Complexes*) $(CpCoX)_2$ or CpCoLX with cobalt in oxidation state II are known. $CpCo^{III}$ occurs in various $CpCoL_nX_m$ compositions (Section 9.2).

5.1 $CpCoL_2$

5.1.1 CpCo(CO)₂

$CpCo(CO)_2$ (**18**) is obtained on heating cobaltocene under CO or by heating $Co_2(CO)_8$ with cyclopentadiene. Since the latter reaction works with substituted cyclopentadienes as well, a variety of substitution products are easily accessible. $CpCo(CO)_2$ is a dark red, air- and light-sensitive oil (mp −22 °C) with a musty odor. The crystal structure has been determined and shows a conformation with one CO eclipsed by a Cp edge, whereas the Cp* derivative has a different conformation with the CO–Co–CO plane parallel to one side of the Cp ring. The latter was first obtained from C_5Me_5COMe and $Co_2(CO)_8$, but it can be prepared more conveniently by reaction of Cp*H with $Co_2(CO)_8$, or via CO substitution on Cp*Co half-sandwich complexes (Section 9.1).

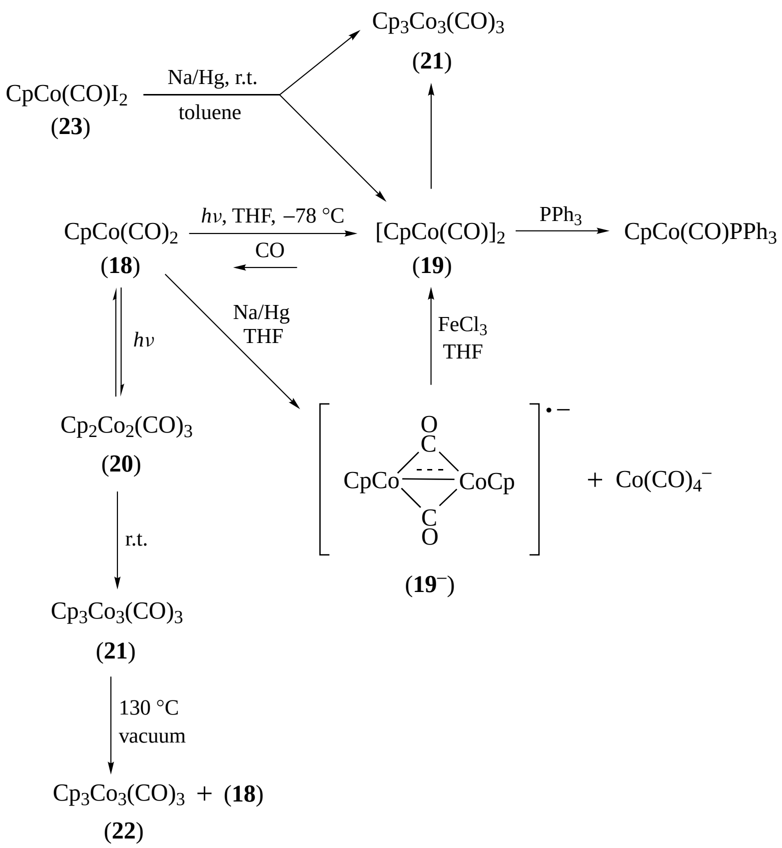
Complex (**18**) is commercially available and has been used extensively for the preparation of CpCo complexes. The CO ligands are substituted thermally or photochemically under conditions similar to those required for the substitution of $Fe(CO)_5$ (i.e. at about 100–120 °C). The products formed from irradiation of (**18**) under different conditions are depicted in Scheme 20.

A complex reaction pathway occurs owing to the existence of two different oligomers of CpCo(CO) and the transient nature of most of the reaction products. When irradiated at low temperature in THF under an inert atmosphere, (**18**) gives the dimeric monocarbonyl $[CpCo(CO)]_2$ (**19**), which reverts to (**18**) when CO is admitted.[64] In contrast, irradiation in a closed system at 5 °C in toluene gives an equilibrium mixture with $(CpCo)_2(CO)_3$ (**20**) as a major component that can be isolated as crystals on cooling. Since the CO liberated in forming (**20**) is still present in this system, conversion to (**20**) is incomplete. When redissolved at room temperature, (**20**) forms green $(CpCo(CO))_3$ (**21**) and (**18**). On heating, (**21**) converts to black $(CpCo)_4(CO)_2$ (**22**) and (**18**).[65]

Another route to CpCo carbonyls is by reduction. A mixture of (**19**) and (**21**) has been obtained by reduction of (**23**) in toluene. The anion ($\mathbf{19}^-$) is obtained by Na/Hg reduction of (**18**) in THF. If the process is followed by cyclic voltammetry, a reversible reduction is observed. The anion $CpCo(CO)_2{}^-$ either loses a Cp^- ligand or forms the corresponding dimer. Loss of Cp^- is preferred if the complex is stabilized through substitution by electron-withdrawing groups.

The Co–Co distance of this dimer is 2.36 and 2.37 Å, respectively, in the two independent molecules of the unit cell. This distance is consistent with a bond order greater than 1 and is shorter than in any of the known cluster molecules with a formal Co–Co single bond (all have Co–Co distances around 2.45–2.52 Å). The EPR spectrum of ($\mathbf{19}^-$) shows a symmetric 15-line pattern, indicating equal coupling of the odd electron to either cobalt nucleus ($I = 7/2$). EPR studies of the related complex $CpCo(CO)_2{}^-$ indicate that the odd electron in this complex also resides on the cobalt center. However, DFT studies indicate that the odd electron in this complex is approximately evenly distributed over cobalt metal, the Cp ring, and the CO ligands; this discrepancy stems from the neglect of spin polarization when calculating atomic orbital spin populations from EPR hyperfine coupling constants (*see Electron Paramagnetic Resonance*).[66]

The hapticity of the Cp ring in $CpCo(CO)_2{}^-$ has been the topic of much debate. If an associative mechanism for substitution is followed, a hapticity (*see Hapticity*) of η^3 from ring slippage would result in a 19-electron intermediate and 17-electron product, while a hapticity of η^5 would result in a more unstable 21-electron intermediate. However, it has been shown that CO substitution follows a dissociative mechanism



Scheme 20

for this complex, and several experimental and theoretical studies have added credibility to the argument of $CpCo(CO)_2^-$ possessing an η^5-Cp ligand. It is now generally accepted that $CpCo(CO)_2^-$ is a 19-electron complex with an η^5-Cp moiety.[64]

A different product of the series, $Cp_3Co_3(CO)_2$, has been obtained from the reaction of (**18**) and $CpCo(C_2H_4)_2$ (**24**). It is not stable in solution and can be isolated only because it precipitates out as it is being formed. It has 46 valence electrons, which is two electrons short of the requirement for a 5-vertex *closo* structure (*see Closo Cluster*). At room temperature, the solution magnetic moment of $\mu_{eff} = 3.0 \pm 0.2$ BM (Evans method) indicates a triplet; however, solid-state susceptibility measurements at 100 K show it to be diamagnetic. The structural determination disclosed a trigonal bipyramidal motif (D_{3h}, threefold crystallographic axis).[65] Like $Cp_3Co_3(CO)_3$, it converts in solution into (**18**) and (**22**).

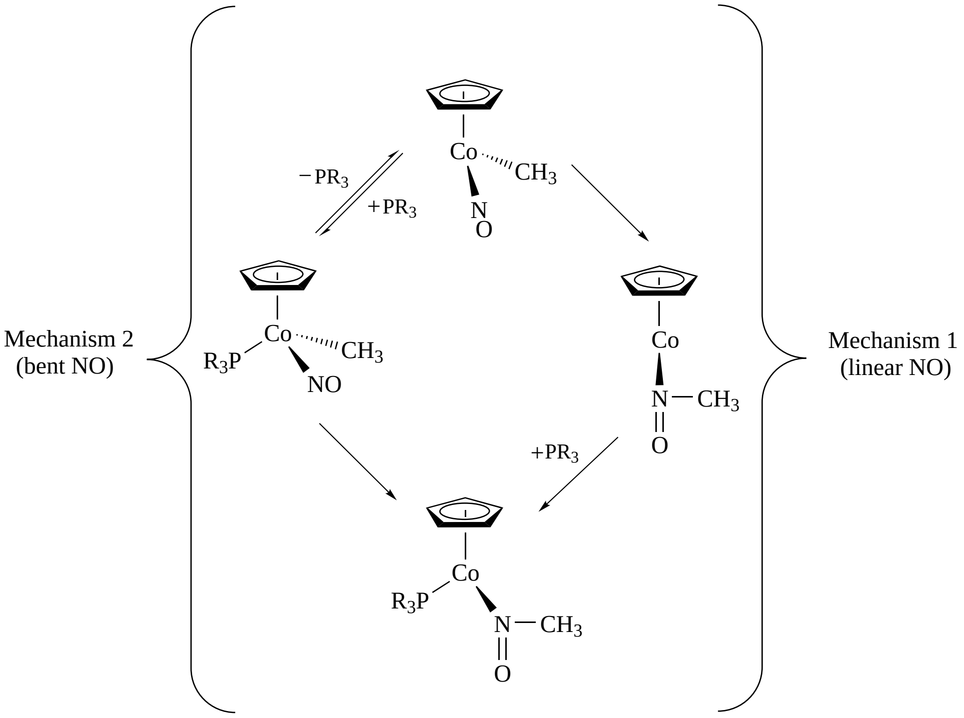
Most of the unsaturated CpCo carbonyls are active catalysts in alkyne oligomerization (Section 5.1.4), as CO can be displaced for alkynes. In addition to cyclization reactions, CpCo(CO) complexes have been studied as C–H bond activators. Bergman determined that, unlike the corresponding rhodium and iridium complexes, CpCo(CO) is unreactive toward C–H activation.[67] Theoretical studies were used to probe the inability of CpCo(CO) to activate alkanes, and it was determined that a triplet ground state is responsible for the inertness of CpCo(CO) toward methane insertion.[68]

Thermal substitution of $CpCo(CO)_2$ with alkenes, phosphines, and other two-electron ligands has furnished many more $CpCoL_2$ variants. Mention should be made of nitrosyl complexes (*see Nitrosyl Complexes*), as migratory insertion of NO into cobalt–carbon bonds is an area of interest. The addition of phosphines to $CpCo(NO)CH_3$ results in a nitrosyl insertion product (equation 45). An intramolecular insertion followed by phosphine addition (mechanism 1) was proposed for the reaction; this mechanism is similar to the one for CO insertion (Scheme 21). However, the versatility of NO (a 3-electron linear ligand or a one-electron bent ligand) could allow NO insertion after phosphine addition (mechanism 2). Ab initio and DFT studies show that NO insertion is the rate-determining step for both mechanisms, and insertion with phosphine association (mechanism 1) occurs with lower activation energy of 10–20 kcal mol^{-1}.[69]

$$CpCo(NO)(CH_3) + PPh_3 \longrightarrow CpCo(PPh_3)(N(O)CH_3) \quad (45)$$

5.1.2 *CpCo(alkene)$_2$ and CpCo(diene)*

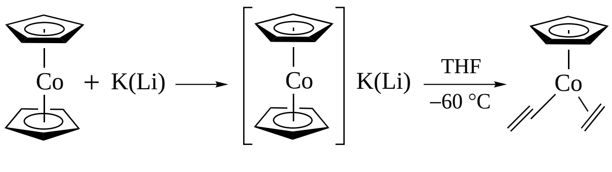
Complexes of composition $CpCo(alkene)_2$ and CpCo (diene) are easily formed by different routes and have



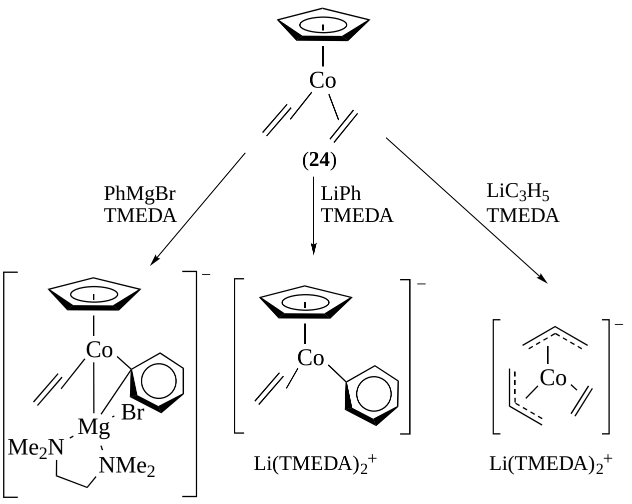
Scheme 21

played important roles in a variety of applications. Cycloalkene ligands are generated directly from cobaltocene, for example, $CpCo(C_5H_6)$, by addition of hydride to the cobaltocenium ion. All common alkenes and dienes (ethylene, butadiene, cyclodienes, cyclotrienes, cod, norbornadiene, cyclooctatetraene, and many others) have been coordinated to a CpCo moiety. A general route for the preparation of these compounds is substitution of $CpCo(CO)_2$ or reductive cleavage of cobaltocene in the presence of an alkene.

A one-electron reduction of cobaltocene (Section 7.1) transforms the sandwich complex into a 20-electron anion of low stability, the principal decomposition path being cleavage into Cp^- and a neutral CpCo fragment. This fragment can form derivatives upon addition of alkenes with alkali metals (Scheme 22). The reaction using potassium has produced the thermally unstable ethylene complex $CpCo(C_2H_4)_2$ (**24**), which dissociates ethylene above room temperature and is now generally employed as a source for the CpCo fragment. This method can generate CpCo under much milder conditions than if it were generated from the dicarbonyl (**18**).

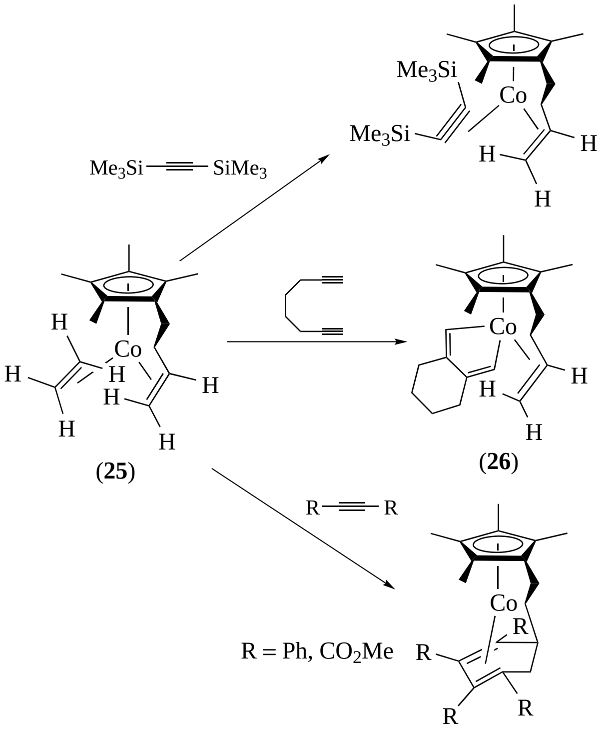


Scheme 22



Scheme 23

The bis(ethylene) complex (**24**) can be derivatized in several ways (Scheme 23). The product isolated from PhMgBr and (**24**), after addition of TMEDA, has been characterized by X-ray diffraction and can be viewed as an alkene complex in which an ethylene molecule is replaced by a Mg–Ph bond of the Grignard reagent (*see Grignard Reagents*). Thus, the phenyl ring is coordinated to cobalt via a σ-bond and has interaction with magnesium; the magnesium center is bound to cobalt as well.



Scheme 24

Whereas Mg(allyl)Br gives a similar product, Li(allyl) instead replaces the Cp and one ethylene and forms anionic $Co(allyl)_2(ethylene)^-$. Note that this anion is related to tris(allyl)cobalt; it is much more stable as an ionic compound and can be isolated conveniently at ambient temperature.[70] The pentamethyl analog of (**24**), $Cp^*Co(C_2H_4)_2$, is best prepared by amalgam reduction of $[Cp^*CoBr]_2$ (Section 9.1) in the presence of ethylene.

In the intriguing derivative (**25**) of (**24**), one ethylene ligand is linked through a carbon bridge to a Cp* ring (Scheme 24). A $(CH_2)_2$ bridge has proved to be the best size with which to stabilize the coordinated alkene by the chelate effect (*see Chelate Effect*). The ethylene unbridged in (**25**) is more labile than is the pendant one, and as a consequence, facile monosubstitution occurs with many two-electron ligands, including alkynes. Cyclization (Section 5.1.4) can occur with alkynes and the pendant ethylene to form a pendant cyclohexadiene. Reaction intermediates of alkyne oligomerization at Co can be detected during this reaction sequence, as is demonstrated by the isolation of the stable cobaltacyclopentadiene (**26**).[71]

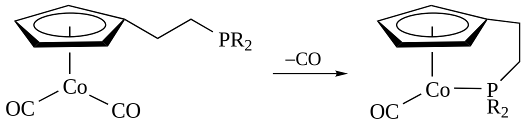
5.1.3 *Cyclopentadienyl Cobalt Phosphine and Related Complexes*

Among the wide variety of known $CpCoL_2$ complexes, the mono- or bis(phosphine) complexes bear special mention. If the phosphine has bulky substituents, such as PPh_3, there will be one labile PPh_3 ligand that dissociates easily, thereby liberating a coordination site accessible to smaller molecules. With the Cp* ligand, in fact, a bis PPh_3 complex is no longer formed. This reactivity has been exploited in studies concerned with alkyne oligomerization at a cobalt center (Section 5.1.4). Conversely, the metal becomes a strong Lewis base and readily reacts with protons, alkyl halides, and even mild electrophiles (*see Electrophile*) if phosphines with electron-donating substituents (e.g. PMe_3) are introduced.

As has been shown and comprehensively reviewed,[72] many d^8 $CpCoL_2$ complexes are readily protonated at the metal. Protonation (*see Protonation*) does not lead to simple products with L = CO, however, and requires strong acids for L = alkene. If both L ligands are phosphines, protonation can be effected with relatively mild acids such as NH_4^+ in an organic solvent to give salts of the cations $CpCo(PR_3)_2H^+$; $CpCo(PMe_3)_2$ is protonated even by methanol. These protonated complexes are decomposed on electrochemical reduction into the neutral cobalt complexes $CpCo(PR_3)_2$ and hydrogen at mild potential, depending on the phosphine.

Complexes of the type $CpCo(PR_3)_2$ are alkylated at the metal with small alkyl halides to give $CpCo(PR_3)_2R^+$ (Scheme 25). Bulky halides produce ring-substituted hydrido cations instead, explained by attack of the electrophile from the *exo* site followed by ring-to-metal proton transfer. This reaction could be electrophilic addition (*see Electrophilic Reaction*), $S_{E}1$, or more probably radical addition initiated by electron transfer similar to the RX reaction of cobaltocene (Section 7.1). Since the oxidation potential of $CpCo(P(alkyl)_3)_2$ is more negative than that of cobaltocene, this latter mechanism is very plausible.

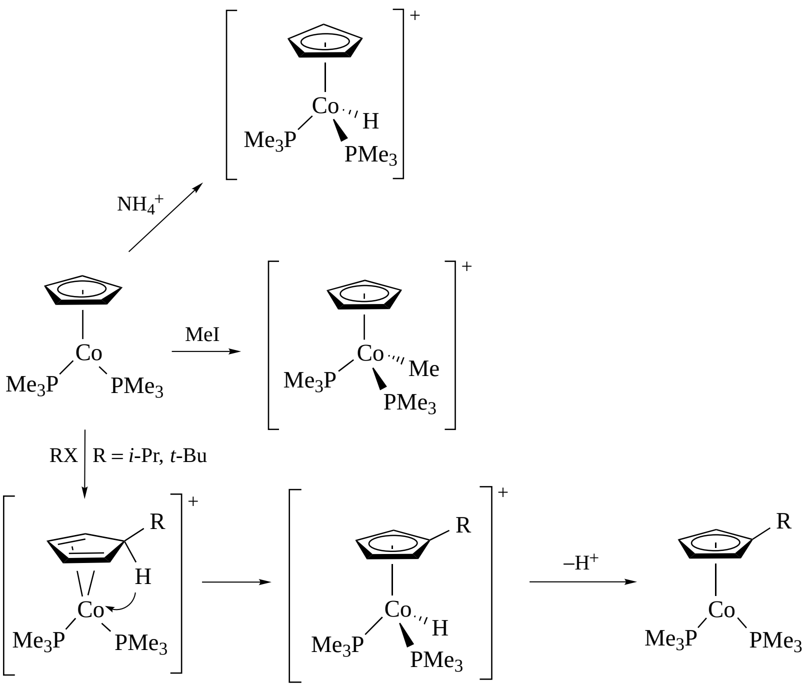
The use of Cp rings with pendant phosphines in $CpCoL_2$ complexes has also been reviewed.[73] Carbonyl complexes of this type ($Cp'Co(CO)_2$) lose CO at room temperature to afford pendant phosphane adducts (equation 46). The chelated phosphane can then be uncoordinated with ligands such as cod; substitution of cod (Section 5.1.4) with alkynes allows the cobalt complex to participate in cyclization reactions (Scheme 26).



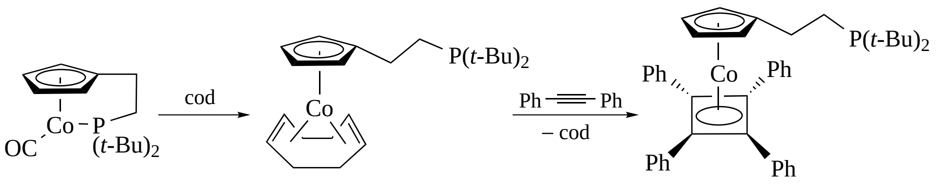
(46)

5.1.4 *Cyclopentadienyl Cobalt Alkyne Complexes*

Many of the complexes discussed in the previous sections are catalysts for alkyne oligomerization. In fact, alkyne dimerization and trimerization (*see Cyclodimerization & -trimerization Reactions*) at a cobalt center is recognized as one of the most synthetically useful catalytic reactions mediated by a homogeneous transition metal complex. The cobalt complexes most useful and extensively studied are $CpCoL_2$, where L is CO, alkene, diene, or phosphine. The complex types



Scheme 25



Scheme 26

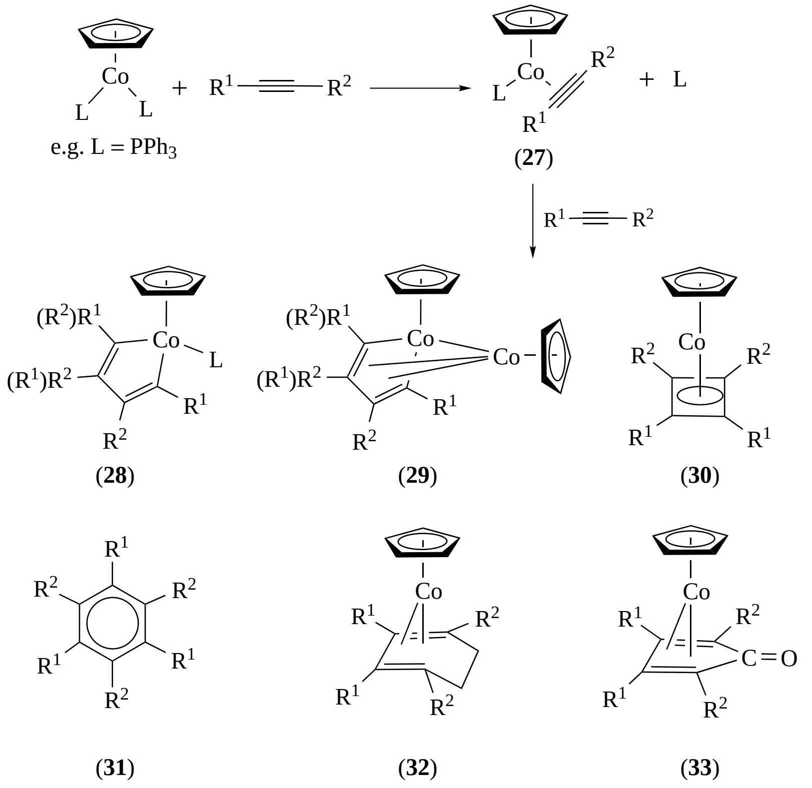
have their specific applications as catalysts. CpCo(diene) and CpCo(alkene) complexes are used for co-trimerization of alkynes with a nitrile to give substituted pyridines, while the carbonyl complex is used for the $2 + 2$ cycloaddition of linked acetylenes. The phosphine complexes are mainly used for mechanistic studies.

The main reaction modes and products that are formed from reaction of $CpCoL_2$ and an alkyne are depicted in Scheme 27. If $CpCo(PPh_3)_2$ is treated with polar alkynes under ambient conditions, a monosubstitution product (**27**) can be isolated. Another isolable product is a cobaltacyclopentadiene (**28**) and, in certain instances, the dinuclear cobaltole complex (**29**) is formed, which has many analogs in the chemistry of $Fe(CO)_3$ and other 14-electron fragments. The cyclobutadiene complex (**30**) is the direct product from collapse of (**28**) and is of high kinetic and thermodynamic stability. In catalytic cycles, (**30**) is inactive. If the ligand L in (**28**) is a third molecule of alkyne, insertion of the latter forms the arene (**31**).

Since a CpCo(arene) is a 20-electron complex, it will not generally be stable; however, it will easily undergo displacement of the arene by new alkyne to regenerate (**27**). An alkene can be incorporated into the organic ligand either by adding to the alkene directly or by starting from CpCo(alkene)L. Addition of an alkyne now results in the formation of cyclohexadiene, which remains complexed to CpCo as in (**32**) (see also Scheme 24); consequently, the reaction cannot be catalytic in this case. If L = CO, complexes containing a cyclopentadienone ligand (**33**) are frequently encountered.

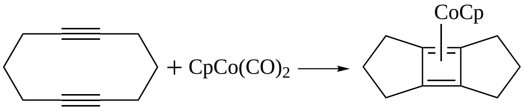
An important and extensively investigated application of CpCo complex chemistry is the catalyzed synthesis of pyridines from alkynes and nitriles.[74] Dissociation of the L ligands liberates the CpCo fragment to react with alkyne to form a cobaltacyclopentadiene complex. The nitrile coordinates to this intermediate and subsequently undergoes insertion to form a seven-membered cobaltacycle. Reductive coupling gives pyridine and reforms CpCo. Asymmetric alkynes add to the carbon with the bulkier substituent adjacent to the nitrile carbon.

Cyclobutadiene complexes are formed preferentially if cyclic dialkynes are treated with $CpCo(CO)_2$. Depending

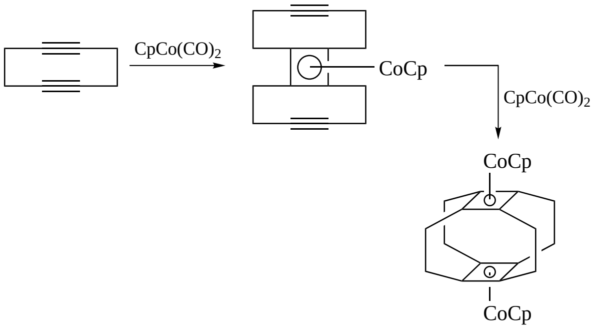


Scheme 27

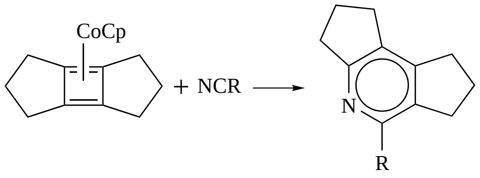
on the ring size, either intramolecular cyclization to form a tricyclic CpCo cyclobutadiene complex (equation 47) or intermolecular cyclization combining two different rings through a cyclobutadiene (equation 48) can occur. An intramolecular pathway requires rings of 10 to 12 carbon atoms, whereas intramolecular double cyclization is no longer feasible with an eight-carbon cyclic dialkyne. In this case, the cyclobutadiene product is formed by intermolecular cyclization. This latter product then can undergo a second $2 + 2$ cycloaddition at the opposite end of the molecule to give a 'superphane' having two CpCo cyclobutadiene units linked in a paracyclophane-like manner.[75] The free hydrocarbon can be liberated from the metals by Ce^{4+} oxidation (however, the expected double $2 + 2$ cycloaddition of two cyclobutadienes in the free superphane to yield an all edge-bridged cubane does not take place). Reaction of CpCo(cbd) with nitrile to give pyridine, as well as related reactions, proved that under appropriate conditions the Cyclobutadiene (cbd) complex, once formed, can undergo ring opening or insert again (equation 49).



(47)



(48)



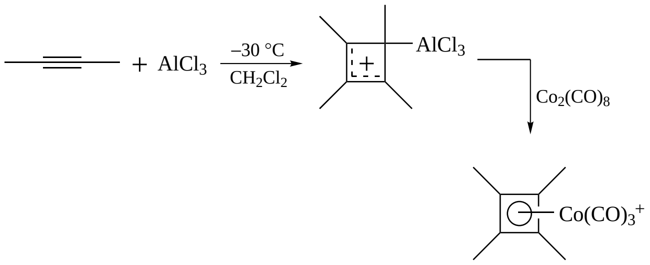
(49)

6 CYCLOBUTADIENE AND ARENE COMPLEXES

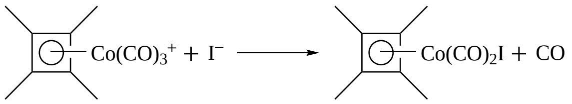
6.1 Cyclobutadiene Complexes

The majority of cobalt cbd complexes are of the type CpCo(cbd) (**34**). Cbd derivatives of $Co_2(CO)_8$, that is,

(cbd)$Co_2(CO)_4$ (**35**), and (cbd)$Co(CO)_2X$ (**36**) are also known. The preparation of (**36**) is achieved by halogen cleavage from (**35**). Complex (**35**) is accessible along the common routes for the preparation of cbd complexes,[76] that is, (i) ligand transfer from a Ni or Pd complex, and (ii) reaction of (2^-) with 1,2-dichlorobutene. An elegant method for the preparation of the tetramethylcyclobutadiene derivative of (**36**) has made use of Hogeveen's complex, which is formed from 2-butyne and $AlCl_3$ in dichloromethane (equation 50). Carbonyl cations (cbd)$Co(CO)_3^+$ easily exchange CO for donor ligands (equation 51) and are susceptible to nucleophilic attack at the cbd ring.[77]



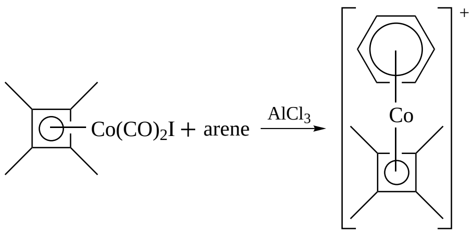
(50)



(51)

Complexes of type (**34**) are obtained from many different alkynes and suitable $CpCoL_2$ precursors, as detailed in the foregoing section. Early workers studied the reaction between CpCo(diene) or $CpCo(CO)_2$ with phenylacetylenes, which gives the respective phenylcyclobutadiene complexes. The tetracyclone complex is a major reaction product when carbonyls are employed. Complexes of type (**34**) have exceptional stability and normally do not react by substitution of the cbd ring. However, the cbd ligand can undergo electrophilic substitution if free positions are available on the ring. Thus, CpCo(cbd) was the only $CpCoL_2$ compound that was found to be inactive in the Co-mediated pyridine synthesis.[78]

Even as CpCo(cbd) can be viewed as the 18-electron analog of cobaltocene (Section 7.1), the cationic complexes $Co(arene)(cbd)^+$ are analogs of the cobaltocenium ion. They can be prepared from either $C_4Ph_4Co(CO)_2Br$ or $C_4Me_4Co(CO)_2I$ and a broad variety of arenes in the presence of $AlCl_3$ to give phenyl- or methyl-substituted sandwich complexes, respectively (equation 52).[77] Homogeneous reduction of (arene)$Co(C_4Ph_4)^+$ with CpFe(HMB) (HMB = hexamethylbenzene) gives the neutral 19-electron sandwich complex (arene)$Co(C_4Ph_4)$. It shows the characteristic reactivity for 19-electron sandwich complexes, for example oxidative addition (*see Oxidative Addition*) of mild electrophiles such as MeI (Section 7.1).

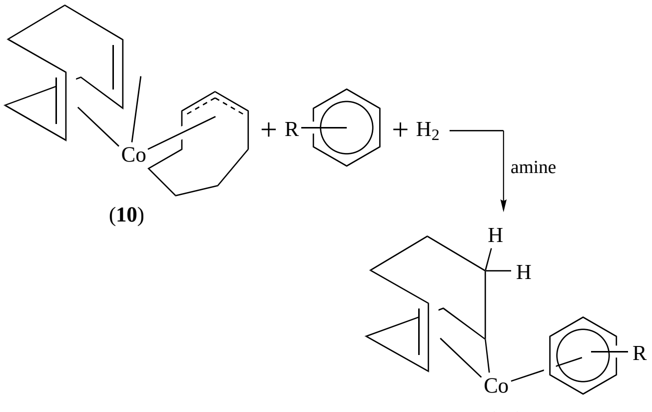


(52)

6.2 Arene Complexes

Cationic sandwich complexes of the type $CpCo(arene)^{2+}$ were first prepared by hydride abstraction from cyclohexadienyl cations (Section 7.1). They are accessible in broader variation from the reaction of CpCoX half-sandwich complexes with arene in the presence of $AlCl_3$. Their electrochemical reductions to the corresponding 19-electron monocations and to 20-electron neutral complexes have been studied.[79] The stability of electron-rich sandwich complexes increases with increasing alkyl substitution in either ring despite the more negative redox potential; mass spectrometry studies of bond dissociation energies of (arene)Co^+ complexes corroborate these results.[80] However, neutral sandwich complexes are not very stable in the polar solvents necessary for the reduction of mono- or dications and have been isolated only from alkyne trimerization with CpCo precursors in nonpolar solvents (Section 5.1.4).

Co arene chemistry has been expanded by the preparation of a number of (arene)Co(η^4-diene)$^+$ and (arene)Co(η^1,η^2-enyl) complexes starting from (**10**).[81] Hydrogenation of (**10**) in the presence of an arene and a base (piperidine or quinuclidine for obvious stabilization of coordinatively unsaturated cobalt intermediates) gives cyclooctenyl complexes (**37**) (equation 53). This reaction occurs with a large number of arenes; even C_6F_6 gives an η^6-arene complex. The resulting complexes (**37**) are moderately active catalysts in the pyridine synthesis from alkynes and nitriles (Section 5.1.4).



(**10**) (**37**)

(53)

Another preparation method for (arene)Co(η^4-diene)$^+$ complexes is the reaction of dienes with 20-electron

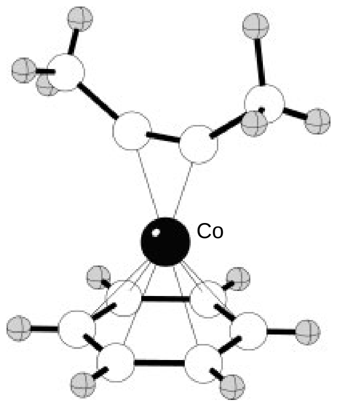


Figure 11 Structure of benzene(butyne)cobalt complex

bis(arene)Co^+ complexes (equation 54). Arene displacement can occur in polar media with a variety of dienes – cyclohexadiene, cycloheptadiene, cod, and norbornadiene. The resulting 18-electron cationic complexes can be electrochemically reduced to 19-electron neutral radicals. EPR studies have shown that these complexes to have a ground state similar to those of $[CpCoL_2]^-$ analogs.[82]

$$[(\text{arene})_2\text{Co}]^+ + \text{diene} \longrightarrow [(\text{arene})\text{Co}(\eta^4\text{-diene})]^+ + \text{arene} \quad (54)$$

Cobalt-arene complexes can also be synthesized from metal vapor reactions. For example, $(\eta^6\text{-}C_6H_5Me)Co(C_6F_5)_2$ is made at low temperature and low pressure conditions (equation 55).

A remarkable cobalt-arene complex was also isolated from the metal vapor reaction of cobalt atoms with toluene (Scheme 13) and subsequent addition of an alkyne (acetylene, butyne, or BTSA).[52] According to EPR spectra, compounds of the type (toluene)Co(alkyne) are 19-electron complexes of near-axial symmetry where the alkyne acts as a four-electron ligand on the cobalt atom. The methyl derivative has been structurally characterized with Co–C_{alkyne} distances of 1.88 and 1.90 Å, and a C≡C distance of 1.254 Å (Figure 11).

$$2\text{Co} + 2\text{C}_6\text{F}_5\text{Br} + \text{C}_6\text{H}_5\text{Me} \xrightarrow{-190\,^\circ\text{C},\ 10^{-5}\ \text{torr}} (\eta^6\text{-C}_6\text{H}_5\text{Me})\text{Co}(\text{C}_6\text{F}_5)_2 + \text{CoBr}_2 \quad (55)$$

7 COBALTOCENE AND COBALTOCENE DERIVATIVES

7.1 Cobaltocene

7.1.1 Synthesis and Properties

The compound $(C_5H_5)_2Co$ (Cp_2Co) (**38**) was one of the earliest examples of transition metal sandwich compounds to be synthesized (*see Cobaltocene*). In fact, the cation (**38**$^+$) was prepared in 1952, a year before the neutral metallocene. The sandwich compound (**38**) (equation 56) was first prepared from the cobalt hexammine complex $Co(NH_3)_6(C_5H_5)_2$ that lost ammonia under high vacuum. Subsequently, many different preparations, starting from CoX_2, or diverse complex cobalt salts and either NaCp, MgXCp, TlCp, or CpH/KOH in THF, were employed. A recommended procedure that gives high and reliable yields of (**38**) is the reaction of $CoCl_2$ with NaCp in THF,[83] which is basically equation (56) performed in one step. Under an inert atmosphere, the compound is indefinitely stable.

$$\text{Co(NH}_3)_6\text{Cl}_2 + 2\text{NaCp} \longrightarrow \text{Co(NH}_3)_6(\text{Cp})_2 \xrightarrow{\text{heat}} \text{Cp}_2\text{Co} + 6\text{NH}_3 \quad (56)$$

Compound (**38**) crystallizes with a unit cell isomorphous with that of ferrocene; there is a smooth variation of the cell parameters along the series from ferrocene, cobaltocene, and nickelocene. A crystal structure determined at two different temperatures, 100 and 297 K,[84] indicated that one ring is rotated by 22 and 34°, respectively. Occupancy for this second orientation was 10% at 100 K and 20% at 297 K. Moreover, one ring is tilted with respect to the other by 6° in the 100 K structure and 3° in the 297 K structure and slipped (parallel distance of the two ring centers) by 0.231 and 0.162 Å, respectively. Owing to this ring slip, Co–C distances are unequal in the molecule.

Whereas ferrocene (*see Ferrocene*) is an 18-electron complex with filled bonding and nonbonding orbitals, cobaltocene has 19 electrons with the extra electron residing in an e^*_{1g} antibonding orbital (*see Antibonding*) and is thus paramagnetic. This antibonding orbital occupancy weakens the Co–C_{ring} bonds and results in longer metal–carbon distances than in ferrocene, but shorter distances than in the 20-electron complex nickelocene (*see Nickelocene*).

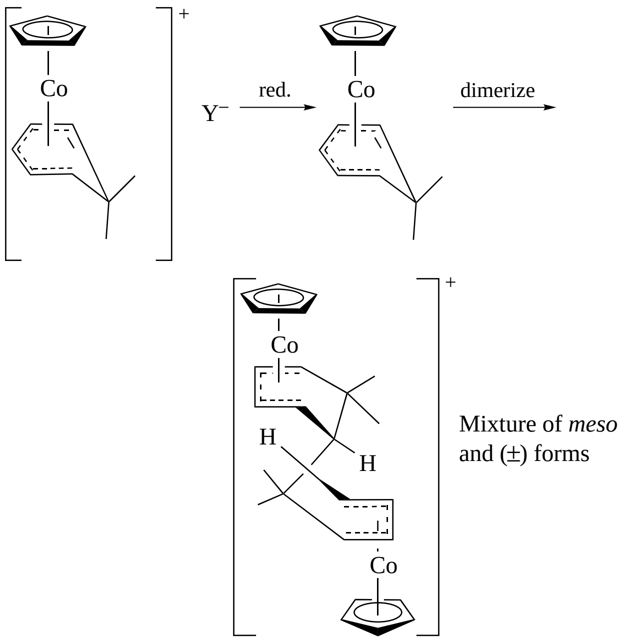
The dynamic Jahn–Teller effect (*see Jahn–Teller Effect*) has been investigated in metallocenes by means of experimental and DFT methods. A sandwich complex with an orbitally degenerate ground state (only ^2E states are known for orbitally degenerate sandwich molecules) lifts the degeneracy through vibrational modes in the ring plane that have the same symmetry as the degenerate MOs. Cobaltocene and various substituted cobaltocenes have played an important role in understanding the effects of electronic configuration and MO levels in the bonding characteristics and chemical reactivities of metallocenes.[85]

Redox potentials of cobaltocene and substituted cobaltocenes (Section 7.3) have been determined; for the reduction of cobaltocenium to cobaltocene, a potential of −0.95 V (vs. SCE) in acetonitrile or −0.86 V (vs. SCE) in CH_2Cl_2 was measured (−1.35 V vs. the ferrocene/ferrocenium couple in aprotic solvents). The large potential difference between oxidation of ferrocene and cobaltocene is intriguing, since it is related in a simple fashion to the difference in the HOMO–LUMO gap

in these two sandwich complexes. At a more negative potential (−1.88 V vs. SCE in acetonitrile, −2.30 V vs. Fc/Fc^+), a cobaltocenate anion has been detected electrochemically.[86,87] This species is short-lived in polar solvents but has some stability in dry ether solvents, such as DME. Reduction to cobaltocenate plays an important role in the reductive cleavage of cobaltocene (Section 7.1.2). Redox potentials of Cp_2Co^{2+} (3.15 V vs. SCE) and Cp_2Co^{2-} (−3.1 V vs. SCE) have also been obtained from oxidation of cobaltocenium and reduction of cobaltocenate; owing to the extreme potentials needed for these systems, liquid sulfur dioxide was used for its low nucleophilicity and tetrahydrofuran was used for its low electrophilicity.[88]

7.1.2 *Reactions of Cobaltocene*

Cobaltocene is stable as a monomer under all conditions, showing no tendency to dimerize, as does the rhodium congener rhodocene. Cobaltocenium salts are easily prepared by several routes, including mild oxidation of cobaltocene, and are stable as cations. However, neutral electron-rich monomers are no longer stable if the aromaticity of one of the Cp rings is perturbed by interposed CH_2 groups (e.g. CpCo(cyclohexadienyl)). Dimerization of a C–C bond adjacent to the π-system frequently occurs (Scheme 28). The process can be followed electrochemically on reduction of the $CpCo(\eta^5\text{-L})^+$ cation to the neutral sandwich, which then dimerizes. Logically, the same dimerization is observed with so-called 'half-open' cobaltocene, that is, a bis(pentadienyl)cobalt, which has one pentadienyl (*see Pentadienyl Ligand*) and one pentadiene ligand linked to a second unit through a terminal carbon.[89]



Scheme 28

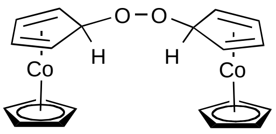


Figure 12 Structure of $[CpCo(\eta^4\text{-}C_5H_5)]_2(\mu\text{-}O_2)$

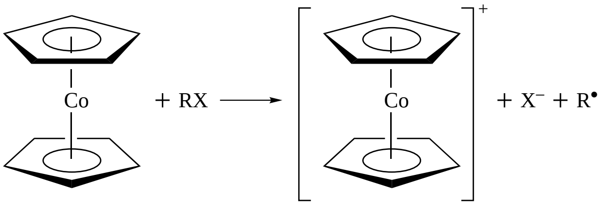
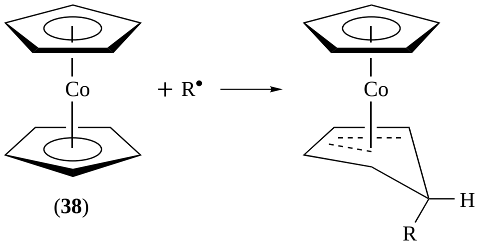
At low temperature, (**38**) reacts with stoichiometric O_2 to form a transient diamagnetic adduct (**38**)–O_2–(**38**) (Figure 12) from which oxygen can be transferred to α-diketones.[90] A similar dimer has been observed in which two molecules of (**38**) are linked via an acetylene bridge, that is, (**38**)–C≡C–(**38**).

Because of facile oxidation, there is no possibility for electrophilic substitution (*see Electrophilic Reaction*) at cobaltocene. On the other hand, owing to its positive charge, the cobaltocenium ion is deactivated towards electrophilic substitution. Thus, apart from simple electron-transfer oxidation, one of the most important reactions undergone by cobaltocene is a two-step oxidative addition, as depicted in equations (57) and (58).



(**38**) (**38**⁺)

(57)

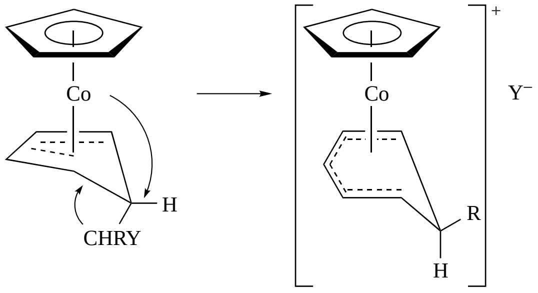


(58)

The mechanism of this reaction has been investigated in some detail.[90] RX must be an activated halide, such as a benzyl halide, α-halo ether, or a 1,1-dihalocarbon where at least one of the halides is Br or I. Simple halocarbons do not react, nor does methylene chloride. Reaction with chloroform is slow, while reaction with carbon tetrachloride is instantaneous at room temperature. The (pseudo) first-order rate constant is linearly correlated to the polarographic reduction potential of the halide; thus electron transfer from (**38**) to RX (equation 57) is the rate-determining step, followed by rapid cleavage of the RX^- radical anion into R• and X^-.

When the electrophile is a dihaloalkane R–CHXY, the ensuing *exo*-halomethyl derivative (**39**) undergoes a metal-assisted solvolytic ring-expansion reaction in polar solvents to

give an *endo*-R-cyclohexadienyl(cyclopentadienyl)Co cation (**40**) (equation 59). This reaction is highly stereoselective, leading preferentially to the *endo*-R derivative.



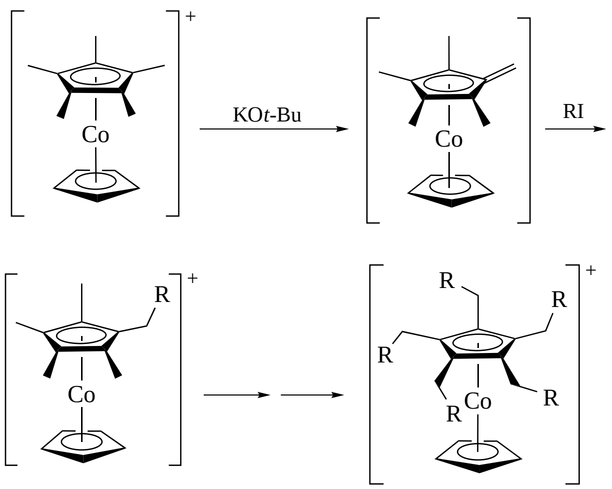
(59)

(**39**) (**40**)

A transformation of some synthetic versatility is the oxidation of methyl groups in a methylcobaltocenium salt by MnO_4^- to give the respective carboxylic acid. In this way, mono- and dicarboxylatocobaltocenium salts have been prepared. These acids can be further functionalized and used as receptors for the selective recognition of anion guest species.[91] A pyrrole-functionalized cobaltocenium salt has also been electropolymerized on an electrode surface; this system displays anion sensing in solution and when immobilized.[92]

Methyl groups in the cobaltocenium ion are sufficiently acidic to be deprotonated by strong bases. The ensuing fulvene complexes are not isolated, but can be alkylated in situ with alkyl iodide. Starting from pentamethylcobaltocenium, derivatives which bear five or 10 alkyl, benzyl, or other functionalized organic groups have been prepared (Scheme 29).[93]

An intriguing reaction of cobaltocene involves protonic acids as reagents, which in the case of a noncoordinating anion, gives (38^+) and hydrogen in a very clean reaction.



Scheme 29

Cobaltocene is a one-electron reducing agent, which makes the overall reaction a non-complementary electron transfer. Thus, a kinetic barrier is expected, although the redox potential indicates the reaction is highly favorable.[94]

7.2 Permethylated Cobaltocene

Permethylated Cp derivatives (Cp*) have proven to be valuable not only in metallocene chemistry, but also in the chemistry of half-sandwich complexes. Pentamethylcyclopentadiene is stable as a monomer and is a considerably weaker CH acid than cyclopentadiene. It can be converted into the anion by alkali metals (in ammonia) or more conveniently by *n*-BuLi. The Cp* anion is a strong base, but a poor nucleophile. The methyl groups strengthen the electron-donating ability of the ligand, which in turn augments the reducing properties of the permethylated cobaltocene (**41**); the redox potential is 0.6 V more negative in comparison to unsubstituted cobaltocene.[90]

Reactivity of (**41**) is largely analogous to that of (**38**) despite steric shielding by the methyl groups. As expected from the more negative redox potential, reactivity towards electrophiles is enhanced. Thus (**41**) reacts with alkyl and aryl monohalides such as PhI as in equations (57–59), where (**38**) has been found to be unreactive. A further difference lies in the orientation of the group R in solvolytic ring expansion of the *exo*-CHYR derivatives of (**38**) and (**41**) (equation 59); the group R in the methylated cyclohexadienyl complex now has an *exo* orientation, which stems from the steric influence of methyl groups on the rings.

7.3 Other Cp analogs

Several other derivatives of cobaltocene have been synthesized and studied. Heavily substituted cobaltocenes have been made with triisopropyl- (Cp^{3i}) and tetraisapropyl (Cp^{4i}) cyclopentadienyl ligands from alkali metal Cp salts and $CoCl_2$. These ‘encapsulated’ complexes exhibit exceptional stability with $(Cp^{4i})_2Co$ (Figure 13) being stable in air indefinitely. These complexes can be chemically oxidized with ammonium salts, although steric hindrance of the rings impedes the process. Interestingly, cyclic voltammetric data show the oxidation potentials of $(Cp^{3i})_2Co$ and $(Cp^{4i})_2Co$ to be virtually identical (−1.15 V and −1.14 V vs. SCE).[95]

Other derivatives such as CpCo(indenyl) and $Co(indenyl)_2$ have been prepared.[96] These compounds exhibit properties similar to that of cobaltocene but are of lower thermal stability. There have been numerous studies of linked metallocenes with a focus on the nature of metal–metal interactions.[97] The bis(fulvalene)dicobalt complex was found to be diamagnetic, either because of direct metal–metal coupling or by electron coupling through the linked five-membered ring (Scheme 30).

Isolobal replacement of the exocyclic methylene group of fulvene with a cobalt fragment generates cobaltafulvenes;

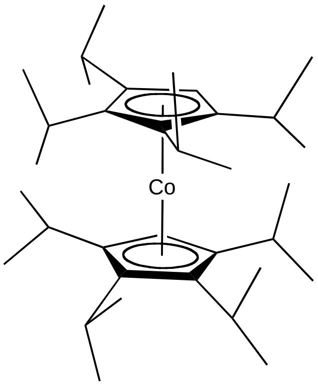


Figure 13 Structure of $(Cp^{4i})_2Co$

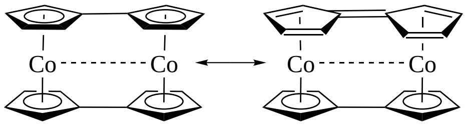
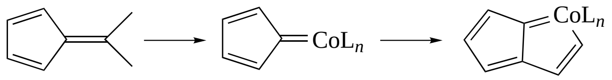


Scheme 30



Scheme 31

these complexes can be further reacted with substituted alkynes to form cobaltapentalenes (Scheme 31). Dicobalt complexes of metallafulvenes and metallapentalenes can be prepared in this manner. The mechanism for the synthesis of cobaltapentalenes begins with oxidative addition of an alkyne to the cobalt atom of a cobaltafulvene (**42**) followed by nucleophilic attack of the acetylide on the fulvene system; a 1,3-hydrogen shift converts the metallabicyclic ring system to the cobaltapentalene (**43**) (Scheme 32).[98]

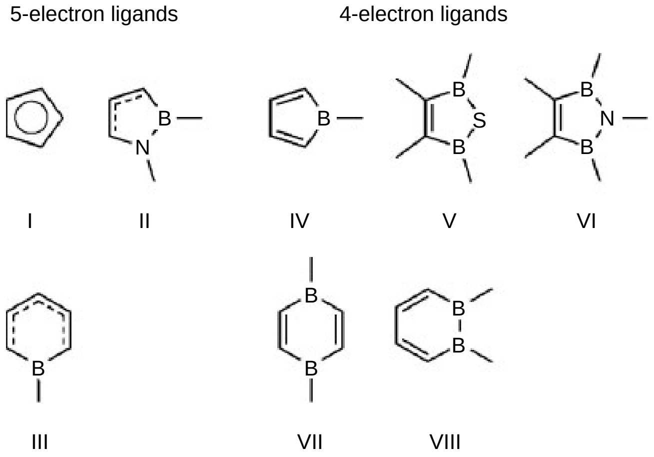


Figure 14 Boracyclic ligands used in cobalt sandwich complexes

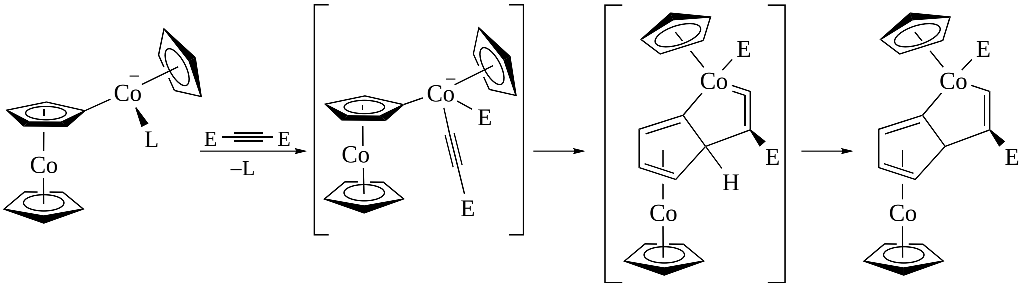
8 COMPLEXES WITH BORACYCLIC LIGANDS

Cobalt does not complex to any group 15 or 16 heterocycles such as pyridine, pyrroline, or even thiophene. It appears that these electron-rich rings will not stabilize the metal as π-ligands and prefer to complex as σ-ligands. In contrast, a variety of cobalt sandwich complexes containing a boracyclic ring ligand have been prepared and studied because these complexes are isoelectronic with either cobaltocene, its cation, or analogs of CpCo(cyclobutadiene) (Figure 14). Boracycles are good ligands for cobalt in a sandwich complex because an electropositive atom incorporated in a π-cyclic ring will stabilize an electron-rich central metal.[99]

8.1 Borabenzene Complexes

One of the most intensely studied boracyclic compound is the borabenzene ligand synthesized by Herberich and coworkers.[100] Bis- and monoborabenzene cobalt sandwich complexes were first obtained by treating cobaltocene with boron trihalides BX_3 (R = Cl, Br) or alkyl/arylboron dihalides (R = alkyl, aryl) as outlined in



(**42**) (**43**)

Scheme 32

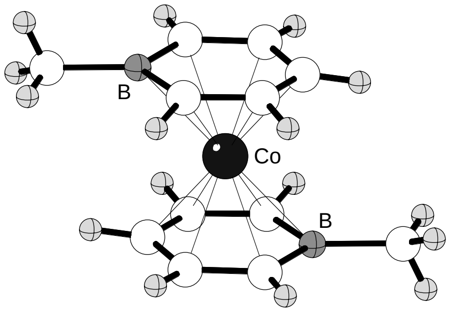


Figure 15 Molecular structure of $Co(C_5H_5BMe)_2$

Scheme 33. The first intermediate in this reaction, the *exo*-haloborylcyclopentadiene(cyclopentadienyl)cobalt (**44**) cannot be isolated because the solvolytic ring expansion to the (1-boratacyclohexadienyl)(cyclopentadienyl)cobalt cation ($\mathbf{45}^+$) occurs spontaneously, even in nonpolar solvents. The boracyclic cation ($\mathbf{45}^+$) is reduced by excess cobaltocene, and the neutral complex (**45**) can undergo the same reaction cycle, leading finally to the bisborabenzene complex (**46**).

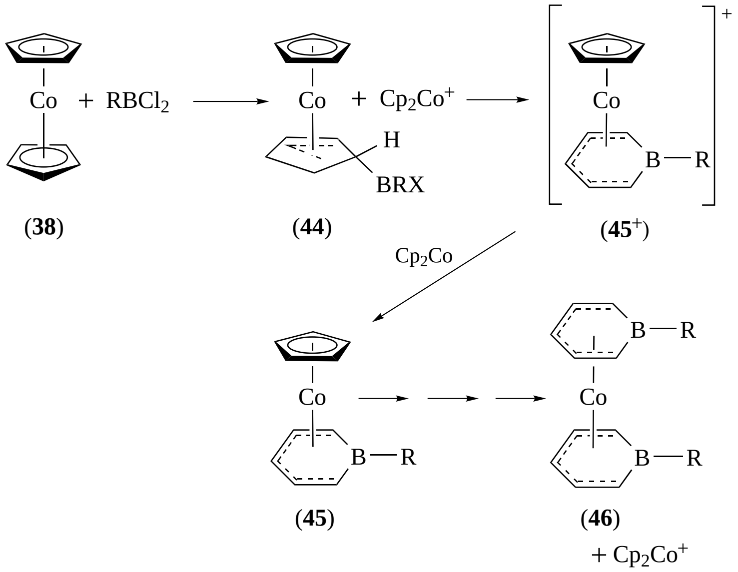
A single-crystal X-ray structural determination of $Co(C_5H_5BMe)_2$ (Figure 15) revealed a planar sandwich where the cobalt atom is displaced towards C(4) by 0.28 Å. The Co–B distance of 2.283(5) Å is considered a bonding distance. The upfield shift of the ^{11}B NMR signal and the diminished nucleophilicity of the boron atom are consistent with this interpretation.

Redox properties of (borabenzene)cobalt complexes have been investigated electrochemically.[101] The reduction potentials are displaced uniformly to more positive values by about 0.5 V per borabenzene ligand. The existence of the relatively stable anion $Co(C_5H_5BPh)_2^-$ ($\mathbf{46}^-$), isolated as the PPh_4^+ salt, is a consequence of the positively displaced redox potentials; this complex undergoes electrophilic addition to give neutral sandwich complexes with one boratacyclohexadiene ligand. This anion is one of the few isolable 20-electron sandwich complexes of cobalt (see Section 5.1.4).

8.2 Aza- and Thiaborolene Complexes

A heterocycle ligand isoelectronic with cyclopentadiene is the azaborolinene ring for which the 1,2-isomer (II, Figure 14) is accessible and has been complexed to Co.[102] Sandwich compounds $Co(C_3H_3BRNR')_2$ were prepared from the free ligand C_3H_4BRNR' by metal vapor synthesis. Since the ligand has no plane of symmetry perpendicular to the ring plane, two diastereoisomers (a d,l-pair and a *meso* form) are formed having different orientations of the rings. The molecular structure is a sandwich molecule with a *trans* orientation of N and B, respectively, at either ring. Perturbation in the bonding exists between cobalt and the azaborolide ligand; the electron-rich cobalt is displaced from the ring centroid, resulting in shortened Co–C distances and longer Co–heteroatom distances. The neutral complex can be oxidized by ferrocenium ion to give a diamagnetic cation corresponding to cobaltocenium. Mixed ring cobalt complexes have also been prepared with azaborolides and CpCo species.

Aza- and thiadiborolene complexes derived from V and VI are closely related by symmetry and electron distribution, but the thia heterocycle exhibits better complexing properties. Complexes of the type CpCoL, where L = $C_2Et_2(BMe)S(BMe)$ or $C_2Et_2(BMe)(NMe)(BMe)$, have been prepared by heating the free ligand with $CpCo(CO)_2$. The



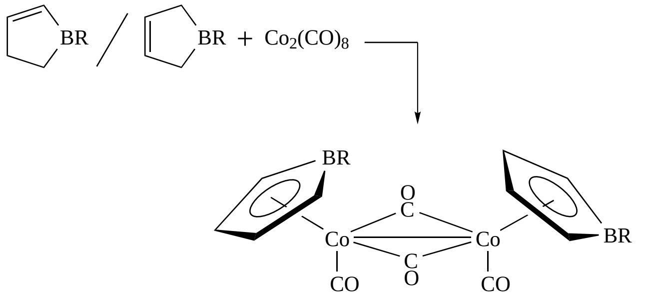
Scheme 33

dimeric carbonyl $[LCo(CO)(\mu\text{-}CO)]_2(Co\text{–}Co)$ is obtained as a by-product.

8.3 Borole Complexes

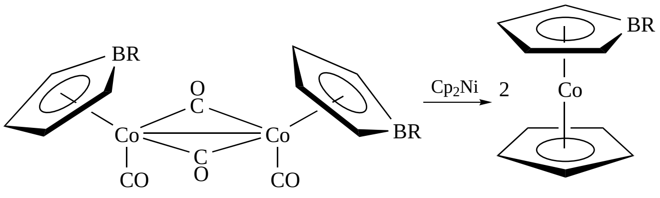
The four-electron boracycles IV, VII, and VIII (Figure 14) have been complexed to cobalt in sandwich structures. The type of complex formed with these ligands is CpCoL; these are electronic analogs of CpCo(diene) or CpCo(cyclobutadiene), respectively (Sections 5.1.2 and 6.1).

Borole (IV in Figure 14) has been used to synthesize a plethora of sandwich and half-sandwich structures; it is the bora analog of cyclopentadiene. Borole is an antiaromatic system (*see Antiaromatic Compound*), and only the blue pentaphenyl derivative has been prepared.[103] The general route to borole complexes consists of complexation under dehydrogenation of 2- or 3-borolenes, which are prepared from $[Mg(butadiene)]_x$ and RBX_2. Thus, the heating of either isomer of borolene with $Co_2(CO)_8$ produces $[(borole)Co(CO)_2]_2$ (**47**) (equation 60) from which further cobalt borole complexes are prepared (equation 61). CpCo(borole) (**48**) can be made from (**47**) by Cp transfer from the labile 20-electron nickelocene (equation 61). Pyrolysis of (**48**) at 160–180 °C gives a triple-decker complex (**49**) in nearly quantitative yield, which in turn can be cleaved by Cp^- into (**48**) and the bis(borole)cobaltate anion ($\mathbf{50}^-$) (Scheme 34).



(**47**)

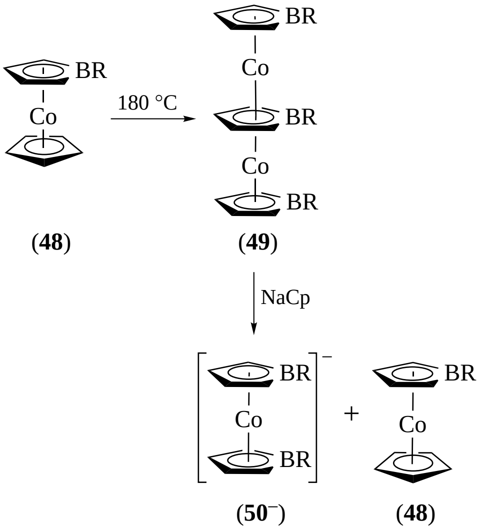
(60)



(**47**) (**48**)

(61)

This chemistry is analogous to that of $Co(diene)_2{}^-$ (Section 5.1.2), but boracyclic complexes are stabilized relative to anionic alkene complexes. Thus, bis(borole)cobaltate is stable in water at pH > 6 and can be precipitated as a $NMe_4{}^+$ salt. Electrophilic substitution of (**48**) occurs exclusively at the 2-position of the boracyclic ring.[103]



Scheme 34

9 CpCo HALF-SANDWICH COMPLEXES

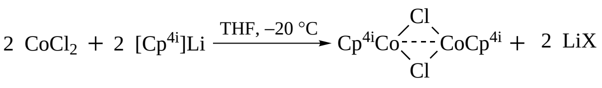
9.1 Derivatives of $CpCo^{II}$

A few half-sandwich complexes containing a $CpCo^{II}$ unit are known; some of them are of synthetic utility and will be discussed below. The $[CpCo(CO)]_2{}^-$ anion ($\mathbf{19}^-$) can be methylated with MeI to give a dimethyl derivative, $[CpCoMe(CO)]_2$. This complex decomposes to produce acetone in high yield, a reaction that is reminiscent of the use of $Fe(CO)_4H^-$ in the carbonylation (*see Carbonylation*) of alkyl halides.

Dinuclear complexes $[CpCo(PR_2)]_2$ or $[CpCo(SR)]_2$ are prepared from $CpCo(CO)_2$ (**18**) or cobaltocene (**38**) with phosphines PR_2H, sulfides RSH, or disulfides RSSR, respectively. They are diamagnetic, puckered molecules having a Co–Co single bond (2.56 Å in $[CpCo(PPh_2)]_2$). Electrophiles or π-acceptor ligands (*see π-Acid Ligand*) add to the Co–Co bond to afford dinuclear Co^{III} complexes. Phosphine complexes, such as $CpCo(PPh_3)_2$, are much more stable thermally as the 17-electron cation $[CpCo(PPh_3)_2]^+$. The latter is readily isolated with various anions.[104]

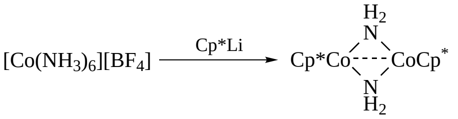
Substituted cyclopentadienyl ligands have also been used to synthesize half-sandwich complexes of cobalt. For example, if $(C_5R_4H)Li$ ($R = {}^i Pr$; $Cp^{4i}Li$) is treated with $CoCl_2$ in a 1:1 ratio at – 20 °C, the half-sandwich complex $[Cp^{4i}CoCl]_2$ (**51a**) is produced in excellent yield (equation 62). A similar type of complex with amide bridging groups (**52**) is formed from $[Co(NH_3)_6](BF_4)_2$ and LiCp* (equation 63). The product complexes are paramagnetic at ambient temperature and show antiferromagnetic coupling (*see Antiferromagnetism*) when cooled below 100 K, although the coupling is weaker in the tetraisopropyl species.[105] These dimers are EPR silent,

but in solvents more polar than hydrocarbons, a certain fraction of a monomeric complex Cp*CoX(S) (S = solvent) is found in equilibrium with the dimer; the monomer was identified by a hyperfine coupling to one cobalt and with EPR parameters very similar to characterized mononuclear species (see below). With donor ligands, these dimers are cleaved into stable monomers (**53**), for example, Cp*Co(pyridine)Cl and Cp*Co(PMe_3)Cl (Scheme 35).



(62)

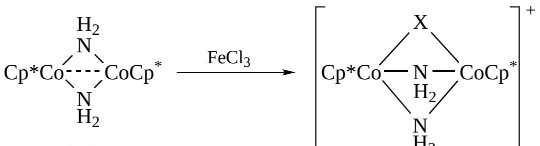
(**51a**)



(63)

(**52**)

The dinuclear halides (**51**) are starting materials for a great variety of synthetic transformations, some of which are depicted in Scheme 35, giving either Cp*Co^{I} derivatives by reduction or valence disproportionation upon reaction with acceptor ligands, or Cp*Co^{III} complexes by valence disproportionation or oxidation (equation 64 and Scheme 35). Many of these reactions are analogous to those that occur with the unsubstituted CpCo moiety.



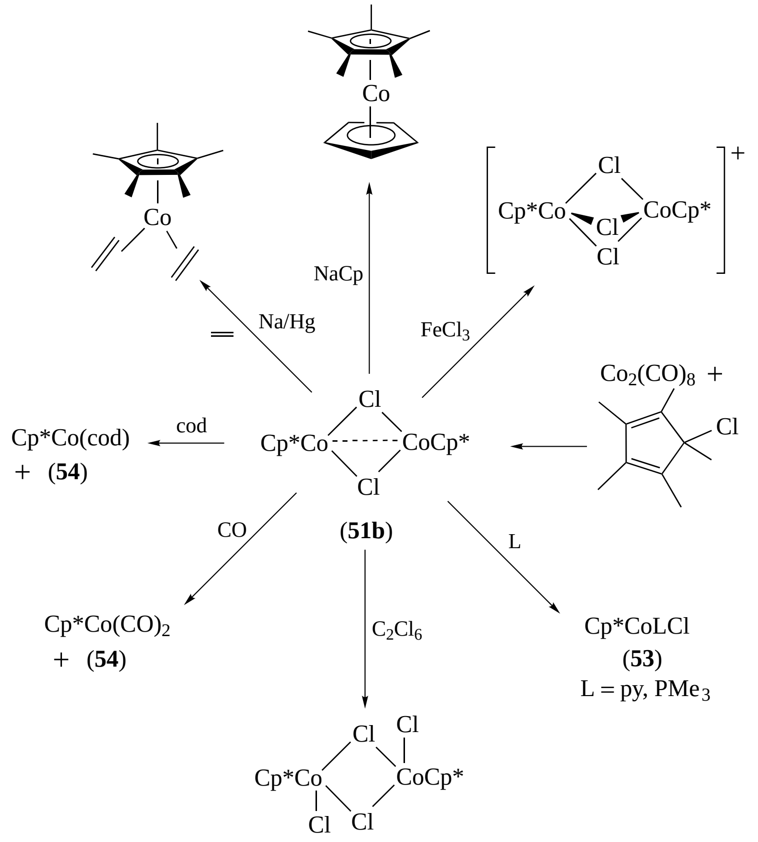
(**52**)

(64)

9.2 Derivatives of CpCo^{III}

The organometallic chemistry of cobalt in oxidation state III is more extensive than that of iron and nickel. This observation is certainly connected to the high stability of octahedral Co^{III} coordination complexes. These compounds are of types I–V as depicted in Figure 16.

The use of a Cp* or other alkylated Cp ligand instead of unsubstituted Cp in CpCo^{III} chemistry is preferred for two reasons. First, there is less of a tendency to form oligomers and polymers with type I and III compounds, which ensures higher solubility; secondly, there seems to be a favorable electronic effect. Electron-donating alkyl groups on the Cp



(**54**)

Scheme 35

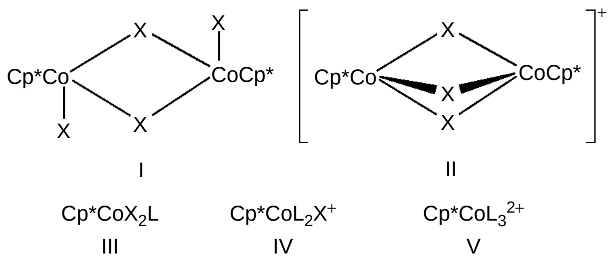


Figure 16 Co(III) octahedral complex types

ring tend to stabilize Co^{III} in its complexes. Addition of oxoanions (RCO_2^-, SO_4^{2-}), THF, water, or primary amines to $CpCo(NCMe)_3^{2+}$ causes rapid disproportionation, leading finally to Co^{2+} and Cp_2Co^+,[106] whereas Cp*Co derivatives with many kinds of hard σ-donor ligands have been isolated.

Cp derivatives of types III and IV containing soft donor or acceptor ligands, L, have been known for a long time. The only Cp derivative known of type I is the iodo complex $(CpCoI_2)_n$, which is formed from $CpCo(CO)_2$ and I_2. It is rather insoluble and is probably polymeric, but it reacts with strong nucleophiles and can be transformed into more soluble derivatives of type III with donor bases.

Cp^*CoX_2 complexes are known with X = Cl, Br, or I. They are soluble in organic solvents of medium polarity and are dimeric.[107] $[Cp^*CoCl_2]_2$ (**54**) is prepared from $[Cp^*CoCl]_2$ by disproportionation or by selective oxidation with C_2Cl_6 (Scheme 35). It is of limited stability and slowly decomposes even below room temperature into $CoCl_2$ and $(Cp^*)_x$. It is easily cleaved by donor ligands into complexes of type III–V and can serve as the starting material for many different kinds of Cp*Co complexes owing to its substitutional lability.

As an example, spontaneous hydrolysis gives the aqua ion $Cp^*Co(H_2O)_3^{2+}$, which can be derivatized as shown in Scheme 36. In this way, a series of complexes with ligands ranging from I (e.g. $[Cp^*CoI_2]_2$) to CN (e.g. $Cp^*Co(CN)_3^-$) with O-, N-, and S-donor atoms can be prepared. The ligand series essentially covers the whole spectrochemical series (*see Spectrochemical Series*), and a regular shift of the two absorption bands in the visible region characteristic for octahedral Co^{III} complexes ($^1A \rightarrow {}^1T_1$ and $^1A \rightarrow {}^1T_2$ descendants) is seen from about 700 nm in the iodide complex to 320 nm in the cyanide complex, with concomitant color change from green to blue, mauve, red, and yellow, providing a unique visualization of the spectrochemical series through a range of analogous complexes.[108]

A further derivative of type V should be mentioned, where L is $P(OR)_2O$ or PR_2O. The phosphonate group is formally uninegative; thus $CpCo[P(OR)_2O]_3^-$ (**55**) is a monoanion. This anion functions as a tridentate (*see Tridentate Ligand*) chelating ligand through the oxygen atoms, and it imposes a weak ligand field (*see* ***Ligand Field Theory & Spectra***) and low nephelauxetic parameter (*see Nephelauxetic Effect*) on the complexed central metal with a high binding constant. Complexes of the types $[CpCo[P(OR)_2O]_3]_2M$ and $[CpCo[P(OR)_2O]_3]\,ML_n$ have been prepared where M can be a p- or a d-block metal and ML_n any of a number of common transition organometallic fragments ($M(CO)_n$ or $CpM(CO)_n$, e.g.).[109]

The first compound of this type that was obtained was the cobalt complex $\{[CpCo[P(OR)_2O]_3]_2Co\}^+$ (**56**) (Scheme 37) of Co^{III}. It is formed when cobaltocene is treated with $P(OR)_3$ at about 120 °C in a reaction that comprises substitution of a Cp by $P(OR)_3$ followed by a triple Arbuzov rearrangement (*see Arbuzov Rearrangement*) and complexation of the cobalt ion liberated during the reaction. When (**56**) is treated with cyanide, the central cobalt ion is extracted as $Co(CN)_6^{3-}$, thereby liberating the free ligand (**55**) (Scheme 37).[110] Remarkably, the very inert cobalt atom incorporated in the

	$[Cp^*CoI_2]_2$	$[Cp^*Co(N_3)_2]_2$	$Cp^*Co(acac)Cl$	$Cp^*Co(bipy)(H_2O)^{2+}$	$Cp^*Co(NO_2)_3^-$	$Cp^*Co(CN)_3^-$
λ_{max}(nm):	720	615	610	530	490	382

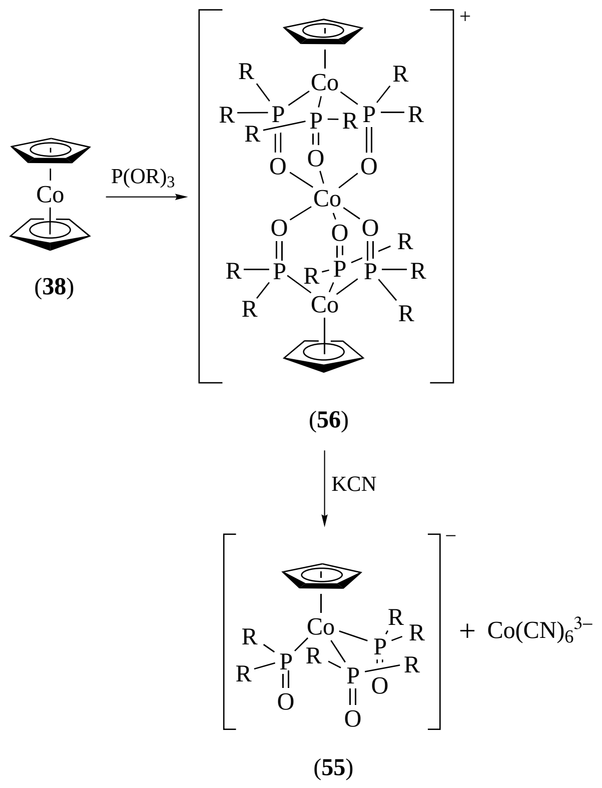
Scheme 36



Scheme 37

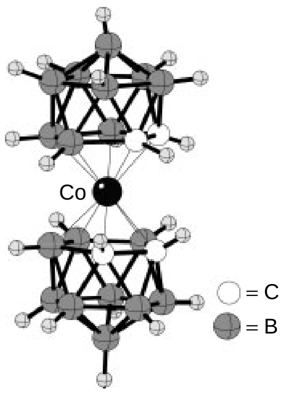


Figure 17 Structure of $[3,3'\text{-}Co(1,2\text{-}C_2B_9H_{11})_2]^-$

tripodal complex (**55**) is not abstracted by this procedure. This tripodal ligand, despite its hard donor properties, has been proven to stabilize transition metal fragments in low as well as in high oxidation states. Its position at the left end (weak ligand) of the spectrochemical series (*see Spectrochemical Series*) is indicated by the observation of a low spin–high spin equilibrium in (**56**), where the exact value for the equilibrium constant at a given temperature depends on the group R. The central cobalt in (**56**) is thus one of the very few examples of high-spin Co^{III}.

10 COBALT CARBORANE COMPLEXES

Boron adopts a wide variety of cluster geometries because it has only three valence electrons; many stable architectures of boranes (*see* ***Boron: Organoboranes***) and carboranes (*see* ***Boron: Polyhedral Carboranes***) have been synthesized.[111] It has long been recognized that $B_9C_2H_{11}^{2-}$ acts as an analog of Cp (and especially Cp*) in many transition metal complexes, and can be used to form metallacarboranes (*see* ***Boron: Metallacarbaboranes***) including cobaltacarboranes.[112] The complex $(Et_3NH)[3,3'\text{-}Co(1,2\text{-}C_2B_9H_{11})_2]$ was one of the first metallacarboranes to be synthesized and structurally characterized (Figure 17).[113]

Cobaltacarboranes have been shown to be useful as extraction agents for ions, and competitive extractions have been conducted with ions associated with dyes used in photometric determinations of bases.[114] Lipophilic moieties can be substituted on cobaltacarboranes to allow efficient extraction of radioactive metal ions such as ^{90}Sr, ^{137}Cs, and ^{152} Eu in water at low pH.[115]

Cobaltacarboranes also have been used in sensor technology. The sandwich complex $[Co(B_9C_2H_{11})_2]^-$ can be used as a lipophilic coreceptor instead of tetraarylborate ion additives in ion selective electrodes, producing electrodes that are more selective for specific alkali metal ions.[116]

As carboranes are chemically stable and exhibit low toxicity to humans, biomedical applications of carborane systems, including cobaltacarboranes, have slowly emerged. The boron isotope ^{10}B accounts for about 20% of boron in nature, and it has the ability to capture a slow neutron and release an α-particle (equation 65). This reaction, if conducted in live tissue, will kill the immediate cell, but not its neighbors. Although early studies were done with toxic boron compounds, carboranes, with their low toxicities and high boron content, have been proven to be good substrates for boron capture neutron therapy (BCNT).[111] Cobaltacarboranes have been employed in radioimmunodetection and radioimmunotherapy as well.[117]

$$^{10}B + {}^{1}n \longrightarrow {}^{4}He + {}^{7}Li \qquad (65)$$

1 INTRODUCTION

Coordination chemistry deals with a wide variety of substances and reactions (*see* ***Coordination & Organometallic Chemistry: Principles***). This discussion of its history is confined to the major discoveries, both experimental and theoretical, in the evolution of the discipline, and many interesting but minor events must necessarily be omitted. In view of Alfred Werner's central role in the field, considerable space is allotted to his monumental achievements, but contributions of lesser-known pioneers will also be included.

In this broad chronological survey, some of the most historically significant coordination compounds are first discussed, along with several pre-Werner theories of their formation and constitution, followed by Werner's theory and his most important discoveries. This article concludes with a brief consideration of discoveries and developments from Werner's time through 2003.[1–5]

2 HISTORICALLY IMPORTANT COORDINATION COMPOUNDS

The development of our knowledge of coordination compounds has been a very slow, gradual, and cumulative process.

2.1 Alizarin

The earliest known coordination compound is possibly bright red alizarin dye, a calcium aluminum chelate compound of hydroxyanthraquinone. Clay was the source of the calcium and aluminum ions; the hydroxyanthraquinone was obtained from the roots of the madder plant. Although the origin of this dye is shrouded in antiquity, it was first used in India and by ancient Persians and Egyptians, long before it was used by the Greeks and Romans. It may have been used to dye Joseph's biblical 'coat of many colors' (Genesis 37:3).

Herodotus (ca. 450 BC) mentioned alizarin, and it may have been the dye that Alexander the Great used in winning a battle against a much larger Persian army 120 years later. Alexander dyed his soldiers' clothing with bloodlike splotches, enticing the Persians into attacking what they believed was a demoralized force of wounded men, possibly the first recorded example of chemical camouflage. Alizarin was used to dye the British 'redcoats', making it an integral part of American Revolutionary history.

2.2 The Tetraamminecopper(II) Ion

In 1597, the German physician and alchemist Andreas Libavius (ca. 1540–1616) reported that *aqua calcis* (lime water or saturated $Ca(OH)_2$ solution) containing *sal ammoniac* (NH_4Cl) becomes blue in contact with brass (an alloy of copper and zinc), probably the first scientifically recorded observation of a completely inorganic coordination compound; in this case the familiar tetraamminecopper(II) ion, $[Cu(NH_3)_4]^{2+}$ (*see* ***Copper: Inorganic & Coordination Chemistry***).

2.3 Prussian Blue

Prussian Blue, potassium iron(III) hexacyanoferrate(II) ($KCN{\cdot}Fe(CN)_2{\cdot}Fe(CN)_3$), was first obtained accidentally in 1704 by a manufacturer of artists' colors from Berlin named Diesbach (*see* ***Iron: Inorganic & Coordination Chemistry*** and ***Mixed Valence Compounds***). This dark blue substance precipitated from an iron-containing solution when he added an alkali that he had obtained from the wandering German alchemist Johann Conrad Dippel. In 1710, it was first described as a nontoxic pigment for oil colors. Its method of preparation was not given, probably because Diesbach wanted to sell his discovery, but a recipe for the substance appeared in Latin in 1724. Ferrocyanides (hexacyanoferrates(II)) probably antedate Diesbach's discovery because materials containing iron, potash, and nitrogenous matter such as blood or animal hooves were most likely to have been heated together in earlier times. They may possibly be the first known examples of coordination compounds containing transition metal carbon bonds (organometallic compounds) because they contain Fe–CN bonds (*see Organometallic Complexes*).

2.4 The Hexaamminecobalt(III) Ion

Many historians credit the discovery of the first metal – ammine to Citizen (Citoyen) Tassaert, a Parisian

chemist about whom virtually nothing is known, not even his first name. Some of them imply or state that he was the first to prepare the parent compound from which all cobalt–ammines may be considered to be derived, hexaamminecobalt(III) chloride, $[Co(NH_3)_6]Cl_3$ (*see* ***Cobalt: Inorganic & Coordination Chemistry***). However, Tassaert, in 1798, only reported the brownish mahogany color of a solution formed by adding excess aqueous ammonia to a cobalt chloride or cobalt nitrate solution, and he failed to isolate any compounds or pursue his accidental discovery.

2.5 Vauquelin's Salt and Magnus' Green Salt

In 1813, the pink compound tetraamminepalladium(II) tetrachloropalladate(II), ($[Pd(NH_3)_4][PdCl_4]$), was discovered by Louis-Nicolas Vauquelin (1763–1829). Known as Vauquelin's Salt, it contains coordinated palladium in both the cation and the anion. In 1828, the corresponding platinum compound ($[Pt(NH_3)_4][PtCl_4]$) was discovered by Heinrich Gustav Magnus (1802–1870). The first platinum–ammine to be discovered, it is known as Magnus' Green Salt. Both Vauquelin's Salt and Magnus' Green Salt differ markedly in color from their constituent ions, which indicates the presence of an interaction between the cationic metal atom and the anionic metal atom. They are 'polymerization isomers' of the *cis* and *trans* isomers of the diamminedichloro complexes of the corresponding metals (see Section 2.8).

2.6 Gmelin's Compounds

Some authorities consider the reddish yellow hexaamminecobalt(III) oxalate ($[Co(NH_3)_6]_2(C_2O_4)_3$), described in 1822 by Leopold Gmelin (1788–1853), to be the first metal–ammine to be isolated in the solid state. Other historically significant coordination compounds discovered by Gmelin include a number of double salts: potassium ferricyanide (potassium hexacyanoferrate(III), $K_3[Fe(CN)_6]$), the cobalticyanides (hexacyanocobaltates(III), $M_3[Co(CN)_6]$), and the platinocyanides (tetracyanoplatinates(II), $M_2[Pt(CN)_4]$).

2.7 Zeise's Salt

This compound, potassium trichloro(ethylene)platinate(II) monohydrate ($K[PtCl_3(C_2H_4)]\cdot H_2O$), has played an important role in both inorganic and organic bonding theory. Discovered in 1827 by William Christoffer Zeise (1789–1847),[6] it was the first organometallic compound containing an unsaturated organic ligand, and its discovery later led to the preparation and characterization of many other platinum–alkene compounds. Its structure and bonding only began to be understood after Kealy and Pauson (1951)[7] in the United States and Miller *et al.* (1952)[8] in England prepared and characterized the first 'sandwich' compound, ferrocene (bis(cyclopentadienyl)iron(II)).

2.8 Peyrone's Salt and Reiset's Second Chloride

Two significant isomeric platinum(II) complexes were discovered in the same year, 1844. Although both possess the same formula ($PtCl_2(NH_3)_2$), they differ in physical and chemical properties and represent the simplest, best, and longest known case of stereoisomeric platinum compounds. One isomer (platosemidiammine chloride or Peyrone's Salt) was prepared by the action of aqueous ammonia on potassium tetrachloroplatinate(II), while the other (platosammine chloride or Reiset's Second Chloride) was prepared by Jules Reiset (1818–1896) by the action of heat or concentrated hydrochloric acid on tetraammineplatinum(II) chloride. In his first paper on the coordination theory,[9] Werner used these compounds, which he rightly considered to be geometric isomers, to assign a square-planar configuration to platinum(II) compounds. Il'ya Il'ich Chernyaev's trans effect[10] (1926) (see Section 5.7) explained the reactions involved in the preparation of these isomers in a generalized form.

2.9 Gibbs and Genth's Researches

During the first half of the nineteenth century, there were few other investigations of cobalt–ammonia compounds except for Gmelin's work. The existence of well-defined, crystalline cobalt–ammine salts was first recognized by Frederick Augustus Genth (1820–1893)[11] in 1847 at the University of Marburg. Before completing his analysis of his new compounds, he emigrated from Germany to the United States. It was 1851 before he published his results in German in an obscure Philadelphia journal for German physicians.

Genth described salts of two cations, roseocobalt (pentaammineaquacobalt(III)) and luteocobalt (hexaamminecobalt(III)). Although several similar compounds of platinum had been prepared in Europe before this, Genth's work drew attention to the neglected field of coordination compounds. In 1852, Oliver Wolcott Gibbs (1822–1908) began a collaboration with Genth, which has become famous in the annals of coordination chemistry. In November 1852, Gibbs made his first original contribution to this field by discovering a new cobalt–ammonia cation, xanthocobalt (pentaamminenitrocobalt(III)), which he obtained by passing oxides of nitrogen into solutions of Genth's compounds.

In 1856, Gibbs and Genth published their results in a 67-page monograph,[12] describing in detail the preparation, properties, analytical data, and reactions of 35 salts of four cobalt–ammine cations: (1) Genth's roseocobalt or pentaammineaquacobalt(III) ($[Co(NH_3)_5H_2O]X_3$); (2) purpureocobalt or pentaamminechlorocobalt(III) ($[CoCl(NH_3)_5]X_2$); (3) Genth's luteocobalt or hexaamminecobalt(III) ([Co

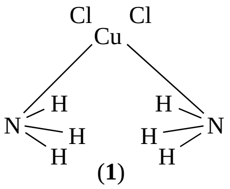
$(NH_3)_6]X_3$); and (4) Gibbs' xanthocobalt or pentaamminenitrocobalt(III) ($[CoNO_2(NH_3)_5]X_2$). Roseo and purpureo compounds were clearly differentiated for the first time, although Gibbs and Genth erroneously supposed them to be isomeric. They correctly predicted the existence of coordination compounds in which one or more equivalents of ammonia are replaced by an equal number of equivalents of an organic amine, as well as compounds with other metals in place of cobalt. Their experimental results link Libavius', Diesbach's, and Tassaert's primitive, qualitative observations to the most recent sophisticated, quantitative, contemporary studies.

3 SOME PRE-WERNER THEORIES OF COORDINATION COMPOUNDS

Because sufficient experimental data must be accumulated before attempts can be made to explain them and to predict new phenomena, theories usually lag behind practice. During the first half of the nineteenth century, discoveries of coordination compounds were few, sporadic, and often accidental. Only after Gibbs and Genth's work did chemists devote themselves to systematic studies of these compounds. It might therefore be expected that few theories of coordination compounds would be proposed until late in the second half of the nineteenth century. In fact, theories were devised promptly because of the great importance of coordination compounds to the general problem of chemical bonding.

3.1 Graham's Ammonium Theory (1837)

As more coordination compounds were discovered, theories to explain their constitution were proposed.[13–15] Thomas Graham (1805–1869) proposed the first theory of metal–ammines, the ammonium theory, in which metal–ammines are considered to be substituted ammonium compounds. He explained the constitution of compounds such as diamminecopper(II) chloride by the formula shown in structure (**1**).



(**1**)

He suggested that two hydrogen atoms, one from each ammonia molecule, were displaced by the copper atom, and he viewed the salt as a 'chloride of cuprammonium' similar to the 'chloride of ammonium', thus explaining the strong retention of the ammonia in the compound. Graham's theory is very similar to the modern Lewis acid–base explanation for the formation of coordinate covalent bonds. Although it could be applied only when the number of ammonia molecules in the coordination compound equaled the electrovalence of the metal, it attained a fair degree of success, largely because of modifications proposed by chemists such as Gerhardt, Wurtz, Reiset, von Hofmann, and Weltzien.

3.2 Berzelius' Conjugate Theory (1841)

In his conjugate theory, which used terms and ideas (*corps copulés*) borrowed from Gerhardt, Jöns Jacob Berzelius (1779–1848) viewed metal–ammines as conjugated or copulated compounds consisting of ammonia and a conjugate or copula.[16] The conjugate cannot be removed by reaction with an acid, and it neither decreases nor increases the saturation capacity of a base, that is, a metal conjugated with ammonia can still combine with other substances.

Berzelius introduced his theory of copulae to make his electrochemical theory (1811) compatible with newly discovered organic compounds, but with time the supporters of his theory were outnumbered by its opponents. Increasingly complicated and improbable formulas became necessary to reconcile the theory with experimental facts. In many cases, Berzelius' device of regarding some compounds as conjugated species bore little resemblance to reality. Claus (1854) and Blomstrand (1869) tried to revive and modify Berzelius' ideas, but otherwise his theory was of little value.

3.3 Claus'Ammonia Theory (1854)

In 1854, Carl Ernst Claus (1796–1864), a professor of Chemistry at the University of Kazan and the discoverer of ruthenium (also known by the Russian name of Karl Karlovich Klaus), rejected the ammonium theory and proposed a return to Berzelius' view of complexes as conjugated compounds. He compared the platinum–ammines with metal oxides, rather than with ammonium salts or ammonium hydroxide. He called the coordinated ammonia molecule 'passive, in contrast to the active, alkaline state in the ammonium salts, where it can easily be detected and replaced by other bases'.

Claus's ideas were summarized in his paper of 1856:[17] (1) 'If several equivalents of ammonia (from two to six) combine with an equivalent of certain metal chlorides, neutral substances are formed, in which the basic property of ammonia has been destroyed, and simultaneously the ammonia can be neither detected by the usual methods nor be eliminated by double decomposition.' (2) 'If the chlorine in these compounds is replaced by oxygen, strong bases are obtained, whose saturation capacity is always determined by the oxygen equivalents contained in them but not by the number of equivalents of ammonia present in them.' (3) 'The number of equivalents of ammonia entering into these substances is not a random one; as is evident from a number of facts, it is determined by the number of equivalents of water contained

in the hydrates of the metal oxides that can enter into such compounds along with the ammonia.'

Claus's first idea was attacked by Carl Weltzien (1813–1870), who considered the term 'passive' to be indefinite and confusing. Weltzien, one of the leading proponents of the rival ammonium theory, insisted that every part of a molecule affects every other part and therefore no part can be considered passive. Hugo Schiff (1834–1915) attacked not only Claus's first idea but also his second. Schiff pointed out that the oxides of the metal–ammines are much stronger bases than the metal oxides themselves. This criticism seems to imply that Schiff was confusing the strength of a base, that is, the hydroxide ion concentration of its solution, with its saturation capacity, that is, the number of equivalents of acid with which it could combine. Claus's third idea, the close parallel between metal salt hydrates and metal–ammines, was attacked on the grounds that many hydrates were known for which corresponding ammines were unknown. Claus's third idea foreshadows Werner's concepts of the coordination number, and of the transition series between metal–ammines and metal salt hydrates. All three ideas reappeared in a modified form almost four decades later in Werner's coordination theory.

3.4 Constant Valency and Kekulé's 'Molecular Compounds'

When Claus proposed his ammonia theory, the valence concept was being developed by several chemists, especially, Kekulé, Frankland, Williamson, Odling, Kolbe, and Couper. The main difficulty lay in applying valence to *all* types of chemical compounds, and one of the principal controversies involved the question of whether a given element could possess more than one valence. Because coordination compounds pose several fundamental problems of constitution, they soon became involved in the question of variable versus constant valence.[18]

Although most of the valence theory pioneers readily admitted the possibility of variable valence, August Kekulé (1829–1896) adhered rigidly to the principle of constant valence. Despite the overwhelming amount of data that accumulated to contradict this view, he maintained that atomicity (valence) was 'a fundamental property of the atom that is just as constant and unchangeable as the atomic weight itself.' However, this principle's simplicity was more than outweighed by the complicated, unrealistic formulas required to maintain it. Eventually, Kekulé stood alone in defending it.

Kekulé tried to buttress his theory of constant valence by dividing compounds into 'atomic compounds' and 'molecular compounds': 'Compounds in which all the elements are held together by the affinities of the atoms that mutually saturate one another could be called *atomic compounds*. They are the only ones that can exist in the vapor state. We must distinguish a second category of compounds that I shall designate *molecular compounds*.'

Because for Kekulé the valence of nitrogen, phosphorus, and cobalt was invariably three and that of copper was invariably two, he considered phosphorus(V) chloride, ammonium chloride, copper(II) sulfate pentahydrate, and hexaamminecobalt(III) chloride as 'molecular compounds' with the formulas $PCl_3 \cdot Cl_2$, $NH_3 \cdot HCl$, $CuSO_4 \cdot 5H_2O$, and $CoCl_3 \cdot 6NH_3$, respectively. His artificial dichotomy of compounds into 'atomic compounds', obeying the rules of classical valence theory, and 'molecular compounds', not obeying these rules, possessed, at most, limited value as a formal classification. It failed to explain the nature or operation of the forces involved in forming 'molecular compounds' except to assume that they were acting between molecules rather than atoms. The forces acting between molecules were supposedly weaker than those acting between atoms. Therefore, Kekulé assumed that the resulting 'molecular compounds' would be less stable than 'atomic compounds'. Some substances of limited thermal stability cited by Kekulé as 'molecular compounds', for example, phosphorus(V) chloride, ammonium chloride, and copper(II) sulfate pentahydrate, did decompose in the vapor state, but this was a relative rather than an absolute phenomenon. In time, many chemists considered Kekulé's classification meaningless.

Kekulé's instability criterion, however, failed completely for many coordination compounds. Although they were extremely resistant to heat and chemical reagents, he was forced to consider them 'molecular compounds'. Hexaamminecobalt(III) chloride, for example, contains ammonia, yet it does not evolve ammonia on mild heating, and it fails to react with acids to form ammonium salts. Furthermore, adding a base to its aqueous solution does not precipitate hydrated cobalt(III) hydroxide.

3.5 The Blomstrand–Jørgensen Chain Theory

While Kekulé dealt with coordination compounds by relegating them to the limbo of 'molecular compounds', other chemists elaborated theories explaining their constitution and properties. The most widely accepted and successful of these pre-Werner theories was the so-called chain theory,[19] proposed by Christian Wilhelm Blomstrand (1826–1897),[20] and modified by Sophus Mads Jørgensen (1837–1914).[21] Werner's ideas triumphed eventually, but Jørgensen's experiments have proven completely reliable. They provided the experimental foundation not only for the chain theory but for Werner's coordination theory as well.[22]

During the latter half of the nineteenth century, organic chemistry exerted a great influence on other branches of the science. According to Blomstrand, ammonia molecules could link together as $-NH_3-$ chains, analogous to $-CH_2-$ chains in hydrocarbons. Although nitrogen can form at most four bonds, these chains involved 'quinquevalent' nitrogen, a concept that was quite common in Blomstrand's time.

The length of the chain, that is, the number of ammonia molecules associated with the metal, depended on the metal and its valence. This was later explained far better by Werner's coordination number. Jørgensen accounted for differing reactivities of atoms and groups. He called halogen atoms that could not be precipitated immediately by silver nitrate 'nearer' and considered them as bonded directly to the metal atom; he called halogen atoms that could be precipitated immediately by silver nitrate 'farther' and considered them as bonded through the ammonia chains. Werner later explained these two types of bonding more satisfactorily by the terms 'nonionogenic' and 'ionogenic', respectively, and by his concepts of inner and outer spheres of coordination. In spite of its limitations, the chain theory correlated much empirical data.

In 1883, Jørgensen reported that tertiary amines form compounds analogous to metal–ammines. Because tertiary amines contain no replaceable hydrogen, Jørgensen's discovery eliminated Graham's ammonium theory (Section 3.1) from serious consideration, leaving the chain theory and Kekulé's concept of 'molecular compounds' in the running. In Werner's words, Kekulé's dichotomy merely 'substituted a beautiful word for a confused concept'. Therefore, for almost a quarter of a century, until displaced by Werner's coordination theory, the chain theory became the most popular and satisfactory explanation of metal–ammines.

Jørgensen did not create a new theory of his own, but he logically and consistently extended and modified Blomstrand's chain theory to interpret the many new series of complexes that he, Jørgensen, had discovered. In 1893, Alfred Werner (1866–1919)[1,23] challenged this theory with a revolutionary new theory. According to Werner's own admission, it was based on Jørgensen's painstaking experimental data. In fact, Jørgensen's own work bore the seeds of the chain theory's destruction; some of Jørgensen's compounds later were crucial in Werner's proof of his coordination theory.

4 WERNER'S COORDINATION THEORY AND HIS CONTROVERSY WITH JØRGENSEN

4.1 Werner's Coordination Theory

In a classic example of the 'flash of genius', Alfred Werner, a 26-year-old *Privat-Dozent* at the University of Zürich, awoke at 2 A.M. one night in late 1892. In a dream, he had solved the riddle of the constitution of 'molecular compounds'. Writing furiously and without interruption, by 5 P.M. of the following day he had finished his most famous paper, 'Beitrag zur Konstitution anorganischer Verbindungen' (Contribution to the Constitution of Inorganic Compounds).[1,9]

Werner's theory abruptly broke with classical theories of valence and structure, postulating two types of valence: primary or ionizable valence (Hauptvalenz) and secondary or nonionizable valence (Nebenvalenz). Every metal in a given oxidation state (primary valence) also has a fixed coordination number (a specific number of secondary valences that must be satisfied). Primary valences can be satisfied only by anions, but secondary valences can be satisfied by anions and neutral molecules. Secondary valences are directed in space around the central metal atom. The combined aggregate forms a 'complex', which usually exists as a discrete unit in solution. The most common configurations are octahedral (coordination number six) and square planar or tetrahedral (coordination number four). Werner's view of the two types of linkage, 'ionogenic' (ionizable) and 'nonionogenic' (nonionizable), clarified ideas of chemical bonding, a generation before Kossel's and Lewis's views (1916) led to present concepts of ionic and covalent bonding, respectively.

The following comparison between the chain theory and the coordination theory will be limited to the most common type of complexes, octahedral (hexacovalent) cobalt(III)–ammines, but Werner used similar arguments to prove the constitution and configuration of compounds of the coordination number four. This survey includes only the most important aspects of the Werner–Jørgensen controversy. It is arranged according to compound type, that is, in a logical rather than strictly chronological order. Type MA_6, in which the coordination number of the central metal atom is satisfied by six ammonia molecules, is considered first. These ammonia molecules are then replaced one at a time with other groups.[22,24,25]

In examining the comparative successes of the chain theory and the coordination theory in explaining known facts and predicting new ones, the metal–ammines will be considered under two aspects: (1) *constitution* (the manner of bonding of the constituent atoms and groups) and (2) *configuration* (the spatial arrangement of these atoms and groups).

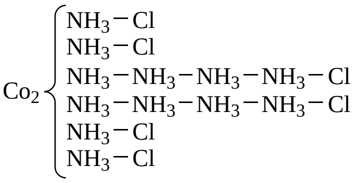
4.2 Constitution of Cobalt–ammines

4.2.1 Hexaammines (Type MA_6)

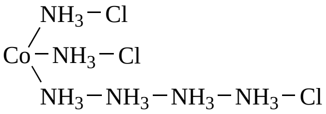
In solution, all the chlorine in luteo cobaltic chloride ($[Co(NH_3)_6]Cl_3$, hexaamminecobalt(III) chloride) is immediately precipitated by silver nitrate. None of its ammonia is removed by treatment with hydrochloric acid at 100 °C. Sulfuric acid does not remove any ammonia but yields $Co_2(SO_4)_3{\cdot}12NH_3$, that is, the chlorine atoms are replaced by sulfate groups.[26] Some sort of very stable metal–ammonia bonding but much less stable metal–chlorine bonding is obviously indicated.

Heating removes one-sixth of the ammonia, and only two-thirds of the chlorine in the resulting purpureo cobaltic chloride ($[CoCl(NH_3)_5]Cl_2$) is precipitable by silver nitrate. Considering that halogen atoms bonded to the metal atom through other groups such as ammonia are precipitable by silver nitrate, while those bonded directly to the metal atom are not, Jørgensen proposed formula (**2**) for the luteo salt.

Jørgensen's (**3**) and Werner's (**4**) structures are both compatible with the experimental observations (for simplicity,



(**2**)



$[Co(NH_3)_6]Cl_3$

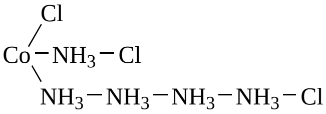
Jørgensen (**3**) Werner (**4**)

monomeric formulas are used for this discussion although they were not used by Jørgensen until 1890). However, Jørgensen regarded the chlorine atoms as attached to the metal atom through ammonia molecules, whereas Werner regarded them as ionogenic and outside the coordination sphere. Werner regarded the central metal atom and the ammonia molecules as comprising a discrete unit, a complex cation. This structure should yield four ions in solution, a fact later confirmed by Werner and Miolati's conductance studies.[27,28]

4.2.2 *Pentaammines (Type MA_5B)*

These compounds can be regarded as luteo salts in which another group has replaced one-sixth of the ammonia molecules. This type can be subdivided into several series, depending on the replacing group. Pentaammines in which the replacing group is sulfate, nitrate, oxalate, or a halogen are called purpureo salts. Ammonia is not evolved even on heating purpureo cobaltic chloride ($[CoCl(NH_3)_5]Cl_2$) to 100 °C, evidence that the ammonia molecules are strongly bonded to the cobalt atom. Jørgensen reported that cold concentrated sulfuric acid does not react with the ammonia in the salt but yields the compound $[CoCl(NH_3)_5]SO_4$, which gives no immediate precipitate with silver nitrate, although it contains chlorine. Furthermore, he found that only two-thirds of the chlorine in the original salt is immediately precipitated by silver nitrate, while the remaining third is precipitated only on long boiling.

In order to account for this difference in reactivity, Jørgensen proposed, as Werner did after him, that the 'unreactive' or 'masked' chlorine is bonded directly to the metal atom. The structures that they proposed, (**5**) and (**6**), are both compatible with the experimental facts but again differ in the mode of attachment of the 'reactive' chlorine atoms. Jørgensen considered these atoms as linked to the metal atom through ammonia molecules, whereas Werner considered them as not linked to any particular atom but attracted by electrostatic forces to the complex cation as a whole. According to Werner's structure, a solution of purpureo cobaltic chloride should furnish three ions, a fact confirmed by conductance studies.[27,28] The roseopentammines (aquapentaammines, $[M(NH_3)_5H_2O]X_3$), and the isomeric xantho and isoxantho salts (nitropentaammines and nitritopentaammines, $[MNO_2(NH_3)_5]X_2$ and $[MONO(NH_3)_5]X_2$) were other pentaammine series over whose structures Jørgensen and Werner disagreed.[12,28,29]

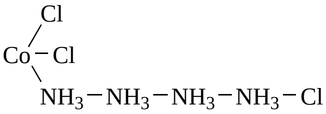


$[CoCl(NH_3)_5]Cl_2$

Jørgensen (**5**) Werner (**6**)

4.2.3 *Tetraammines (Type MA_4B_2)*

These compounds can be regarded as luteo salts in which other groups have replaced one-third of the ammonia. Both the Blomstrand–Jørgensen (**7**) and Werner (**8**) formulas predicted two ions for this type of compound, a fact confirmed by conductance studies.[27,28] The stereoisomerism of these compounds is discussed in Section 4.3.



$[CoCl_2(NH_3)_4]Cl$

Jørgensen (**7**) Werner (**8**)

4.2.4 *Triammines (Type MA_3B_3)*

These compounds can be regarded as luteo salts in which other groups have replaced one-half of the ammonia. Although Jørgensen's and Werner's formulations for hexaammines, pentaammines, and tetraammines were compatible with the experimental facts, allowing two rival hypotheses to coexist for a time, the scales began to tip in favor of Werner's theory as additional experimental evidence accumulated.

As negative groups such as chlorine atoms successively replace ammonia molecules in a hexaammine, they enter the coordination sphere and become nonionic or 'masked'. The ionic character of the compounds predicted by the two theories is in complete agreement with the replacement of the first two ammonia molecules. However, the ionic character of the resulting compounds (**9**) and (**10**) differs radically according to the two theories when the third ammonia molecule is replaced. The formulas and predicted numbers of ions for the transition series $[Co(NH_3)_6](NO_2)_3$-$K_3[Co(NO_2)_6]$ according to the two theories are compared in Table 1, and Figure 1 shows the results of Werner's study of conductances carried out in collaboration with his friend and former fellow student Arturo Miolati (1869–1956), the first experimental work published in support of his coordination theory.

Table 1 A Comparison of Blomstrand–Jørgensen's Chain Theory with Werner's Coordination Theory. (Ref. 2b. Reproduced by permission of Dover Publications, Inc.)

	Blomstrand–Jørgensen		Werner	
Class of compound	Formula	No. of ions	Formula	No. of ions
Hexaammines MA_6	Co(–NH_3–NO_2)(–NH_3–NO_2)(–NH_3–NH_3–NH_3–NH_3–NO_2) ↓–NH_3	4	$[Co(NH_3)_6](NO_2)_3$ ↓–NH_3	4
Pentaammines MA_5B	Co(–NO_2)(–NH_3–NO_2)(–NH_3–NH_3–NH_3–NH_3–NO_2) ↓–NH_3	3	$[CoNO_2(NH_3)_5](NO_2)_2$ ↓–NH_3	3
Tetraammines MA_4B_2	Co(–NO_2)(–NO_2)(–NH_3–NH_3–NH_3–NH_3–NO_2) ↓–NH_3	2	$[Co(NO_2)_2(NH_3)_4]NO_2$ ↓–NH_3	2
Triammines MA_3B_3	Co(–NO_2)(–NO_2)(–NH_3–NH_3–NH_3–NO_2)	2	$[Co(NO_2)_3(NH_3)_3]$ ↓–NH_3	0
Diammines MA_2B_4	Unaccountable	–	$K[Co(NO_2)_4(NH_3)_2]$ ↓–NH_3	2
Monoammines MAB_5	Unaccountable	–	Unknown for Cobalt ↓–NH_3	(3)

Werner
(**10**)

Werner and Miolati's first publication on this subject[27] showed that the molecular conductances (μ) of coordination compounds decrease as molecules of ammonia are successively replaced by acid residues (negative groups or anions). For cobalt(III) salts, μ for luteo salts (hexaammines) $>$ μ for purpureo salts (acidopentaammines) $>$ μ for praseo salts (diacidotetraammines). The conductance decreases almost to zero for the triacidotriammine $Co(NO_2)_3(NH_3)_3$ and then increases for tetraacidodiammines, in which the complex behaves as an anion. Werner and Miolati used these measurements to determine the number of ions in cobalt(III) and platinum(II) and -(IV) complexes, which supported the coordination theory and also elucidated the process of dissociation of salts in aqueous solution and the progress of aquation reactions.

Werner and Miolati's second article on conductances of complexes[28] showed a complete agreement in magnitude, variation, and pattern between their experimentally measured conductances and those predicted by the coordination theory. For example, the experimentally measured conductances for the $[Co(NH_3)_6]Cl_3$–$K_3[Co(NO_2)_6]$ transition series (Figure 1) agreed completely with the numbers of ions predicted by the coordination theory (Table 1), and were also concordant with the number of 'masked' and 'unmasked' acid radicals. The Werner theory also explained anionic complexes and demonstrated the existence of a continuous transition series (Übergangsreihe) between metal–ammines (MA_6) and double salts (MB_6), an area in which the Blomstrand–Jørgensen theory was unable to complete.

4.3 Configuration of Cobalt(III)–Ammines

The technique of 'isomer counting' used by Werner to prove the configuration of cobalt–ammines and other complexes did not originate with him,[25] but had been used earlier by Wilhelm Körner for benzene derivatives in 1874, and was also suggested by Jacobus Henricus van't Hoff in 1875. However, the technique of comparing the number and type of isomers actually prepared with the number and type theoretically predicted for different configurations probably attained its zenith with Werner. Not only did he use this method to discredit completely the chain theory but also to

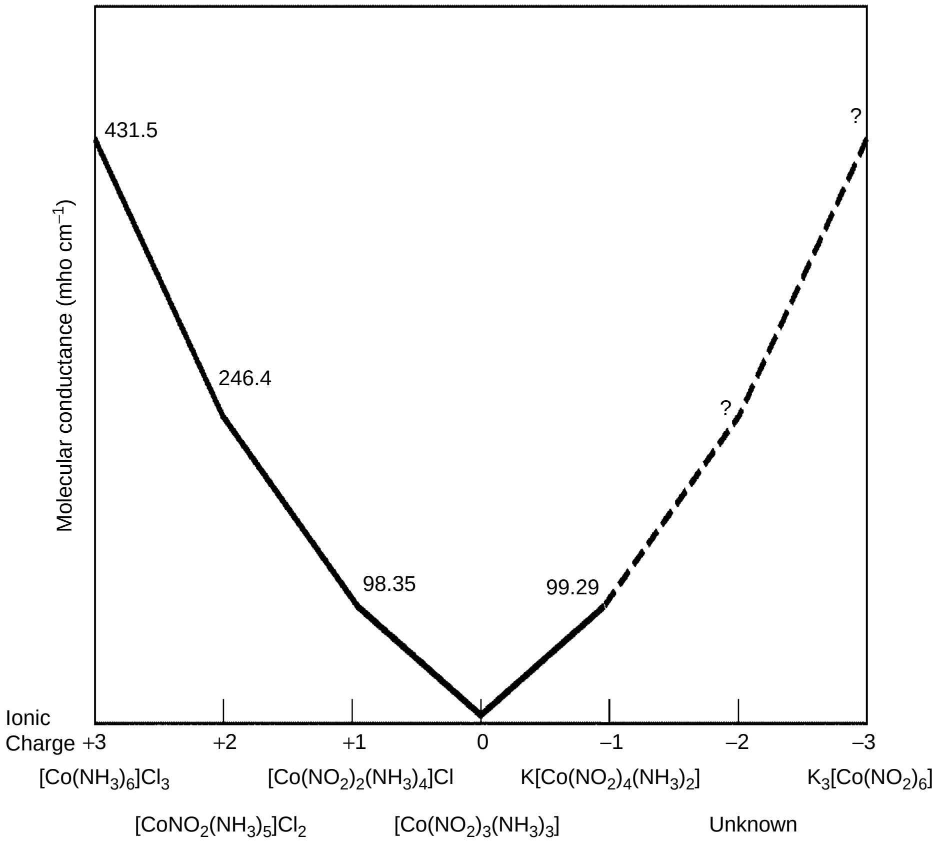

Figure 1 Conductances of cobalt(III) coordination compounds. (Ref. 28. Reproduced by permission of Dover Publications, Inc.)

demonstrate unequivocally an octahedral configuration for cobalt(III) rather than any other symmetrical arrangement, for example, hexagonal planar or trigonal prismatic. Werner's method is summarized in Figure 2 and Table 2. Werner's proof of the configuration of cobalt–ammines involves two types of stereoisomerism, geometric and optical.

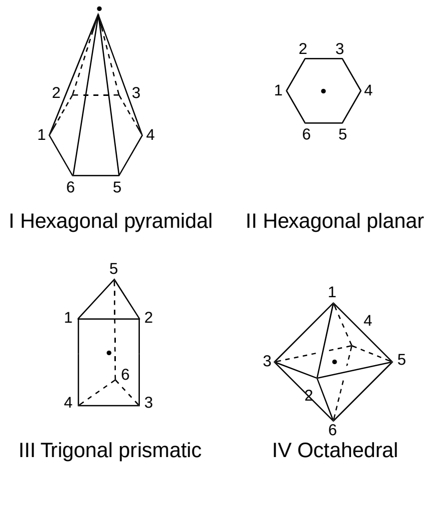

Figure 2 Configurational possibilities for coordination number 6

4.3.1 Geometric Isomerism[11,22,25,30]

Werner and his students prepared and characterized, in most cases for the first time, geometric isomers of 53 series of cobalt and chromium complexes.[30] Comparing columns IV and V of Table 2 shows that, in most cases, the number and type of isomers prepared agrees with the expectations for the octahedral configuration. However, there were a few exceptions; it took Werner more than 20 years to accumulate a definitive proof for his structural ideas. For example, the best-known case of geometric (*cis–trans*) isomerism was observed by Jørgensen (1889), not among simple tetraammines MA_4B_2 but among salts $M(\overline{AA})_2B_2$, in which the four ammonia molecules had been replaced by two molecules of a chelating ligand, ethylenediamine (en), that is, among the praseo (green) and violeo (violet) salts of formula $CoCl_3{\cdot}2en$. Jørgensen ascribed the difference in color to *structural* isomerism connected with the linking of the two ethylenediamine molecules, while Werner considered the salts *stereoisomers*, compounds with the same atoms and bonds but differing only in the orientation of these atoms and bonds in space (Figure 3).

If, as Werner insisted, this isomerism were only a geometric consequence of the octahedral structure, it should also be observed among simple tetraammines MA_4B_2,

Table 2 Proof of configuration for coordination number 6 by 'Isomer Counting'. (Ref. 2b. Reproduced by permission of Dover Publications, Inc.)

	Theoretically predicted isomers					
Compound type[a]	I hexagonal pyramidal	II hexagonal planar (a special case of I)	III trigonal prismatic	IV octahedral	Experimentally found isomers	Result
MA_6	One form only	One form only	One form only	One form only	One form only	None
MA_5B	One form only	One form only	One form only	One form only	One form only	None
$M(\overline{AA})B_4$	One form only	One form only	Two geometric	One form only	One form only	Provisionally eliminates trigonal prismatic (III)
MA_4B_2	Three geometric (1,2; 1,3; 1,4)	Three geometric (1,2; 1,3; 1,4)	Three geometric (1,2; 1,3; 1,4)	Two geometric (1,2 *cis*; 1,6 *trans*)	Two or less geometric	Provisionally proves octahedral (IV); discovered 1907
MA_3B_3	Three geometric (1,2,3; 1,2,4; 1,3,5)	Three geometric (1,2,3; 1,2,4; 1,3,5)	Three geometric (1,2,3; 1,2,5; 1,2,6)	Two geometric (1,2,3 *facial*; 1,2,6 *peripheral*)	Two or less geometric	Provisionally proves octahedral (IV)
$M(\overline{AA})_2B_2$ or $M(\overline{AA})_2BC$	Two geometric	Two geometric	Four geometric, one of which is asymmetric	Two geometric (1,2 *cis*; 1,2 *trans*), the first of which is asymmetric	Two geometric (1,2 *cis*; 1,6 *trans*), the first of which was resolved	Unequivocally proves octahedral (IV); discovered 1911
$M(\overline{AA})_3$	One form only	One form only	Two geometric	One asymmetric pair	One pair optical resolved	Unequivocally proves octahedral (IV); discovered 1912

[a] $\overline{AA}$ represents a symmetrical bidentate (chelate) ligand. Such ligands coordinate at two adjacent positions. They can span *cis* positions but not *trans* positions.

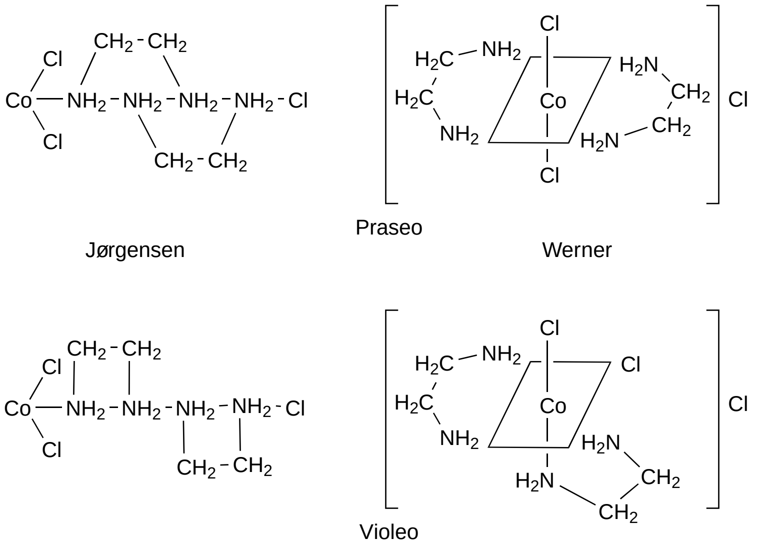

Figure 3 Jørgensen's and Werner's formulas for praseo and violeo ethylenediamine isomers

which do not contain ethylenediamine. However, compounds $[CoCl_2(NH_3)_4]X$ were known in only one series (praseo, green).[12] Jørgensen, a confirmed empiricist, appropriately criticized Werner's theory for implying the existence of unknown compounds. It was only in 1907 that Werner finally prepared the unstable violeo tetraammines, *cis*-$[CoCl_2(NH_3)_4]X$,[31] which are a necessary consequence of his theory but not of Jørgensen's (Figure 4).

4.3.2 Optical Isomerism

Although Werner's discovery of violeo salts proved that Jørgensen's views were incorrect, Werner's preparation of two, and only two, isomers of $[CoCl_2(NH_3)_4]X$ salts and many other MA_4B_2 compounds was insufficient to prove conclusively his octahedral configuration. In spite of this 'negative' evidence, one could argue that failure to isolate a third isomer does not prove its nonexistence. The 'positive' proof chosen by Werner involved resolving certain types of asymmetric coordination compounds containing chelate groups into optical isomers.[32] Comparison of column V with columns I–IV in Table 2 shows that Werner's empirical results agree with the predictions for the octahedral configuration.

Werner recognized in 1899 that resolving optical isomers of certain types of coordination compounds containing chelate groups (which can span *cis* positions only) could provide the 'positive' proof that he sought. After many unsuccessful attempts, he and his American student Victor L. King (1886–1958) resolved *cis*-amminechlorobis(ethylenediamine)cobalt(III) salts with silver d-α-bromocamphor-π-sulfonate, which proved that cobalt(III) has an octahedral configuration (Figure 5).[33]

The resolution of optically active coordination compounds brought the coordination theory widespread recognition and Werner the 1913 Nobel Prize in chemistry.[34] However, at that time, optical activity was almost always connected with carbon atoms, and some of Werner's contemporaries argued that the optical activity of the numerous mononuclear and polynuclear coordination compounds that he resolved[35] was due to the organic chelate groups present, even though all these symmetrical ligands were optically inactive. Werner's 1914 resolution of completely carbon-free coordination compounds, the tris[tetraammine-μ-dihydroxocobalt(III)]cobalt(III) salts (**11**),[36] first prepared by Jørgensen, finally silenced his opponents. These salts are

(**12**)

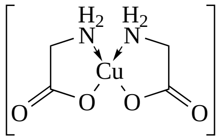
In his doctoral dissertation (1890),[37] Werner had ascribed the geometric isomerism of oximes to the tetrahedral configuration of the nitrogen atom, thus destroying the carbon atom's monopoly on geometric isomerism. Now, at the peak of his career, he demonstrated that the tetrahedron had no monopoly on optical isomerism, thus attaining a major goal by proving that stereochemistry is a general phenomenon not limited to carbon compounds, and that no fundamental difference exists between organic and inorganic compounds. Werner's structural views were later confirmed by X-ray diffraction studies (see Section 5.5), but despite determinations by more *direct* modern techniques; Werner's classical determinations of configuration by simple *indirect* methods remain a monument to his intuitive vision, experimental skill, and inflexible tenacity.

5 TWENTIETH-CENTURY DEVELOPMENTS

5.1 Inner Complexes: Ley and Bruni (1904)

With few exceptions, Werner's coordination theory[9] was accepted by most chemists, and most twentieth-century contributions have been developments, extensions, or confirmations of it rather than ideas incompatible with or opposed to it. One of the earliest of these post-Werner developments is the concept of inner complex salts.[38]

Metal chelates were known in the late-nineteenth century, but the first person to recognize clearly the significance and consequences of cyclic structure in coordination compounds was Heinrich Ley (1872–1938), a German chemist. In 1904, using observations of color, transference, and distribution experiments, and determinations of molecular weight and electrical conductance, he explained the constitution of copper glycinate and similar compounds. He used Werner's primary valence (Hauptvalenz) and secondary valence[38,39] (Nebenvalenz) concepts to show that these compounds are not ordinary salts or even ordinary complex salts but a type of metal chelate, an inner metal complex salt (inneres Metallkomplexsalz) (**13**), in which each chelate ligand is bonded to the central metal ion by both a primary valence and a secondary valence, forming a ring. In the same year, Giuseppe Bruni and C. Fornara proposed a similar formula for copper glycinate.



(**13**) Bis(glycinato)copper(II)

5.2 Cyclic Bonding and Stability: Chugaev's Rule of Rings (1906)

Chugaev's so-called rule of rings is closely related to Ley's concept of inner complexes. For a molecule with two potential coordinating groups (e.g. a diamine, $NH_2(CH_2)_nNH_2$, or an amino acid, $NH_2(CH_2)_nCO_2H$) to function as a chelate group, it must form a ring of low strain. According to Baeyer's strain theory (1885), five- and six-membered rings are the most stable, while four-membered rings are less stable and three-membered rings are unstable. In 1906, Lev Aleksandrovich Chugaev (1873–1922), Professor of Chemistry at St. Petersburg University, showed that these relationships among organic compounds are applicable to coordination compounds. Chugaev's rule of rings served as a basis not only for his own stereochemical research but also for that of others, for example, A. A. Grinberg's method for determining the configuration of Pt^{II} complexes by reaction with oxalic acid (1931) involves the stability of a five-membered ring. By comparing the ability of Co^{III}, Ni^{II}, and Pt^{II} to form chelates with various diamines, Chugaev also demonstrated the stability of pentatomic and hexatomic ring systems.[40]

5.3 Alternative Theories of Coordination Compounds

5.3.1 *Friend (1908)*

In 1908, the English chemist John Albert Newton Friend (1881–1966) criticized Werner's theory and suggested an alternative explanation for coordination compounds. According to Friend, classical valency theory was unable to explain why the valency of most elements apparently varies, why electropositive elements combine readily with electronegative elements to form the most stable compounds, why electropositive and electronegative elements combine with themselves and with other elements of the same sign to form stable molecules, and why molecules can combine with other molecules to form very stable coordination compounds. Friend postulated three kinds of valency: (1) free positive, (2) free negative, and (3) residual or latent valency. Residual valency referred to positive and negative valencies that differ from free valencies in that they can only function in pairs of equal and opposite sign. Free valencies correspond to Werner's primary valences and his latent valencies to Werner's secondary valences, with certain differences in the second case.

In a 1908 article[41] Friend criticized Werner's theory, differentiated between his latent valencies and Werner's

secondary valences, and applied his valency theory to ammonium salts, metal–ammines, and halide 'double salts'. For hexacoordinate central atoms, he suggested that a 'hexatomic shell' forms around the metal with all the elements or groups joined *together* by latent valencies and not necessarily to the metal itself. In 1916, he applied his theory to hexaamminecobalt(III), pentaamminechlorocobalt(III), and tetraamminedichlorocobalt(III) chlorides, and he emphasized four differences between his theory and Werner's.[42]

5.3.2 Briggs

In 1908, the English chemist Samuel Henry Clifford Briggs (1880–1935) proposed formulas for complexes that he claimed agreed with experimental data and showed how the affinities of the atoms are disposed in the molecule.[43] He did not claim to be proposing a new theory of valence. Like Werner, he thought that 'a totally comprehensive and satisfactory theory of valence will not be possible until we have a much more complete knowledge of the constitution of molecular compounds, and also of the nature of chemical affinity, than we possess today'. He later (1917) reinterpreted his formulas in terms of the electronic theory of valence, differentiated between what he called primary and secondary affinity (similar to Werner's primary and secondary valences), and proposed three different types of chemical combinations.

5.3.3 Povarnin (1915)

In five papers (1915), the Russian chemist Georgi Georgievich Povarnin (1880–1946) attacked Werner's theory because: (1) it required two kinds of valences, with a further differentiation of groups into 'ionogens' and 'nonionogens', three varieties of affinity bonds in all; (2) it required a distinction between atomic and molecular compounds; (3) it assumed that whereas the number of an element's principal valences depended on its position in the periodic table, the number of its secondary valences did not; (4) prediction of the number of possible isomers was difficult in many cases; and (5) it explained only the structure of the inner sphere where atoms or groups are linked directly to the central atom but failed to explain how this sphere was joined to the outer sphere where union with the central atom occurred through other atoms.[44]

To overcome these objections, Povarnin proposed a theory of polar affinities. He suggested that atoms themselves were complex systems of positive and negative affinities in unequal amounts; an element was positive when the positive charge exceeded the negative, and negative when the reverse was true. He thus considered the classical valence unit to be composed of two polar charges not identical in absolute magnitude. He suggested that bonds between atoms have the power to oscillate and that atoms tend to form four- or six-membered rings.

5.3.4 Pfeiffer (1920)

Even Paul Pfeiffer (1875–1951), Werner's former student, onetime 'chief of staff' at the University of Zürich, and the man who first applied coordination theory to crystal structures (see Section 5.4), proposed modifications of Werner's theory. In 1920, Pfeiffer applied his principle of 'affinity adjustment of the valencies' to answer certain shortcomings of Werner's theory. He considered ionizable radicals or atoms in the outer sphere as combined with the entire complex radical rather than attached to the central atom or any of its associated molecules, and he applied this idea to organic molecular compounds. His modifications, however, are not to be interpreted as attacks on Werner's ideas.

5.4 Pfeiffer's 'Crystals as Molecular Compounds' (1915)

Werner failed to recognize that polynuclear coordination compounds[45] represent a transition between mononuclear complexes and the infinite structure of the crystal lattice. However, Paul Pfeiffer, Paul Niggli (1888–1953), and others reported crystal structures agreeing with Werner's coordination theory, as revealed by the new X-ray diffraction technique.[46]

Pfeiffer applied Werner's coordination theory to new areas. He regarded crystals as very high-molecular-weight coordination compounds, in which atoms act as coordination centers, about which further atoms group themselves in specific symmetrical relationships.[47] He proposed that they obey the same structural chemical and steric laws as coordination compounds and that atoms or groups of atoms in crystals are held together by the same chemical forces operating among coordination compounds.

Pfeiffer regarded sodium chloride as a highmolecular–weight coordination compound $(NaCl)_n$ constructed of equal numbers of $[NaCl_6]$ and $[ClNa_6]$ units. The difference between primary valences and secondary valences disappears in crystals of symmetrical compounds. He demonstrated that, in other crystals, coordination centers can be groups of atoms as well as single atoms, and that coordination numbers as high as 12 must sometimes be considered. He proposed that, in crystals of simple organic molecular compounds of type AB, each constituent acts as a coordination center; AB_6 and BA_6 units interpenetrate exactly as in sodium chloride.

5.5 Configurational Determination by X-ray Diffraction

5.5.1 Wyckoff and Posnjak (1921)

Pfeiffer's application of Werner's theory to crystals and the advent of new experimental techniques led a number of scientists in various countries to use X-ray diffraction to determine crystal structures of coordination compounds. American chemist Ralph W. G. Wyckoff (1897–1994) 'chose ammonium hexachloroplatinate(IV) as a crystal that should

provide a clear-cut test of Werner coordination',[48] and, together with Eugen Posnjak (1888–1949), he published the first experimental crystallographic study of a coordination compound[49] (*see* ***Platinum: Inorganic & Coordination Chemistry***). According to Wyckoff, 'All six chlorine atoms in $(NH_4)_2PtCl_6$... were crystallographically identical. They were equally distant from the metal atom, and hence there was no difference in the bonds they formed with it. Furthermore, chlorines were found to be at the corners of a regular octahedron having the platinum atom at its center. A more complete agreement with the predictions of the Werner theory could scarcely have been imagined.'[48]

Other scientists soon used X-ray diffraction to confirm the octahedral configuration of the six halogen atoms in similar hexacoordinate complexes. Wyckoff also confirmed Werner's view that the molecules of water and of ammonia in most crystalline hydrates and ammines are associated with the metallic atom in the same way as the coordinated atoms and radicals in a complex anion. Since the early 1920s, the structures of numerous coordination compounds of various coordination numbers have been determined by X-ray diffraction.

5.5.2 Dickinson (1922)

Less than a year after Wyckoff and Posnjak determined the octahedral configuration for platinum(IV) (coordination number six), Roscoe Gilkey Dickinson (1894–1945) used the same technique to confirm Werner's predicted planar configuration for platinum(II) (coordination number four)[50] (*see* ***Platinum: Inorganic & Coordination Chemistry***). After determining the crystal structure of ammonium hexachlorostannate(IV), $(NH_4)_2[SnCl_6]$ (isomorphous with Wyckoff and Posnjak's $(NH_4)_2[PtCl_6]$), Dickinson determined the crystal structures of potassium tetrachloroplatinate(II), $K_2[PtCl_4]$, and potassium and ammonium tetrachloropalladates(II), $K_2[PdCl_4]$ and $(NH_4)_2[PdCl_4]$ (*see* ***Palladium: Inorganic & Coordination Chemistry***), and found each platinum or palladium atom to be surrounded by four equivalent and equidistant chlorine atoms in a plane. The ammonia molecules in $[Pt(NH_3)_4]Cl_2$ show a similar structure.

The crystal structures of numerous other complexes of various coordination numbers have been determined, completely and *directly* confirming Werner's earlier *indirect* configurational proofs by the preparation of isomers and resolution of optically active compounds (see Section 4). Today, the terminology and concepts of coordination chemistry are universally used in crystallography.

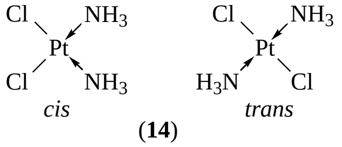
5.6 Sidgwick's Effective Atomic Number Concept (1923)

In 1923, Nevil Vincent Sidgwick (1873–1952) and Thomas Martin Lowry (1874–1936) made the first attempts to interpret Werner's views on an electronic basis. Sidgwick tried to explain the coordination number according to the sizes of the subgroups of electrons in the Bohr atom,[51] and he systematized coordination numbers in his 'effective atomic number' (EAN) concept. He regarded ligands as Lewis bases that donate electrons (usually one pair per ligand) to the metal ion, which consequently acts as a Lewis acid. By this process, ions add electrons until the EAN (sum of the electrons on the metal ion and the electrons donated by the ligand) of the next noble gas is reached. This EAN rule is still of importance; although some elements obey it, there are many important stable exceptions. However, it is very useful as a predictive rule for organometallic compounds (*see* ***Carbonyl Complexes of the Transition Metals***). Finally, it is of historical significance in being the result of the first attempt to explain Werner's coordination theory in terms of electronic structure.

5.7 Chernyaev's Trans Effect (1926)

Just as substitution reactions in organic chemistry do not occur in a random manner, those among coordination compounds are not random. However, the general principles concerning the directive influences of coordinated ligands were not proposed until the late 1920s; they were deduced from reactions of platinum(II) complexes.

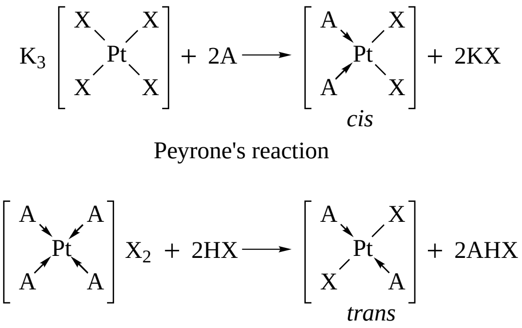
These compounds were among the earliest known complexes. Werner cited the well-known regularities in their substitution reactions to assign *cis* and *trans* configurations to platinum(II) complexes, which he rightly regarded as square planar.[9] On the basis of their substitution reactions, Werner assigned platosemidiammine chloride (Peyrone's Salt) and platosammine chloride (Reiset's Second Chloride), both with the formula $PtCl_2(NH_3)_2$ (see Section 2.8), the configurations of structure (**14**).



(**14**)

The preparations of both these compounds involve directive influences, the syntheses being known as Peyrone's reaction and Jørgensen's reaction, respectively. They were said to exemplify Peyrone's rule (*cis* orientation) and Jørgensen's rule (*trans* orientation) (see Scheme 1).

In 1893, the Russian chemist Nikolai Semenovich Kurnakov (1860–1941) observed a third important regularity. During a study of the substitution of ligands by thiourea and thioacetamide, he found a replacement of all the ligands of the *cis* compound but only of the acid radicals of the *trans* compound (Scheme 2). Because the two isomers yield different products, this reaction (Kurnakov's reaction or Kurnakov's test) has been used to differentiate *cis* from *trans* isomers of platinum(II) or palladium(II). It was crucial in



Jørgensen's reaction

tu = thiourea

Scheme 2

Werner's proof of the square-planar configuration[9] of Pt^{II}, as well as in Chernyaev's formulation of the trans effect.[10]

Werner recognized the principle of 'trans elimination' in 1893,[9] but it was only in 1926 that the Russian chemist Il'ya Il'ich Chernyaev (1893–1966) enunciated his trans effect describing the influence of a coordinated ligand on the ease of preparing compounds in which the group trans to it had been replaced.[10] According to Chernyaev, a negative group coordinated to a metal atom loosens the bond of any group trans to it. Thus Peyrone's, Jørgensen's, and Kurnakov's reactions are all specialized cases of Chernyaev's more general directive influence.

Chernyaev also studied substitution reactions of chromium, cobalt, tellurium, and osmium complexes, and he reported that the trans effect of atoms is inversely proportional to their metallic character (directly proportional to their electronegativities). Electronegative ligands, for example, NO_2^-, NCS^-, F^-, Cl^-, Br^-, and I^-, have a greater 'trans influence' than neutral ligands, for example, NH_3, ammines, or H_2O. His original trans-directing series has now been extended to include additional ligands: $CN^- \sim CO \sim C_2H_4 \sim NO > CH_3^- \sim SC(NH_2)_2 \sim SR_2 \sim PR_3 > SO_3H^- > NO_2^- \sim I^- \sim SCN^- > Br^- > Cl^- > C_5H_5N > RNH_2 \sim NH_3 > OH^- > H_2O$.

5.8 Proof of the Square-planar Configuration for Platinum(II): Mills and Quibell (1935)

The octahedral configuration of cobalt(III) and platinum(IV) (coordination number six) was proven in three ways: (1) chemical evidence such as 'isomer counting' and transformation reactions (see Section 4.3); (2) resolution of selected compounds (see Section 4.3); and (3) X-ray diffraction studies (see Section 5.5). The first two methods were pursued successfully, largely by Werner.

The square-planar configuration of platinum(II) was proven by the same methods but with a different chronology and a difference in interpretation of the resolutions. Three symmetrical configurations for the coordination number four are theoretically possible (see Figure 6).

The square-pyramidal configuration has never been observed experimentally. Although theoretically possible, it is considered unlikely and is usually eliminated from active consideration in stereochemical work. The method is summarized in Table 3.

Because only a few platinum(II) and palladium(II) isomers were known and similar isomerism among other elements was not discovered for a number of years, Werner's square-planar configuration (1893)[9] was increasingly questioned as time went by, and other proposals were made to account for the structures of these compounds. For example, several workers claimed to have isolated more than two isomers for compounds of type MA_2B_2, which would eliminate a square-planar configuration although it is also not compatible with either the tetrahedral or square-pyramidal arrangements. Also, others claimed to have resolved tetracoordinate platinum(II) complexes of type $M(\overline{AB})_2$, a fact inexplicable by the square-planar configuration.

Dickinson's X-ray diffraction proof of a square-planar arrangement of chloride ions around the central metal atoms in $K_2[PtCl_4]$, $K_2[PdCl_4]$, and $(NH_4)_2[PdCl_4]$ (see Section 5.5.2) was confirmed by additional X-ray structural studies of other compounds. Linus Pauling explained the square-planar structure of platinum(II) and palladium(II) compounds on a theoretical basis and predicted a similar configuration for diamagnetic compounds of nickel(II), gold(III), copper(III), and silver(III).

In 1928, Chernyaev used his trans effect to confirm the square-planar configuration for platinum(II) by preparing the three theoretically possible geometric isomers of a compound of type MABCD (**15**). The occurrence of three

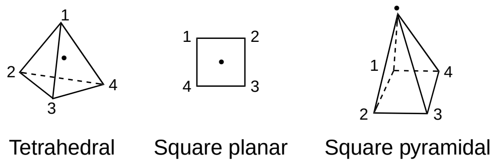

Figure 6 Theoretically possible symmetrical configurations for coordination number 4

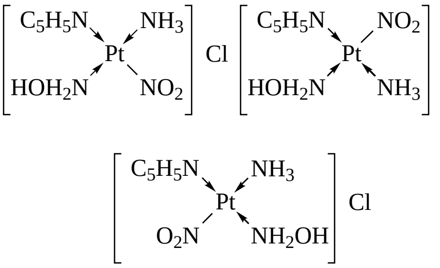
Table 3 Proof of configuration for coordination number 4 by 'Isomer Counting'. (Ref. 2c. Reproduced by permission of Dover Publications, Inc.)

Compound type[a]	Theoretically predicted isomers: I tetrahedral	II square-planar (a special case of III)	III square-pyramidal	Conclusions
MA_4	One form only	One form only	One form only	None possible
MA_3B	One form only	One form only	One form only	None possible
MA_2B_2	One form only	Two geometric (1,2 *cis*; 1,3 *trans*)	Two geometric (1,2 *cis*; 1,3 *trans*)	More than one isomer would eliminate I and prove II or III
MA_2BC	One form only	Two geometric (1,2 *cis*; 1,3 *trans*)	Two geometric (1,2 *cis*; 1,3 *trans*); *cis* is asymmetric	More than one isomer would eliminate I; resolution of *cis* isomer would prove III
MABCD	One asymmetric pair	Three geometric (1,2,3,4; 1,2,4,3; 1,3,2,4)	Three geometric (1,2,3,4; 1,2,4,3; 1,3,2,4); each consists of an asymmetric pair	Optical isomerism without geometric isomerism would prove I; geometric isomerism without optical isomerism would prove II; both optical isomerism and geometric isomerism would prove III
$M(\overline{AA})_2$	One form only	One form only	One form only	None possible
$M(\overline{AB})_2$	One asymmetric pair	Two geometric (1,2; 4,3 *cis*; 1,2; 3,4 *trans*)	Two geometric (1,2; 4,3 *cis*; 1,2; 3,4 *trans*) *trans* is asymmetric	Optical isomerism without geometric isomerism would prove I; geometric isomerism without optical isomerism would prove II; both optical isomerism and geometric isomerism would prove III
$M(\overline{AA})CD$	One form only	One form only	One asymmetric pair	Two isomers would indicate that both I and II exist; resolution would indicate III
$M(\overline{AA})CD$	One asymmetric pair	Two geometric	Two geometric; each consists of an asymmetric pair	One resolvable form would indicate I; two nonresolvable isomers would indicate II; two resolvable isomers would indicate III

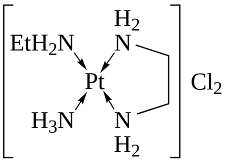
[a] $\overline{AA}$ represents a symmetrical bidentate (chelate) ligand, which can span *cis* positions but not *trans* positions. $\overline{AB}$ represents an unsymmetrical bidentate (chelate) ligand, which can span *cis* positions but not *trans* positions.

geometric isomers eliminated the tetrahedral arrangement but did not absolutely rule out the square-pyramidal configuration (Table 3). One could still argue that each of Chernyaev's isomers consists of an asymmetric pair but that he was unable to resolve them. Because it is impossible to prove a negative proposition, another problem of 'negative' evidence similar to that which Werner had faced (see Section 4.3) had again arisen.

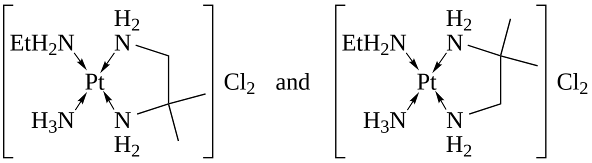


(**15**)

In 1934 and 1937, Harry D. K. Drew *et al.* tried to solve the problem by preparing isomers of compound types $M(\overline{AA})CD$ and $M(\overline{AB})CD$ (see Table 3). For the symmetrical chelate group he chose ethylenediamine and, for the unsymmetrical one, isobutylenediamine (1,2-diamino-2-methylpropane). As an example of the first type complex, he obtained one and only one form of (**16**). For the second type complex, he obtained the two geometric isomers (**17**). His experimental data agreed with the square-planar configuration; he did not consider the square-pyramidal configuration.



(**16**)

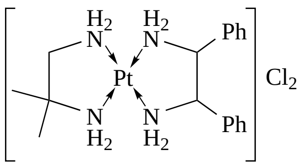


(**17**)

As Werner, a generation before, had realized that successful resolution of coordination compounds would offer a 'positive' proof that hexacoordinate cobalt(III) possesses

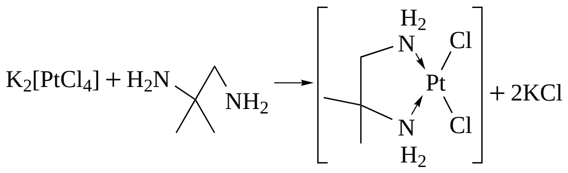
an octahedral configuration, the English chemist William Hobson Mills (1873–1959) realized that resolution of a certain type of bisbidentate complex of platinum(II) would permit a definite decision to be made between the planar and tetrahedral configurations. In 1935, Mills and Thomas Henry Hall Quibell (1907–1997) prepared dichloro(1,2-diamino-2-methylpropane)platinum(II) by the reaction of isobutylenediamine with potassium tetrachloroplatinate(II) (Scheme 3).[52]

By reacting *meso*-1,2-diphenylethylenediamine (stilbenediamine) with this compound, they obtained (1,2-diamino-2-methylpropane)(*meso*-1,2-diamino-1,2-diphenylethane)platinum(II) chloride (**18**). If the arrangement of the bonds around the platinum atom were tetrahedral, the chelate rings would lie in planes perpendicular to each other, a configuration with a median plane of symmetry that could not give rise to optical isomerism. However, if the two chelate rings were coplanar, the cation would be disymmetric, and optical isomerism would be possible.



(**18**)

Mills and Quibell resolved the compound into stable enantiomorphs using diacetyl-*d*-tartaric anhydride as the resolving agent. Because simple complexes such as $[(en)Pt(bn)]Cl_2$ (en = ethylenediamine and bn = isobutylenediamine) have never been resolved, there is no evidence favoring the square-pyramidal configuration. Mills and Quibell's resolution eliminated the tetrahedral configuration and offered unequivocal proof for the planar configuration of platinum(II). In 1939, A. G. Lidstone and Mills resolved the corresponding palladium(II) compound by the same method. By this time, other stereochemical and crystallographic evidence for the configuration of platinum(II) and palladium(II) existed, but Mills' resolutions afforded ingenious, elegant, and entirely independent proofs.



Scheme 3

6 OTHER DEVELOPMENTS

In his 1965 book *History of the Concept of Valency to 1930*, W. G. Palmer stated that it is 'yet too early to assess the very rapid developments since 1930 in a just historical perspective'. The same can be said about coordination chemistry. For this reason and because of space limitations, this historical account of coordination chemistry must close at this point. In general, research, discoveries, and innovations in the field since the 1930s have taken place at an ever-accelerating rate.

Despite the guiding star of Werner's coordination theory, classical coordination chemistry was largely empirical. Modern coordination chemistry has been characterized by increased emphasis on comprehensive theories of chemical bonding that have served to integrate and explain the large amount of experimental data. The valence bond (VB) theory of coordination was developed by Linus Pauling and John C. Slater from Gilbert Newton Lewis's covalent model (1916). Closely related to theories of hybridization and resonance, this theory was the first successful application of the electronic theory of valence to coordination compounds. From the early 1930s to the early 1950s, virtually all coordination phenomena were interpreted in its terms. It gave simple and satisfactory answers to geometric and magnetic susceptibility questions, with which chemists were then concerned.

Walther Kossel's ionic model (1916) was revitalized and developed into the crystal field theory (CFT) of coordination by Hans Bethe and John H. Van Vleck. Although used to some extent by physicists as early as the 1930s, it was not generally accepted by chemists until the 1950s. When modified to include some degree of covalence, CFT is usually known as ligand field theory (LFT) or adjusted crystal field theory (ACFT), and is currently the best and most popular method for treating spectra and other properties quantitatively. A simpler electrostatic theory is the valence shell electron pair repulsion (VSEPR) theory of directed valency, proposed in 1957 by Ronald J. Gillespie and the late Ronald S. Nyholm. Both the VB theory and CFT are only simplifications of the more general, but more complicated, molecular orbital (MO) theory, which today offers the best interpretation of the properties of coordination compounds. In the future, these theories will probably be modified, or even totally new ones may arise.

Another characteristic of modern coordination chemistry is the increasing reliance upon physicochemical methods unknown to Werner and his contemporaries. Simultaneously with an introduction of these newer techniques, emphasis shifted from preoccupation with qualitative studies of structure and stereochemistry to quantitative studies of thermodynamics, kinetics, and reaction mechanisms. Some areas of current research interest include unusual ligands, oxidation states and coordination numbers, solid-state chemistry, photochemistry, relationship between structure and reactivity, variable oxidation state, chelates, heteropoly complexes, organometallic

Table 4 Some historically significant events in coordination chemistry

Date	Chemist(s)	Event
1838	J. Gros	Gros's Salt, *trans*-$[PtCl_2(NH_3)_4]Cl_2$
1852	Edmond Fremy	Color nomenclature
1852	O. Wolcott Gibbs	Pentaamminenitrocobalt(III) salts $[CoNO_2(NH_3)_5]X_2$
1853	Wilhelm Hittorf	Transference number determination: first method of studying complexes in solution
1863	Discovered by J. Morland (1860); investigated by A. Reinecke (1863)	Reinecke's Salt, NH_4 *trans*-$[Cr(SCN)_4(NH_3)_2]$
1866	O. L. Erdmann	Erdmann's Trinitrite; Gibbs's Salt, $[Co(NO_2)_3(NH_3)_3]$
1870	Per Theodor Cleve	Cleve's Salt, *cis*-$[PtCl_4(NH_3)_2]$
1890	Ludwig Mond, C. Langer, and F. Quincke	Nickel tetracarbonyl (the first metal carbonyl)
1893	Alfred Werner	Coordination theory
1897	Alfred Werner	Nomenclature of coordination compounds

1969	D. Brown, J. F. Easey, and C. E. F. Rickard	Cubic 8-coordination, $Na_3[PaF_8]$
1969	Eugene E. van Tamelen *et al.*	Nitrogen fixation with titanium(II) alcoholate
1969	James P. Collman	Interconvertibility of linear and bent modes of NO coordination
1970	I.H. Sabherval and Anton B. Burg	Synthesis of $Co(NO)_3$
1970	D. A. Owen and M. Frederick Hawthorne	Carborane–transition metal chelate complexes
1970	Jean-Marie Lehn *et al.*	Cryptand metal complexes
1971	Rachel Countryman and W. S. McDonald	Cubic 8-coordination, $[NEt_4][U(SCN)_8]$
1971–1974	P. W. R. Confield and P. G. Eller (1971); P. H. Davis, R. L. Belford, and I. C. Paul (1973); N. C. Baenziger, K. M. Dittemore, and J. R. Doyle (1974); J. A. Tiethof, A. T. Hetey, and Devon W. Meek (1974)	Planar 3-coordination, $[(Me_3PS)_3Cu]ClO_4$, $(Ph_3P)_2CuBr$, $(Ph_3P)_2AuCl$, and $(Me_3PS)_3Cu$
1973	James P. Collman and S. R. Winter	First stable formyl complex, $(CO)_4Fe(CHO)^-$
1973	G. L. Simon and Lawrence F. Dahl	First 'naked' phosphorus complex
1973	Ernst Otto Fischer and Geoffrey Wilkinson	Nobel Chemistry Prize 'for their pioneering work, performed independently, on the chemistry of the organometallic so-called sandwich compounds
1974	James P. Collman *et al.*	Picket fence porphyrin
1974	James L. Dye *et al.*	Cryptated sodium cation and sodium anion
1974	Lawrence F. Dahl	Platinum carbonyl cluster dianions ('tinker toy' construction) with trigonal prismatic configuration
1974–1975	N. J. de Stephano, D. K. Johnson, and L. M. Venanzi (1974); Isao Mochida, J. Arthur Mattern, and John C. Bailar, Jr. (1975)	Trans spanning ligands in planar complexes
1975	C. M. Lukehart, G. P. Torrence, and J. V. Zerle	Diacetylmetallate anions
1976	E. C. Baker *et al.*	Lanthanide and actinide organometallics
1976	Loren D. Lower and Lawrence F. Dahl	Cube-shaped metal-cluster compound, $Ni_8(CO)_8(PPh_3)_6$, the first transition metal analog of cubane
1976	Earl L. Muetterties *et al.*	Metal clusters as homogeneous catalysts for reduction of carbon monoxide in Fischer-Tropsch reaction
1976	David G. Whitten *et al.*	Photoinduced electron transfer to produce hydrogen and oxygen from water using tris(2,2'-bipyridine)ruthenium(II) ion
1977	James P. Collman	Synthesis and characterization of a 'face-to-face' iron(II)-porphyrin compound
1977	David Dolphin and Brian James	Ru(II)-porphyrin complex acting as oxygen carrier at room temperature
1978	R. D. Gillard and F. L. Wimmer	Third resolution of a completely inorganic complex, $[Pt(S_5)_3]^{2-}$
1978	Alan M. Sargeson *et al.*	Sepulchrate complex completely encapsulates the metal
1978	Kenneth O. Hodgson, Richard H. Holm, *et al.*	EXAFS (extended X-ray absorption fine structure) study of structure of FeMo protein component of nitrogenase
1979	Satoru Shimba, Shuhei Fujinami, and Muraji Shibata	Fourth and fifth resolutions of completely inorganic complexes, *cis,cis,cis*-$[Co(CN)_2(NH_3)_2(H_2O)_2]^+$ and *cis,cis,cis*-$[Co(NO_2)_2(NH_3)_2(H_2O)_2]^+$
1979	Alan M. Sargeson	Caged metal ions (macrocycles in three dimensions)
1979	Stephen J. Lippard	Reaction of *cis*- and *trans*-$[PtCl_2(NH_3)_2]$ with DNA still attached to nucleosome core particle
1979	Duward F. Shriver *et al.*	Reduction of carbon monoxide to methane by protonation of a polynuclear metal carbonyl anion, $[Fe_4(CO)_{13}]^{2-}$
1979	Petra Köpf-Maier	Metallocene dihalides, especially titanocene dichloride, as antitumor drugs
1980	Milenko ãelap	Resolution of $W(OCOC_5H_4N)_2(ONC_9H_4Cl_2)_2$, the first resolution of an 8-coordinate compound
1980	Brice Bosnich *et al.*	Chiral rhodium complexes that are highly stereoselective catalysts
1980	Roger Y. Tsien	Fluorescent indicators/sensors for intracellular calcium
1980	K. Barry Sharpless and Tsutomu Katsuki	Titanium-catalyzed asymmetric epoxidation

Table 4 cont'd

Date	Chemist(s)	Event
1981	R. N. Shchelokov and V. E. Karasev	Introduction of Eu(III) complexes into polymeric matrix permits preparation of light transducers for greenhouses
1981	Thomas J. Meyer	First experimental observation of proton-coupled electron transfer
1982	Gregory J. Kubas	First complex of molecular hydrogen
1982	Harry B. Gray	Experimental demonstration of long-range electron tunneling in proteins (Ru-cytochrome c)
1982	Carlo Floriani	Reversible addition of CO_2 to bifunctional metal complexes containing acidic and basic sites
1983	Brian M. Hoffman	Electron tunneling in hybrid hemoglobins
1983	George McLendon *et al.*	Electron tunneling in a physiological heme-protein complex
1983	Thomas J. Meyer	First well-defined molecular catalyst for water oxidation
1984	Robert G. Bergman; William A. G. Graham	Oxidative addition of alkanes by iridium complexes
1984	Patricia L. Watson; Tobin J. Marks	Oxidative addition of alkanes by lanthanide and actinide compounds, respectively
1984	Duward F. Shriver; Harry R. Allcock	Inorganic ion-conducting solids
1985	Kenneth N. Raymond	New class of macrocyclic polycatecholates
1986	William C. Trogler	$[Pt(H)Cl\{P(CH_3)_3\}_2]$ as homogeneous catalyst for addition of water to terminal olefins in anti-Markovnikov manner
1986	Tobin J. Marks	Selective binding of $(\eta^5\text{-}C_5H_5)_2VCl_2$ to phosphate groups of DNA
1986	Karl O. Christe	Chemical synthesis of fluorine by reaction of SbF_5 with K_2MnF_6
1986	James L. Dye	$[NaC]^+$ and $[CsC]^+$ salts (C = 18-crown-6 ether)
1987	Wolfgang A. Herrmann	Organometallic compounds of rhenium(VII)
1987	Thomas G. Richmond	Facile chelate-assisted C–F bond cleavage at tungsten(0)
1987	M. Frederick Hawthorne	Macrocyclic carbaborane derivatives with bound chlorine
1987	Donald J. Cram, Jean-Marie Lehn, and Charles J. Pedersen	Nobel Chemistry Prize 'for their development and use of molecules with structure-specific interactions of high selectivity'
1988	Jonathan L. Sessler	Porphin-like macrocyclic ligand with 5 nitrogen atoms coordinated to a cadmium atom
1988	C. Frank Shaw III	Protein chemistry of antiarthritic gold(I) complexes
1988	G. M. Larin and B. B. Umarov	Super hyperfine structure (SHFS) from ligand atoms not bonded to central metal atom show unpaired electron of metal atom is delocalized over peripheral atom of chelate ligands
1989	Dieter Otto Sellmann	Iron-diazene complex as model for enzymatic nitrogen fixation
1989	Jean-Pierre Sauvage	Molecular trefoil knots
1990	Richard H. Holm	Substitution of other metals for iron in iron–sulfur clusters $[MoFe_3S_4]^{n+}$ and ($[Fe_{18}S_{30}]^{10-}$ containing two Na atoms)
1990	Dimitri Coucouvanis	Substitution of other metals for iron in iron–sulfur clusters ($[Mo_2Fe_6S_6]^{n+}$)
1990	Stephen J. Lippard	Molecular 'ferric wheel', $[Fe(OCH_3)_2(O_2CCH_2Cl)]_{10}$
1990	G. Attillio Ardizzoia	Ring-shaped $[Cu_8(C_5N_2H_7)_8(OH)_8]$ can substitute alcohols for hydroxides and can catalytically oxidize CO to CO_2
1990	Richard G. Finke	(1,5-cyclooctadienyl)iridium$[P_2W_{12}Nb_3O_{62}]^{8-}$ catalytically reduces cyclohexene to cyclohexane
1990	Jon A. Zubieta and Qin Chen	Polyoxovanadate, $[V_6O_{13}\{O_2NC(CH_2O)_3\}_2]^{2-}$, bonds organic fragments to a structure resembling a metal oxide
1990	Rafaele Acerete	$Na_{20}[P_6W_{18}O_{79}]$, first phosphotungstate proved to have a P:W ratio of 1:3
1990	Robert Haushalter	Heteropoly molybdophosphate containing 35% empty space reversibly absorbs 12% water by weight without changes in crystal structure
1991	Jay Winkler	Flash-quench method for measurements of electron tunneling over long distances
1991	M. Fujita	Molecular squares
1991	Wolfgang Saak and Siegfried Pohl	Self-assembly of $[Fe_3Ni_5S_6I_8]^{4-}$ cluster
1991	L. Jos de Jongh, Fokko N, Mulder, Timeke A. Stegink, and Roger C. Thiel	Mössbauer spectroscopy of Günter Schmid's platinum clusters shows that 147-atom cluster shows metallic behavior
1991–1992	Alan F. Williams, Claude Piguet, and Gerald Bernardelli	$[Co_2L_3]^{4+}$ (L = bis[1-methyl-2-(6′-methyl-2′-pyridyl)benzimidazol-5-yl]methane), similar to helical DNA and RNA structure
1992	Douglas C. Rees	X-ray diffraction determination of structure of metal centers in the two component proteins of nitrogenase
1992	Song-ping Huang and Mercouri G. Klanatzidis	Synthesis of cryptand $[NaAu_{12}\ Se_8]^{3-}$

Date	Chemist(s)	Event
1992	Boon K. Teo and Hong Zhang	Polyicosahedron of Ag and Au atoms with two trapped Au atoms
1992	Karl S. Hagen	Macrobicyclic diaza hexaoxa cryptand
1993	Amilra Prasanna de Silva	Molecular logic gates and computation
1993	Vincenzo Balzani, Sebastiano Campagna, and Gianfranco Denti	1,090-atom dendrimer containing 22 Ru atoms, believed to be largest transition metal complex of its kind
1993	Jean-Marie Lehn	Ru-(bipyridyl) complex that acts as a molecular 'switch'
1993	Walter Leitner	Synthesis of formic acid from CO_2 and H_2 with Rh-based catalyst
1993	Dieter Fenske	Properties of Cu_{146} $Se_{73}[P(C_6H_5)_3]_{30}$ cluster like those in bulk Cu_2 Se
1994	Isabelle M. L. Billas, A. Châtelain, and Walt A. de Heer	Development of magnetic properties with cluster size in Fe, Co, and Ni clusters
1995	Craig L. Hill and Xuan Zhang	'Smart' catalyst, complex polyanion cluster α-$[(CoII)PW_{11}O_{39}]^{5-}$ assembles itself from four precursor species
1995	P. Andrew Karplus	Structure of Ni-containing metalloenzyme urease by X-ray crystallography
1995	Christopher C. Cummins	$Mo(NRAr)_3$ amide complexes react with N_2 to yield $(NRAr)_3MoN$ nitrido complexes as result of N≡N bond cleavage
1995	Christopher C. Cummins and Richard R. Schrock	First Mo and W complexes containing M≡P bonds
1995	Gerard Parkin	First complex with indium multiple bond (In=Se)
1996	Douglas C. Rees	Structure of metalloenzyme DMSO reductase in oxidized and reduced form
1996	Hubert Schmidbauer	Structure of pair of Ag(I) and Au(I) complexes showing that Au is smaller than Ag
1996	John A. Gladysz	Linear chain of 20 carbon atoms (C_{20}) capped at both ends with organometallic Rh-containing groups (longest carbon chain with metals at each end)
1996	Gregory J. Kubas	Stable Pt complexes with chlorocarbon, bromocarbon, and iodocarbon ligands
1996	Roeland Nolte	Micrometer-sized 'wheels' composed of connected molecules of Pd-porphyrin complex
1996	Christopher C. Cummins	Transition metal complexes cleave N_2 triple bond
1996	Robert F. Curl, Jr., Harold W. Kroto, and Richard E. Smalley	Nobel Chemistry Prize 'for their discovery of fullerenes'
1997	Günter Wächtershäuser and Claudia Huber	Primordial model for reductive acetyl-coenzyme pathway found in living organisms
1997	John A. Gladysz and István Horváth	$RhCl\{P(CH_2CH_2(CF_2)_5CF_3)_3\}_3$ catalyst in fluorocarbon solvents for transformations of organic compounds
1997	Gianluca Pozzi	Cobalt porphyrin-based catalyst with perfluoroalkyl groups bonded to porphyrin
1997	Christopher A. Reed and Peter D. W. Boyd	Compound with bond between metal atom and C–H bond of a free alkane
1997	Gregory H. Robinson	$Na_2[ArGa{=}GaAr]$ (Ar = 2,6-disubstituted phenyl group) contains unprecedented Ga≡Ga triple bond
1997	Karl W. Klinkhammer	Molecular orbital study of Robinson's compound
1997	John G. Brennan	New ways of synthesizing cluster compounds of samarium
1998	Daniel Stack	Cu complex that reproduces the essential reactivity of galactose oxidase
1998	Carlo Floriani *et al.*	Nitrogen fixation by stepwise reduction of N_2 to form nitride dimer complex $Nb_2(\mu\text{-}N_2)Na_2(thf)_{12}$
1998	Masanobu Hidai, Yoshiaki Nishibayashi, and Shotaro Iwai	Nitrogen fixation by reaction of tungsten complex bonded to a N_2 molecule
1998	Graham E. Ball	$Rh–C_5H_5$ complex – first characterization of compound with metal–alkane bonding
1998	Jim A. Thomas	Self-assembly of a molecular cube
1999	Pat Holland and William B. Tolman	Synthesis of a trigonal Cu(II) complex, a blue copper synthetic analogue
2001	Harry B. Gray	Electron tunneling in heme-protein single crystals
2001	Remir G. Kostyanovsky *et al.*	Wedekind-Fock-Havinga salt as first object for absolute asymmetric synthesis
2001	William S. Knowles and Ryoji Noyori; K. Barry Sharpless	Nobel Chemistry Prize 'for their work on chirally catalyzed hydrogenation reactions; [and] for his work on chirally catalyzed oxidation reactions', respectively
2001	Thomas J. Meyer	Localized-to-delocalized transition in mixed-valence chemistry
2002	F. Albert Cotton and Carlos A. Murillo	Ditungsten paddlewheel complex, a powerful reductant
2002	Stephen D. Kinrade, Ashley Gillson, and Christopher T. G. Knight	First direct evidence for production of organosilicate complex by a living system
2002	K. Barry Sharpless *et al.*	*In situ* click chemistry
2002	Douglas C. Rees	Previously unrecognized atom – possibly nitrogen – coordinated to six iron atoms in MoFe protein of metalloenzyme nitrogenase
2002	Bruce E. Bursten *et al.*	First noble gas-actinide complexes

Table 4 cont'd

Date	Chemist(s)	Event
2002	Kenneth S. Suslick, Steven C. Zimmerman, *et al*.	Zeolite-like metalloporphyrin that adsorbs and desorbs compounds with high selectivity for size, shape, and functional group
2002	Omar M. Yaghi *et al*.	'Isoreticular metal-organic frameworks' with lowest densities and highest methane storage capacities
2002	Harry C. Dorn *et al*.	First organic derivative of a C_{80} metallofullerene
2003	Lawrence Que	Synthesis of a nonheme ferryl complex, an analogue of nonheme iron oxygenase active intermediates
2003	Paul E. Kruger	'Trinity helix', ligand with C_2 symmetry used to prepare metallohelicates
2003	Glenn Millhauser and Stanley B. Prusiner	Prion protein binds five Cu(II) ions
2003	Piet W. N. M. van Leeuwen *et al*.	SPANphos, a C_2 symmetric trans-coordinating diphophane ligand
2003	Dmitry V. Yandulov and Richard R. Schrock	Catalytic reduction of dinitrogen to ammonia at a single Mo center
2003	Paul Smith *et al*.	Stable, soluble semiconductor, $[Pt(NH_2dmoc)_4][PtCl_4]$ (dmoc = dimethyloctane)
2003	Bradley D. Smith	Coordination compound as apoptosis chemosensor
2003	Chad A. Mirkin and Nathan C. Gianneschi	Supramolecular allosteric catalyst
2003	Bryan W. Eichhorn; Manfred Scheer, Junfeng Bai, and Alexandria V. Virovets; Achim Müller	Inorganic fullerene-like molecules

compounds such as metallocenes and π-aromatic complexes with 'sandwich structures', compounds with metal–metal bonds (metal clusters), clathrates, fluxional coordination compounds, borane complexes, macrocyclic and stereochemically nonrigid ligands, and nitrogen- and oxygen-containing complexes. Many biologically active compounds are complexes, and even the simpler types of complexes have served as model compounds in investigating bodily processes. In fact, the new field of bioinorganic chemistry is concerned largely with coordination compounds.

It is difficult, if not impossible, to predict the future of coordination chemistry, an exciting research field in which the solution to any given problem usually opens up a number of new research avenues and poses newer and more challenging problems. If its past history gives any indication of its future course, the continued success, expansion, and vitality of coordination chemistry remain assured.

The chronological list in Table 4 of some historically significant events in coordination chemistry is intended to supplement the more detailed previous historical survey. Being illustrative rather than exhaustive, it is necessarily incomplete, for many other valuable contributions have not been included because of lack of space.

1 INTRODUCTION

A very convenient and widely used method for depicting the 3D structure of molecules AX_n is to imagine that the X atoms are situated at the vertices of various polyhedra centered on atom A.[1,2] In the two most common geometries (i) the arrangement of four groups about a central atom is tetrahedral, as was independently proposed for carbon by van't Hoff and Le Bel in 1874,[3] and (ii) as Werner proposed some 20 years later in 1893, six groups are commonly arranged about a metal atom at the vertices of an octahedron.[4] In some cases, isomers are possible. Thus optical isomers can be obtained when the molecule has no plane of symmetry, for example when four different groups are attached to a tetrahedral carbon atom, [Cabcd], which shows that the molecular rearrangement of such structures must be very slow. Similarly, the ability to isolate optical and geometrical isomers for complexes such as $[Co(NH_2CH_2CH_2NH_2)_2Cl_2]^+$ shows that rearrangement is again very slow.

This structural rigidity of the tetrahedron and octahedron arises from the transition states for rearrangement being substantially disfavored relative to the ground state. Steric repulsion between the ligands is an important component. Five-, seven-, eight-, and nine-coordination geometries tend to be substantially less rigid, and different structural isomers of the same composition cannot be isolated. The relative energy required to convert from one polyhedron into another of the same coordination number can be estimated from the ligand–ligand repulsion energies using an empirical force law (Table 1).[5]
